

GNU Emacs Lisp Reference Manual

For Emacs Version 29.1.90

by Bil Lewis, Dan LaLiberte, Richard Stallman,
the GNU Manual Group, et al.

This is the *GNU Emacs Lisp Reference Manual* corresponding to Emacs version 29.1.90.

Short Contents

1	Introduction	1
2	Lisp Data Types	8
3	Numbers	38
4	Strings and Characters	54
5	Lists	77
6	Sequences, Arrays, and Vectors	102
7	Records	125
8	Hash Tables	127
9	Symbols	133
10	Evaluation	145
11	Control Structures	158
12	Variables	189
13	Functions	230
14	Macros	268
15	Customization Settings	277
16	Loading	298
17	Byte Compilation	316
18	Compilation of Lisp to Native Code	327
19	Debugging Lisp Programs	333
20	Reading and Printing Lisp Objects	371
21	Minibuffers	385
22	Command Loop	423
23	Keymaps	480
24	Major and Minor Modes	524
25	Documentation	595
26	Files	608
27	Backups and Auto-Saving	659
28	Buffers	671
29	Windows	690
30	Frames	785
31	Positions	853
32	Markers	869
33	Text	878

34	Non-ASCII Characters	963
35	Searching and Matching	993
36	Syntax Tables.....	1022
37	Parsing Program Source	1039
38	Abbrevs and Abbrev Expansion	1066
39	Threads	1073
40	Processes	1078
41	Emacs Display	1129
42	Operating System Interface.....	1255
43	Preparing Lisp code for distribution.....	1303
A	Emacs 28 Antinews	1309
B	GNU Free Documentation License	1312
C	GNU General Public License	1320
D	Tips and Conventions	1331
E	GNU Emacs Internals	1346
F	Standard Errors	1390
G	Standard Keymaps	1395
H	Standard Hooks	1398
	Index	1402

Table of Contents

1	Introduction	1
1.1	Caveats	1
1.2	Lisp History	1
1.3	Conventions	2
1.3.1	Some Terms	2
1.3.2	<code>nil</code> and <code>t</code>	2
1.3.3	Evaluation Notation	3
1.3.4	Printing Notation	3
1.3.5	Error Messages	3
1.3.6	Buffer Text Notation	4
1.3.7	Format of Descriptions	4
1.3.7.1	A Sample Function Description	4
1.3.7.2	A Sample Variable Description	6
1.4	Version Information	6
1.5	Acknowledgments	7
2	Lisp Data Types	8
2.1	Printed Representation and Read Syntax	8
2.2	Special Read Syntax	9
2.3	Comments	10
2.4	Programming Types	10
2.4.1	Integer Type	10
2.4.2	Floating-Point Type	11
2.4.3	Character Type	11
2.4.3.1	Basic Char Syntax	11
2.4.3.2	General Escape Syntax	12
2.4.3.3	Control-Character Syntax	13
2.4.3.4	Meta-Character Syntax	13
2.4.3.5	Other Character Modifier Bits	14
2.4.4	Symbol Type	14
2.4.5	Sequence Types	15
2.4.6	Cons Cell and List Types	16
2.4.6.1	Drawing Lists as Box Diagrams	16
2.4.6.2	Dotted Pair Notation	18
2.4.6.3	Association List Type	19
2.4.7	Array Type	19
2.4.8	String Type	20
2.4.8.1	Syntax for Strings	20
2.4.8.2	Non-ASCII Characters in Strings	20
2.4.8.3	Nonprinting Characters in Strings	21
2.4.8.4	Text Properties in Strings	22
2.4.9	Vector Type	22
2.4.10	Char-Table Type	22

2.4.11	Bool-Vector Type.....	23
2.4.12	Hash Table Type.....	23
2.4.13	Function Type.....	23
2.4.14	Macro Type.....	24
2.4.15	Primitive Function Type.....	24
2.4.16	Byte-Code Function Type	24
2.4.17	Record Type	24
2.4.18	Type Descriptors.....	25
2.4.19	Autoload Type.....	25
2.4.20	Finalizer Type.....	25
2.5	Editing Types	25
2.5.1	Buffer Type	26
2.5.2	Marker Type	26
2.5.3	Window Type	27
2.5.4	Frame Type	27
2.5.5	Terminal Type	27
2.5.6	Window Configuration Type.....	27
2.5.7	Frame Configuration Type.....	28
2.5.8	Process Type.....	28
2.5.9	Thread Type	28
2.5.10	Mutex Type.....	28
2.5.11	Condition Variable Type.....	28
2.5.12	Stream Type	29
2.5.13	Keymap Type.....	29
2.5.14	Overlay Type.....	29
2.5.15	Font Type.....	29
2.5.16	Xwidget Type.....	29
2.6	Read Syntax for Circular Objects.....	30
2.7	Type Predicates	30
2.8	Equality Predicates.....	34
2.9	Mutability.....	36
3	Numbers	38
3.1	Integer Basics	38
3.2	Floating-Point Basics.....	39
3.3	Type Predicates for Numbers	41
3.4	Comparison of Numbers	42
3.5	Numeric Conversions	43
3.6	Arithmetic Operations.....	45
3.7	Rounding Operations.....	48
3.8	Bitwise Operations on Integers.....	48
3.9	Standard Mathematical Functions	51
3.10	Random Numbers	52

4 Strings and Characters	54
4.1 String and Character Basics	54
4.2 Predicates for Strings	55
4.3 Creating Strings	55
4.4 Modifying Strings	59
4.5 Comparison of Characters and Strings	60
4.6 Conversion of Characters and Strings	64
4.7 Formatting Strings	66
4.8 Custom Format Strings	70
4.9 Case Conversion in Lisp	72
4.10 The Case Table	74
5 Lists	77
5.1 Lists and Cons Cells	77
5.2 Predicates on Lists	78
5.3 Accessing Elements of Lists	79
5.4 Building Cons Cells and Lists	82
5.5 Modifying List Variables	85
5.6 Modifying Existing List Structure	87
5.6.1 Altering List Elements with <code>setcar</code>	88
5.6.2 Altering the CDR of a List	89
5.6.3 Functions that Rearrange Lists	90
5.7 Using Lists as Sets	91
5.8 Association Lists	95
5.9 Property Lists	99
5.9.1 Property Lists and Association Lists	100
5.9.2 Property Lists Outside Symbols	100
6 Sequences, Arrays, and Vectors	102
6.1 Sequences	102
6.2 Arrays	115
6.3 Functions that Operate on Arrays	116
6.4 Vectors	117
6.5 Functions for Vectors	118
6.6 Char-Tables	119
6.7 Bool-vectors	121
6.8 Managing a Fixed-Size Ring of Objects	123
7 Records	125
7.1 Record Functions	125
7.2 Backward Compatibility	126

8 Hash Tables	127
8.1 Creating Hash Tables.....	127
8.2 Hash Table Access	129
8.3 Defining Hash Comparisons.....	130
8.4 Other Hash Table Functions	131
9 Symbols	133
9.1 Symbol Components.....	133
9.2 Defining Symbols.....	134
9.3 Creating and Interning Symbols	135
9.4 Symbol Properties.....	138
9.4.1 Accessing Symbol Properties.....	138
9.4.2 Standard Symbol Properties	139
9.5 Shorthands.....	142
9.5.1 Exceptions	143
9.6 Symbols with Position	143
10 Evaluation.....	145
10.1 Kinds of Forms.....	146
10.1.1 Self-Evaluating Forms	146
10.1.2 Symbol Forms	146
10.1.3 Classification of List Forms	147
10.1.4 Symbol Function Indirection	147
10.1.5 Evaluation of Function Forms.....	148
10.1.6 Lisp Macro Evaluation	149
10.1.7 Special Forms	149
10.1.8 Autoloading.....	150
10.2 Quoting.....	151
10.3 Backquote	151
10.4 Eval	152
10.5 Deferred and Lazy Evaluation	155
11 Control Structures	158
11.1 Sequencing.....	158
11.2 Conditionals	159
11.3 Constructs for Combining Conditions	162
11.4 Pattern-Matching Conditional	163
11.4.1 The <code>pcase</code> macro.....	164
11.4.2 Extending <code>pcase</code>	170
11.4.3 Backquote-Style Patterns	171
11.4.4 Destructuring with <code>pcase</code> Patterns	172
11.5 Iteration	174
11.6 Generators	175
11.7 Nonlocal Exits	177
11.7.1 Explicit Nonlocal Exits: <code>catch</code> and <code>throw</code>	177

11.7.2 Examples of <code>catch</code> and <code>throw</code>	178
11.7.3 Errors.....	179
11.7.3.1 How to Signal an Error	180
11.7.3.2 How Emacs Processes Errors.....	181
11.7.3.3 Writing Code to Handle Errors	182
11.7.3.4 Error Symbols and Condition Names.....	186
11.7.4 Cleaning Up from Nonlocal Exits	187
12 Variables	189
12.1 Global Variables	189
12.2 Variables that Never Change	189
12.3 Local Variables.....	190
12.4 When a Variable is Void.....	193
12.5 Defining Global Variables	194
12.6 Tips for Defining Variables Robustly.....	196
12.7 Accessing Variable Values	197
12.8 Setting Variable Values.....	198
12.9 Running a function when a variable is changed.....	200
12.9.1 Limitations.....	200
12.10 Scoping Rules for Variable Bindings	201
12.10.1 Dynamic Binding	201
12.10.2 Proper Use of Dynamic Binding	202
12.10.3 Lexical Binding	203
12.10.4 Using Lexical Binding	204
12.10.5 Converting to Lexical Binding	206
12.11 Buffer-Local Variables.....	207
12.11.1 Introduction to Buffer-Local Variables	207
12.11.2 Creating and Deleting Buffer-Local Bindings.....	208
12.11.3 The Default Value of a Buffer-Local Variable	211
12.12 File Local Variables	213
12.13 Directory Local Variables	217
12.14 Connection Local Variables.....	218
12.14.1 Connection Local Profiles	218
12.14.2 Applying Connection Local Variables.....	220
12.15 Variable Aliases.....	222
12.16 Variables with Restricted Values	223
12.17 Generalized Variables	224
12.17.1 The <code>setf</code> Macro	224
12.17.2 Defining new <code>setf</code> forms	225
12.18 Multisession Variables.....	227

13 Functions	230
13.1 What Is a Function?	230
13.2 Lambda Expressions	232
13.2.1 Components of a Lambda Expression	232
13.2.2 A Simple Lambda Expression Example	233
13.2.3 Features of Argument Lists	234
13.2.4 Documentation Strings of Functions	235
13.3 Naming a Function	236
13.4 Defining Functions	237
13.5 Calling Functions	239
13.6 Mapping Functions	241
13.7 Anonymous Functions	243
13.8 Generic Functions	245
13.9 Accessing Function Cell Contents	248
13.10 Closures	249
13.11 Open Closures	250
13.12 Advising Emacs Lisp Functions	252
13.12.1 Primitives to manipulate advices	253
13.12.2 Advising Named Functions	255
13.12.3 Ways to compose advice	257
13.12.4 Adapting code using the old defadvice	258
13.12.5 Advice and Byte Code	259
13.13 Declaring Functions Obsolete	260
13.14 Inline Functions	261
13.15 The <code>declare</code> Form	263
13.16 Telling the Compiler that a Function is Defined	265
13.17 Determining whether a Function is Safe to Call	266
13.18 Other Topics Related to Functions	267
14 Macros	268
14.1 A Simple Example of a Macro	268
14.2 Expansion of a Macro Call	268
14.3 Macros and Byte Compilation	270
14.4 Defining Macros	270
14.5 Common Problems Using Macros	271
14.5.1 Wrong Time	271
14.5.2 Evaluating Macro Arguments Repeatedly	271
14.5.3 Local Variables in Macro Expansions	273
14.5.4 Evaluating Macro Arguments in Expansion	273
14.5.5 How Many Times is the Macro Expanded?	274
14.6 Indenting Macros	275

15 Customization Settings	277
15.1 Common Item Keywords	277
15.2 Defining Customization Groups	279
15.3 Defining Customization Variables	280
15.4 Customization Types	284
15.4.1 Simple Types	285
15.4.2 Composite Types	286
15.4.3 Splicing into Lists	290
15.4.4 Type Keywords	291
15.4.5 Defining New Types	293
15.5 Applying Customizations	294
15.6 Custom Themes	295
16 Loading	298
16.1 How Programs Do Loading	298
16.2 Load Suffixes	300
16.3 Library Search	301
16.4 Loading Non-ASCII Characters	304
16.5 Autoload	304
16.5.1 Autoload by Prefix	307
16.5.2 When to Use Autoload	307
16.6 Repeated Loading	308
16.7 Features	309
16.8 Which File Defined a Certain Symbol	311
16.9 Unloading	313
16.10 Hooks for Loading	313
16.11 Emacs Dynamic Modules	314
17 Byte Compilation	316
17.1 Performance of Byte-Compiled Code	316
17.2 Byte-Compilation Functions	316
17.3 Documentation Strings and Compilation	319
17.4 Dynamic Loading of Individual Functions	319
17.5 Evaluation During Compilation	320
17.6 Compiler Errors	321
17.7 Byte-Code Function Objects	323
17.8 Disassembled Byte-Code	324
18 Compilation of Lisp to Native Code	327
18.1 Native-Compilation Functions	328
18.2 Native-Compilation Variables	330

19 Debugging Lisp Programs	333
19.1 The Lisp Debugger	333
19.1.1 Entering the Debugger on an Error	333
19.1.2 Debugging Redisplay Errors	335
19.1.3 Debugging Infinite Loops	336
19.1.4 Entering the Debugger on a Function Call	336
19.1.5 Entering the debugger when a variable is modified	337
19.1.6 Explicit Entry to the Debugger	337
19.1.7 Using the Debugger	338
19.1.8 Backtraces	338
19.1.9 Debugger Commands	339
19.1.10 Invoking the Debugger	340
19.1.11 Internals of the Debugger	342
19.2 Edebug	344
19.2.1 Using Edebug	345
19.2.2 Instrumenting for Edebug	346
19.2.3 Edebug Execution Modes	347
19.2.4 Jumping	348
19.2.5 Miscellaneous Edebug Commands	349
19.2.6 Breaks	350
19.2.6.1 Edebug Breakpoints	350
19.2.6.2 Global Break Condition	351
19.2.6.3 Source Breakpoints	351
19.2.7 Trapping Errors	351
19.2.8 Edebug Views	352
19.2.9 Evaluation	352
19.2.10 Evaluation List Buffer	353
19.2.11 Printing in Edebug	354
19.2.12 Trace Buffer	355
19.2.13 Coverage Testing	356
19.2.14 The Outside Context	357
19.2.14.1 Checking Whether to Stop	357
19.2.14.2 Edebug Display Update	357
19.2.14.3 Edebug Recursive Edit	358
19.2.15 Edebug and Macros	358
19.2.15.1 Instrumenting Macro Calls	358
19.2.15.2 Specification List	359
19.2.15.3 Backtracking in Specifications	363
19.2.15.4 Specification Examples	363
19.2.16 Edebug Options	364
19.3 Debugging Invalid Lisp Syntax	367
19.3.1 Excess Open Parentheses	367
19.3.2 Excess Close Parentheses	368
19.4 Test Coverage	368
19.5 Profiling	369

20	Reading and Printing Lisp Objects	371
20.1	Introduction to Reading and Printing	371
20.2	Input Streams	371
20.3	Input Functions	374
20.4	Output Streams	375
20.5	Output Functions	377
20.6	Variables Affecting Output	380
20.7	Overriding Output Variables	383

1 Introduction

Most of the GNU Emacs text editor is written in the programming language called Emacs Lisp. You can write new code in Emacs Lisp and install it as an extension to the editor. However, Emacs Lisp is more than a mere extension language; it is a full computer programming language in its own right. You can use it as you would any other programming language.

Because Emacs Lisp is designed for use in an editor, it has special features for scanning and parsing text as well as features for handling files, buffers, displays, subprocesses, and so on. Emacs Lisp is closely integrated with the editing facilities; thus, editing commands are functions that can also conveniently be called from Lisp programs, and parameters for customization are ordinary Lisp variables.

This manual attempts to be a full description of Emacs Lisp. For a beginner's introduction to Emacs Lisp, see *An Introduction to Emacs Lisp Programming*, by Bob Chassell, also published by the Free Software Foundation. This manual presumes considerable familiarity with the use of Emacs for editing; see *The GNU Emacs Manual* for this basic information.

Generally speaking, the earlier chapters describe features of Emacs Lisp that have counterparts in many programming languages, and later chapters describe features that are peculiar to Emacs Lisp or relate specifically to editing.

This is the *GNU Emacs Lisp Reference Manual*, corresponding to Emacs version 29.1.90.

1.1 Caveats

This manual has gone through numerous drafts. It is nearly complete but not flawless. There are a few topics that are not covered, either because we consider them secondary (such as most of the individual modes) or because they are yet to be written. Because we are not able to deal with them completely, we have left out several parts intentionally.

The manual should be fully correct in what it does cover, and it is therefore open to criticism on anything it says—from specific examples and descriptive text, to the ordering of chapters and sections. If something is confusing, or you find that you have to look at the sources or experiment to learn something not covered in the manual, then perhaps the manual should be fixed. Please let us know.

As you use this manual, we ask that you mark pages with corrections so you can later look them up and send them to us. If you think of a simple, real-life example for a function or group of functions, please make an effort to write it up and send it in. Please reference any comments to the chapter name, section name, and function name, as appropriate, since page numbers and chapter and section numbers will change and we may have trouble finding the text you are talking about. Also state the version of the edition you are criticizing.

Please send comments and corrections using `M-x report-emacs-bug`. For more details, See Section “Reporting Bugs” in *The GNU Emacs Manual*.

1.2 Lisp History

Lisp (LISt Processing language) was first developed in the late 1950s at the Massachusetts Institute of Technology for research in artificial intelligence. The great power of the Lisp language makes it ideal for other purposes as well, such as writing editing commands.

Dozens of Lisp implementations have been built over the years, each with its own idiosyncrasies. Many of them were inspired by Maclisp, which was written in the 1960s at MIT’s Project MAC. Eventually the implementers of the descendants of Maclisp came together and developed a standard for Lisp systems, called Common Lisp. In the meantime, Gerry Sussman and Guy Steele at MIT developed a simplified but very powerful dialect of Lisp, called Scheme.

GNU Emacs Lisp is largely inspired by Maclisp, and a little by Common Lisp. If you know Common Lisp, you will notice many similarities. However, many features of Common Lisp have been omitted or simplified in order to reduce the memory requirements of GNU Emacs. Sometimes the simplifications are so drastic that a Common Lisp user might be very confused. We will occasionally point out how GNU Emacs Lisp differs from Common Lisp. If you don’t know Common Lisp, don’t worry about it; this manual is self-contained.

A certain amount of Common Lisp emulation is available via the `cl-lib` library. See Section “Overview” in *Common Lisp Extensions*.

Emacs Lisp is not at all influenced by Scheme; but the GNU project has an implementation of Scheme, called Guile. We use it in all new GNU software that calls for extensibility.

1.3 Conventions

This section explains the notational conventions that are used in this manual. You may want to skip this section and refer back to it later.

1.3.1 Some Terms

Throughout this manual, the phrases “the Lisp reader” and “the Lisp printer” refer to those routines in Lisp that convert textual representations of Lisp objects into actual Lisp objects, and vice versa. See Section 2.1 [Printed Representation], page 8, for more details. You, the person reading this manual, are thought of as the programmer and are addressed as “you”. The user is the person who uses Lisp programs, including those you write.

Examples of Lisp code are formatted like this: `(list 1 2 3)`. Names that represent metasyntactic variables, or arguments to a function being described, are formatted like this: `first-number`.

1.3.2 nil and t

In Emacs Lisp, the symbol `nil` has three separate meanings: it is a symbol with the name ‘`nil`’; it is the logical truth value `false`; and it is the empty list—the list of zero elements. When used as a variable, `nil` always has the value `nil`.

As far as the Lisp reader is concerned, ‘`()`’ and ‘`nil`’ are identical: they stand for the same object, the symbol `nil`. The different ways of writing the symbol are intended entirely for human readers. After the Lisp reader has read either ‘`()`’ or ‘`nil`’, there is no way to determine which representation was actually written by the programmer.

In this manual, we write `()` when we wish to emphasize that it means the empty list, and we write `nil` when we wish to emphasize that it means the truth value `false`. That is a good convention to use in Lisp programs also.

<code>(cons 'foo ())</code>	; Emphasize the empty list
<code>(setq foo-flag nil)</code>	; Emphasize the truth value <code>false</code>

In contexts where a truth value is expected, any non-`nil` value is considered to be *true*. However, `t` is the preferred way to represent the truth value *true*. When you need to choose a value that represents *true*, and there is no other basis for choosing, use `t`. The symbol `t` always has the value `t`.

In Emacs Lisp, `nil` and `t` are special symbols that always evaluate to themselves. This is so that you do not need to quote them to use them as constants in a program. An attempt to change their values results in a `setting-constant` error. See Section 12.2 [Constant Variables], page 189.

`booleanp object` [Function]

Return non-`nil` if `object` is one of the two canonical boolean values: `t` or `nil`.

1.3.3 Evaluation Notation

A Lisp expression that you can evaluate is called a *form*. Evaluating a form always produces a result, which is a Lisp object. In the examples in this manual, this is indicated with ‘ \Rightarrow ’:

```
(car '(1 2))
      ⇒ 1
```

You can read this as “`(car '(1 2))` evaluates to 1”.

When a form is a macro call, it expands into a new form for Lisp to evaluate. We show the result of the expansion with ‘ \mapsto ’. We may or may not show the result of the evaluation of the expanded form.

```
(third '(a b c))
      ↪ (car (cdr (cdr '(a b c))))
      ⇒ c
```

To help describe one form, we sometimes show another form that produces identical results. The exact equivalence of two forms is indicated with ‘ \equiv ’.

```
(make-sparse-keymap) ≡ (list 'keymap)
```

1.3.4 Printing Notation

Many of the examples in this manual print text when they are evaluated. If you execute example code in a Lisp Interaction buffer (such as the buffer `*scratch*`) by typing `C-j` after the closing parenthesis of the example, the printed text is inserted into the buffer. If you execute the example by other means (such as by evaluating the function `eval-region`), the printed text is displayed in the echo area.

Examples in this manual indicate printed text with ‘ \dashv ’, irrespective of where that text goes. The value returned by evaluating the form follows on a separate line with ‘ \Rightarrow ’.

```
(progn (prin1 'foo) (princ "\n") (prin1 'bar))
      ⌋ foo
      ⌋ bar
      ⇒ bar
```

1.3.5 Error Messages

Some examples signal errors. This normally displays an error message in the echo area. We show the error message on a line starting with ‘`[error]`’. Note that ‘`[error]`’ itself does not appear in the echo area.

```
(+ 23 'x)
```

```
[error] Wrong type argument: number-or-marker-p, x
```

1.3.6 Buffer Text Notation

Some examples describe modifications to the contents of a buffer, by showing the before and after versions of the text. These examples show the contents of the buffer in question between two lines of dashes containing the buffer name. In addition, ‘*’ indicates the location of point. (The symbol for point, of course, is not part of the text in the buffer; it indicates the place *between* two characters where point is currently located.)

```
----- Buffer: foo -----
This is the *contents of foo.
----- Buffer: foo -----  
  

(insert "changed ")
⇒ nil
----- Buffer: foo -----
This is the changed *contents of foo.
----- Buffer: foo -----
```

1.3.7 Format of Descriptions

Functions, variables, macros, commands, user options, and special forms are described in this manual in a uniform format. The first line of a description contains the name of the item followed by its arguments, if any. The category—function, variable, or whatever—is printed next to the right margin. The description follows on succeeding lines, sometimes with examples.

1.3.7.1 A Sample Function Description

In a function description, the name of the function being described appears first. It is followed on the same line by a list of argument names. These names are also used in the body of the description, to stand for the values of the arguments.

The appearance of the keyword **&optional** in the argument list indicates that the subsequent arguments may be omitted (omitted arguments default to **nil**). Do not write **&optional** when you call the function.

The keyword **&rest** (which must be followed by a single argument name) indicates that any number of arguments can follow. The single argument name following **&rest** receives, as its value, a list of all the remaining arguments passed to the function. Do not write **&rest** when you call the function.

Here is a description of an imaginary function **foo**:

foo integer1 &optional integer2 &rest integers	[Function]
---	------------

The function **foo** subtracts **integer1** from **integer2**, then adds all the rest of the arguments to the result. If **integer2** is not supplied, then the number 19 is used by default.

```
(foo 1 5 3 9)
⇒ 16
(foo 5)
⇒ 14
```

More generally,

$$\begin{aligned} & (\text{foo } w \ x \ y...) \\ & \equiv \\ & (+ (- x w) y...) \end{aligned}$$

By convention, any argument whose name contains the name of a type (e.g., *integer*, *integer1* or *buffer*) is expected to be of that type. A plural of a type (such as *buffers*) often means a list of objects of that type. An argument named *object* may be of any type. (For a list of Emacs object types, see Chapter 2 [Lisp Data Types], page 8.) An argument with any other sort of name (e.g., *new-file*) is specific to the function; if the function has a documentation string, the type of the argument should be described there (see Chapter 25 [Documentation], page 595).

See Section 13.2 [Lambda Expressions], page 232, for a more complete description of arguments modified by `&optional` and `&rest`.

Command, macro, and special form descriptions have the same format, but the word ‘Function’ is replaced by ‘Command’, ‘Macro’, or ‘Special Form’, respectively. Commands are simply functions that may be called interactively; macros process their arguments differently from functions (the arguments are not evaluated), but are presented the same way.

The descriptions of macros and special forms use a more complex notation to specify optional and repeated arguments, because they can break the argument list down into separate arguments in more complicated ways. ‘[*optional-arg*]’ means that *optional-arg* is optional and ‘*repeated-args...*’ stands for zero or more arguments. Parentheses are used when several arguments are grouped into additional levels of list structure. Here is an example:

`count-loop (var [from to [inc]]) body...` [Special Form]

This imaginary special form implements a loop that executes the *body* forms and then increments the variable *var* on each iteration. On the first iteration, the variable has the value *from*; on subsequent iterations, it is incremented by one (or by *inc* if that is given). The loop exits before executing *body* if *var* equals *to*. Here is an example:

```
(count-loop (i 0 10)
            (prin1 i) (princ " ")
            (prin1 (aref vector i))
            (terpri))
```

If *from* and *to* are omitted, *var* is bound to `nil` before the loop begins, and the loop exits if *var* is non-`nil` at the beginning of an iteration. Here is an example:

```
(count-loop (done)
            (if (pending)
                (fixit)
                (setq done t)))
```

In this special form, the arguments *from* and *to* are optional, but must both be present or both absent. If they are present, *inc* may optionally be specified as well. These arguments are grouped with the argument *var* into a list, to distinguish them from *body*, which includes all remaining elements of the form.

1.3.7.2 A Sample Variable Description

A *variable* is a name that can be *bound* (or *set*) to an object. The object to which a variable is bound is called a *value*; we say also that variable holds that value. Although nearly all variables can be set by the user, certain variables exist specifically so that users can change them; these are called *user options*. Ordinary variables and user options are described using a format like that for functions, except that there are no arguments.

Here is a description of the imaginary `electric-future-map` variable.

`electric-future-map`

[Variable]

The value of this variable is a full keymap used by Electric Command Future mode. The functions in this map allow you to edit commands you have not yet thought about executing.

User option descriptions have the same format, but ‘Variable’ is replaced by ‘User Option’.

1.4 Version Information

These facilities provide information about which version of Emacs is in use.

`emacs-version &optional here`

[Command]

This function returns a string describing the version of Emacs that is running. It is useful to include this string in bug reports.

```
(emacs-version
  ⇒ "GNU Emacs 26.1 (build 1, x86_64-unknown-linux-gnu,
      GTK+ Version 3.16) of 2017-06-01"
```

If `here` is non-`nil`, it inserts the text in the buffer before point, and returns `nil`. When this function is called interactively, it prints the same information in the echo area, but giving a prefix argument makes `here` non-`nil`.

`emacs-build-time`

[Variable]

The value of this variable indicates the time at which Emacs was built. It uses the style of `current-time` (see Section 42.5 [Time of Day], page 1270), or is `nil` if the information is not available.

```
emacs-build-time
  ⇒ (25194 55894 8547 617000)
```

(This timestamp is `(1651169878008547617 . 1000000000)` if `current-time-list` was `nil` when Emacs was built.)

`emacs-version`

[Variable]

The value of this variable is the version of Emacs being run. It is a string such as “`26.1`”. A value with three numeric components, such as “`26.0.91`”, indicates an unreleased test version. (Prior to Emacs 26.1, the string includes an extra final component with the integer that is now stored in `emacs-build-number`; e.g., “`25.1.1`”.)

`emacs-major-version`

[Variable]

The major version number of Emacs, as an integer. For Emacs version 23.1, the value is 23.

emacs-minor-version [Variable]

The minor version number of Emacs, as an integer. For Emacs version 23.1, the value is 1.

emacs-build-number [Variable]

An integer that increments each time Emacs is built in the same directory (without cleaning). This is only of relevance when developing Emacs.

emacs-repository-version [Variable]

A string that gives the repository revision from which Emacs was built. If Emacs was built outside revision control, the value is `nil`.

emacs-repository-branch [Variable]

A string that gives the repository branch from which Emacs was built. In the most cases this is "`master`". If Emacs was built outside revision control, the value is `nil`.

1.5 Acknowledgments

This manual was originally written by Robert Krawitz, Bil Lewis, Dan LaLiberte, Richard M. Stallman and Chris Welty, the volunteers of the GNU manual group, in an effort extending over several years. Robert J. Chassell helped to review and edit the manual, with the support of the Defense Advanced Research Projects Agency, ARPA Order 6082, arranged by Warren A. Hunt, Jr. of Computational Logic, Inc. Additional sections have since been written by Miles Bader, Lars Brinkhoff, Chong Yidong, Kenichi Handa, Lute Kamstra, Juri Linkov, Glenn Morris, Thien-Thi Nguyen, Dan Nicolaescu, Martin Rudalics, Kim F. Storm, Luc Teirlinck, and Eli Zaretskii, and others.

Corrections were supplied by Drew Adams, Juanma Barranquero, Karl Berry, Jim Blandy, Bard Bloom, Stephane Boucher, David Boyes, Alan Carroll, Richard Davis, Lawrence R. Dodd, Peter Doornbosch, David A. Duff, Chris Eich, Beverly Erlebacher, David Eckelkamp, Ralf Fassel, Eirik Fuller, Stephen Gildea, Bob Glickstein, Eric Hanchrow, Jesper Harder, George Hartzell, Nathan Hess, Masayuki Ida, Dan Jacobson, Jak Kirman, Bob Knighten, Frederick M. Korz, Joe Lammens, Glenn M. Lewis, K. Richard Magill, Brian Marick, Roland McGrath, Stefan Monnier, Skip Montanaro, John Gardiner Myers, Thomas A. Peterson, Francesco Potortì, Friedrich Pukelsheim, Arnold D. Robbins, Raul Rockwell, Jason Rumney, Per Starbäck, Shinichirou Sugou, Kimmo Suominen, Edward Tharp, Bill Trost, Rickard Westman, Jean White, Eduard Wiebe, Matthew Wilding, Carl Witty, Dale Worley, Rusty Wright, and David D. Zuhn.

For a more complete list of contributors, please see the relevant change log entries in the Emacs source repository.

2 Lisp Data Types

A Lisp *object* is a piece of data used and manipulated by Lisp programs. For our purposes, a *type* or *data type* is a set of possible objects.

Every object belongs to at least one type. Objects of the same type have similar structures and may usually be used in the same contexts. Types can overlap, and objects can belong to two or more types. Consequently, we can ask whether an object belongs to a particular type, but not for *the* type of an object.

A few fundamental object types are built into Emacs. These, from which all other types are constructed, are called *primitive types*. Each object belongs to one and only one primitive type. These types include *integer*, *float*, *cons*, *symbol*, *string*, *vector*, *hash-table*, *subr*, *byte-code function*, and *record*, plus several special types, such as *buffer*, that are related to editing. (See Section 2.5 [Editing Types], page 25.)

Each primitive type has a corresponding Lisp function that checks whether an object is a member of that type.

Lisp is unlike many other languages in that its objects are *self-typing*: the primitive type of each object is implicit in the object itself. For example, if an object is a vector, nothing can treat it as a number; Lisp knows it is a vector, not a number.

In most languages, the programmer must declare the data type of each variable, and the type is known by the compiler but not represented in the data. Such type declarations do not exist in Emacs Lisp. A Lisp variable can have any type of value, and it remembers whatever value you store in it, type and all. (Actually, a small number of Emacs Lisp variables can only take on values of a certain type. See Section 12.16 [Variables with Restricted Values], page 223.)

This chapter describes the purpose, printed representation, and read syntax of each of the standard types in GNU Emacs Lisp. Details on how to use these types can be found in later chapters.

2.1 Printed Representation and Read Syntax

The *printed representation* of an object is the format of the output generated by the Lisp printer (the function `prin1`) for that object. Every data type has a unique printed representation. The *read syntax* of an object is the format of the input accepted by the Lisp reader (the function `read`) for that object. This is not necessarily unique; many kinds of object have more than one syntax. See Chapter 20 [Read and Print], page 371.

In most cases, an object’s printed representation is also a read syntax for the object. However, some types have no read syntax, since it does not make sense to enter objects of these types as constants in a Lisp program. These objects are printed in *hash notation*, which consists of the characters ‘#<’, a descriptive string (typically the type name followed by the name of the object), and a closing ‘>’. (This is called “hash notation” because it begins with the ‘#’ character, known as “hash” or “number sign”). For example:

```
(current-buffer)
⇒ #<buffer objects.texi>
```

Hash notation cannot be read at all, so the Lisp reader signals the error `invalid-read-syntax` whenever it encounters ‘#<’.

We describe the read syntax and the printed representation of each Lisp data type where we describe that data type, in the following sections of this chapter. For example, see Section 2.4.8 [String Type], page 20, and its subsections for the read syntax and printed representation of strings; see Section 2.4.9 [Vector Type], page 22, for the same information about vectors; etc.

In other languages, an expression is text; it has no other form. In Lisp, an expression is primarily a Lisp object and only secondarily the text that is the object’s read syntax. Often there is no need to emphasize this distinction, but you must keep it in the back of your mind, or you will occasionally be very confused.

When you evaluate an expression interactively, the Lisp interpreter first reads the textual representation of it, producing a Lisp object, and then evaluates that object (see Chapter 10 [Evaluation], page 145). However, evaluation and reading are separate activities. Reading returns the Lisp object represented by the text that is read; the object may or may not be evaluated later. See Section 20.3 [Input Functions], page 374, for a description of `read`, the basic function for reading objects.

2.2 Special Read Syntax

Emacs Lisp represents many special objects and constructs via special hash notations.

- ‘#<...>’ Objects that have no read syntax are presented like this (see Section 2.1 [Printed Representation], page 8).
- ‘##’ The printed representation of an interned symbol whose name is an empty string (see Section 2.4.4 [Symbol Type], page 14).
- ‘#’ This is a shortcut for `function`, see Section 13.7 [Anonymous Functions], page 243.
- ‘#:’ The printed representation of an uninterned symbol whose name is *foo* is ‘#:foo’ (see Section 2.4.4 [Symbol Type], page 14).
- ‘#N’ When printing circular structures, this construct is used to represent where the structure loops back onto itself, and ‘N’ is the starting list count:

```
(let ((a (list 1)))
  (setcdr a a))
=> (1 . #0)
```
- ‘#N=’
- ‘#N#’ ‘#N=’ gives the name to an object, and ‘#N#’ represents that object, so when reading back the object, they will be the same object instead of copies (see Section 2.6 [Circular Objects], page 30).
- ‘#xN’ ‘N’ represented as a hexadecimal number (#x2a).
- ‘#oN’ ‘N’ represented as an octal number (#o52).
- ‘#bN’ ‘N’ represented as a binary number (#b101010).
- ‘#(...)’ String text properties (see Section 2.4.8.4 [Text Props and Strings], page 22).
- ‘#^’ A char table (see Section 2.4.10 [Char-Table Type], page 22).

'#s(hash-table ...)'	A hash table (see Section 2.4.12 [Hash Table Type], page 23).
'?C'	A character (see Section 2.4.3.1 [Basic Char Syntax], page 11).
'#\$'	The current file name in byte-compiled files (see Section 17.3 [Docs and Compilation], page 319). This is not meant to be used in Emacs Lisp source files.
'#@N'	Skip the next 'N' characters (see Section 2.3 [Comments], page 10). This is used in byte-compiled files, and is not meant to be used in Emacs Lisp source files.
'#f'	Indicates that the following form isn't readable by the Emacs Lisp reader. This is only in text for display purposes (when that would look prettier than alternative ways of indicating an unreadable form) and will never appear in any Lisp file.

2.3 Comments

A *comment* is text that is written in a program only for the sake of humans that read the program, and that has no effect on the meaning of the program. In Lisp, an unescaped semicolon (';') starts a comment if it is not within a string or character constant. The comment continues to the end of line. The Lisp reader discards comments; they do not become part of the Lisp objects which represent the program within the Lisp system.

The '#@count' construct, which skips the next *count* characters, is useful for program-generated comments containing binary data. The Emacs Lisp byte compiler uses this in its output files (see Chapter 17 [Byte Compilation], page 316). It isn't meant for source files, however.

See Section D.7 [Comment Tips], page 1341, for conventions for formatting comments.

2.4 Programming Types

There are two general categories of types in Emacs Lisp: those having to do with Lisp programming, and those having to do with editing. The former exist in many Lisp implementations, in one form or another. The latter are unique to Emacs Lisp.

2.4.1 Integer Type

Under the hood, there are two kinds of integers—small integers, called *fixnums*, and large integers, called *bignums*.

The range of values for a fixnum depends on the machine. The minimum range is -536,870,912 to 536,870,911 (30 bits; i.e., -2^{29} to $2^{29} - 1$) but many machines provide a wider range.

Bignums can have arbitrary precision. Operations that overflow a fixnum will return a bignum instead.

All numbers can be compared with `eq1` or `=`; fixnums can also be compared with `eq`. To test whether an integer is a fixnum or a bignum, you can compare it to `most-negative-fixnum` and `most-positive-fixnum`, or you can use the convenience predicates `fixnump` and `bignump` on any object.

The read syntax for integers is a sequence of (base ten) digits with an optional sign at the beginning and an optional period at the end. The printed representation produced by the Lisp interpreter never has a leading '+' or a final '.'.

```

-1           ; The integer -1.
1            ; The integer 1.
1.           ; Also the integer 1.
+1           ; Also the integer 1.

```

See Chapter 3 [Numbers], page 38, for more information.

2.4.2 Floating-Point Type

Floating-point numbers are the computer equivalent of scientific notation; you can think of a floating-point number as a fraction together with a power of ten. The precise number of significant figures and the range of possible exponents is machine-specific; Emacs uses the C data type `double` to store the value, and internally this records a power of 2 rather than a power of 10.

The printed representation for floating-point numbers requires either a decimal point (with at least one digit following), an exponent, or both. For example, ‘1500.0’, ‘+15e2’, ‘15.0e+2’, ‘+150000e-3’, and ‘.15e4’ are five ways of writing a floating-point number whose value is 1500. They are all equivalent.

See Chapter 3 [Numbers], page 38, for more information.

2.4.3 Character Type

A character in Emacs Lisp is nothing more than an integer. In other words, characters are represented by their character codes. For example, the character `A` is represented as the integer 65. That is also their usual printed representation; see Section 2.4.3.1 [Basic Char Syntax], page 11.

Individual characters are used occasionally in programs, but it is more common to work with *strings*, which are sequences composed of characters. See Section 2.4.8 [String Type], page 20.

Characters in strings and buffers are currently limited to the range of 0 to 4194303—twenty two bits (see Section 34.5 [Character Codes], page 967). Codes 0 through 127 are ASCII codes; the rest are non-ASCII (see Chapter 34 [Non-ASCII Characters], page 963). Characters that represent keyboard input have a much wider range, to encode modifier keys such as Control, Meta and Shift.

There are special functions for producing a human-readable textual description of a character for the sake of messages. See Section 25.5 [Describing Characters], page 601.

2.4.3.1 Basic Char Syntax

Since characters are really integers, the printed representation of a character is a decimal number. This is also a possible read syntax for a character, but writing characters that way in Lisp programs is not clear programming. You should *always* use the special read syntax formats that Emacs Lisp provides for characters. These syntax formats start with a question mark.

The usual read syntax for alphanumeric characters is a question mark followed by the character; thus, ‘?A’ for the character `A`, ‘?B’ for the character `B`, and ‘?a’ for the character `a`.

For example:

```
?Q ⇒ 81      ?q ⇒ 113
```

You can use the same syntax for punctuation characters. However, if the punctuation character has a special syntactic meaning in Lisp, you must quote it with a ‘\’. For example, ‘?\(’ is the way to write the open-paren character. Likewise, if the character is ‘\’, you must use a second ‘\’ to quote it: ‘?\\\’.

You can express the characters control-g, backspace, tab, newline, vertical tab, formfeed, space, return, del, and escape as ‘?\a’, ‘?\b’, ‘?\t’, ‘?\n’, ‘?\v’, ‘?\f’, ‘?\s’, ‘?\r’, ‘?\d’, and ‘?\e’, respectively. (‘?\s’ followed by a dash has a different meaning—it applies the Super modifier to the following character.) Thus,

?\\a	⇒ 7	; control-g, C-g
?\\b	⇒ 8	; backspace, BS, C-h
?\\t	⇒ 9	; tab, TAB, C-i
?\\n	⇒ 10	; newline, C-j
?\\v	⇒ 11	; vertical tab, C-k
?\\f	⇒ 12	; formfeed character, C-l
?\\r	⇒ 13	; carriage return, RET, C-m
?\\e	⇒ 27	; escape character, ESC, C-[
?\\s	⇒ 32	; space character, SPC
?\\\\	⇒ 92	; backslash character, \
?\\d	⇒ 127	; delete character, DEL

These sequences which start with backslash are also known as *escape sequences*, because backslash plays the role of an escape character; this has nothing to do with the character ESC. ‘\\s’ is meant for use in character constants; in string constants, just write the space.

A backslash is allowed, and harmless, preceding any character without a special escape meaning; thus, ‘?\+’ is equivalent to ‘?+’. There is no reason to add a backslash before most characters. However, you must add a backslash before any of the characters ‘()[];\”;’, and you should add a backslash before any of the characters ‘|`#\.,’ to avoid confusing the Emacs commands for editing Lisp code. You should also add a backslash before Unicode characters which resemble the previously mentioned ASCII ones, to avoid confusing people reading your code. Emacs will highlight some non-escaped commonly confused characters such as “” to encourage this. You can also add a backslash before whitespace characters such as space, tab, newline and formfeed. However, it is cleaner to use one of the easily readable escape sequences, such as ‘\\t’ or ‘\\s’, instead of an actual whitespace character such as a tab or a space. (If you do write backslash followed by a space, you should write an extra space after the character constant to separate it from the following text.)

2.4.3.2 General Escape Syntax

In addition to the specific escape sequences for special important control characters, Emacs provides several types of escape syntax that you can use to specify non-ASCII text characters.

1. You can specify characters by their Unicode names, if any. ?\N{NAME} represents the Unicode character named NAME. Thus, ‘?\N{LATIN SMALL LETTER A WITH GRAVE}’ is equivalent to ?à and denotes the Unicode character U+00E0. To simplify entering multi-line strings, you can replace spaces in the names by non-empty sequences of whitespace (e.g., newlines).
2. You can specify characters by their Unicode values. ?\N{U+X} represents a character with Unicode code point X, where X is a hexadecimal number. Also, ?\uxxxx and

`?\\Uxxxxxxxxx` represent code points xxxx and xxxxxxxx, respectively, where each x is a single hexadecimal digit. For example, `?\\N{U+E0}`, `?\\u00e0` and `?\\U000000E0` are all equivalent to `?à` and to ‘`?\\N{LATIN SMALL LETTER A WITH GRAVE}`’. The Unicode Standard defines code points only up to ‘`U+10ffff`’, so if you specify a code point higher than that, Emacs signals an error.

3. You can specify characters by their hexadecimal character codes. A hexadecimal escape sequence consists of a backslash, ‘x’, and the hexadecimal character code. Thus, ‘`?\\x41`’ is the character `A`, ‘`?\\x1`’ is the character `C-a`, and `?\\xe0` is the character `à` (`a` with grave accent). You can use one or more hex digits after ‘x’, so you can represent any character code in this way.
4. You can specify characters by their character code in octal. An octal escape sequence consists of a backslash followed by up to three octal digits; thus, ‘`?\\101`’ for the character `A`, ‘`?\\001`’ for the character `C-a`, and `?\\002` for the character `C-b`. Only characters up to octal code 777 can be specified this way.

These escape sequences may also be used in strings. See Section 2.4.8.2 [Non-ASCII in Strings], page 20.

2.4.3.3 Control-Character Syntax

Control characters can be represented using yet another read syntax. This consists of a question mark followed by a backslash, caret, and the corresponding non-control character, in either upper or lower case. For example, both ‘`?\\^I`’ and ‘`?\\^i`’ are valid read syntax for the character `C-i`, the character whose value is 9.

Instead of the ‘`^`’, you can use ‘`C-`; thus, ‘`?\\C-i`’ is equivalent to ‘`?\\^I`’ and to ‘`?\\^i`’:

`?\\^I` ⇒ 9 `?\\C-I` ⇒ 9

In strings and buffers, the only control characters allowed are those that exist in ASCII; but for keyboard input purposes, you can turn any character into a control character with ‘`C-`’. The character codes for these non-ASCII control characters include the 2^{26} bit as well as the code for the corresponding non-control character. Not all text terminals can generate non-ASCII control characters, but it is straightforward to generate them using X and other window systems.

For historical reasons, Emacs treats the `DEL` character as the control equivalent of `?`:

`?\\^?` ⇒ 127 `?\\C-?` ⇒ 127

As a result, it is currently not possible to represent the character `Control-?`, which is a meaningful input character under X, using ‘`C-?`’. It is not easy to change this, as various Lisp files refer to `DEL` in this way.

For representing control characters to be found in files or strings, we recommend the ‘`^`’ syntax; for control characters in keyboard input, we prefer the ‘`C-`’ syntax. Which one you use does not affect the meaning of the program, but may guide the understanding of people who read it.

2.4.3.4 Meta-Character Syntax

A *meta character* is a character typed with the `META` modifier key. The integer that represents such a character has the 2^{27} bit set. We use high bits for this and other modifiers to make possible a wide range of basic character codes.

In a string, the 2^7 bit attached to an ASCII character indicates a meta character; thus, the meta characters that can fit in a string have codes in the range from 128 to 255, and are the meta versions of the ordinary ASCII characters. See Section 22.7.17 [Strings of Events], page 459, for details about META-handling in strings.

The read syntax for meta characters uses ‘\M-’. For example, ‘?\M-A’ stands for *M-A*. You can use ‘\M-’ together with octal character codes (see below), with ‘\C-’, or with any other syntax for a character. Thus, you can write *M-A* as ‘?\M-A’, or as ‘?\M-\101’. Likewise, you can write *C-M-b* as ‘?\M-\C-b’, ‘?\C-\M-b’, or ‘?\M-\002’.

2.4.3.5 Other Character Modifier Bits

The case of a graphic character is indicated by its character code; for example, ASCII distinguishes between the characters ‘a’ and ‘A’. But ASCII has no way to represent whether a control character is upper case or lower case. Emacs uses the 2^{25} bit to indicate that the shift key was used in typing a control character. This distinction is possible only on a graphical display such as a GUI display on X; text terminals do not report the distinction. The Lisp syntax for the shift bit is ‘\S-’; thus, ‘?\C-\S-o’ or ‘?\C-\\$o’ represents the shifted-control-o character.

The X Window System defines three other modifier bits that can be set in a character: *hyper*, *super* and *alt*. The syntaxes for these bits are ‘\H-’, ‘\s-’ and ‘\A-’. (Case is significant in these prefixes.) Thus, ‘?\H-\M-\A-x’ represents *Alt-Hyper-Meta-x*. (Note that ‘\s’ with no following ‘-’ represents the space character.) Numerically, the bit values are 2^{22} for alt, 2^{23} for super and 2^{24} for hyper.

2.4.4 Symbol Type

A *symbol* in GNU Emacs Lisp is an object with a name. The symbol name serves as the printed representation of the symbol. In ordinary Lisp use, with one single obarray (see Section 9.3 [Creating Symbols], page 135), a symbol’s name is unique—no two symbols have the same name.

A symbol can serve as a variable, as a function name, or to hold a property list. Or it may serve only to be distinct from all other Lisp objects, so that its presence in a data structure may be recognized reliably. In a given context, usually only one of these uses is intended. But you can use one symbol in all of these ways, independently.

A symbol whose name starts with a colon (‘:’) is called a *keyword symbol*. These symbols automatically act as constants, and are normally used only by comparing an unknown symbol with a few specific alternatives. See Section 12.2 [Constant Variables], page 189.

A symbol name can contain any characters whatever. Most symbol names are written with letters, digits, and the punctuation characters ‘-+*=’/. Such names require no special punctuation; the characters of the name suffice as long as the name does not look like a number. (If it does, write a ‘\’ at the beginning of the name to force interpretation as a symbol.) The characters ‘_~!@%^&;>{}?’ are less often used but also require no special punctuation. Any other characters may be included in a symbol’s name by escaping them with a backslash. In contrast to its use in strings, however, a backslash in the name of a symbol simply quotes the single character that follows the backslash. For example, in a string, ‘\t’ represents a tab character; in the name of a symbol, however, ‘\t’ merely quotes the letter ‘t’. To have a symbol with a tab character in its name, you must actually use a tab (preceded with a backslash). But it’s rare to do such a thing.

Common Lisp note: In Common Lisp, lower case letters are always folded to upper case, unless they are explicitly escaped. In Emacs Lisp, upper case and lower case letters are distinct.

Here are several examples of symbol names. Note that the ‘+’ in the fourth example is escaped to prevent it from being read as a number. This is not necessary in the sixth example because the rest of the name makes it invalid as a number.

foo	; A symbol named ‘foo’.
F00	; A symbol named ‘F00’, different from ‘foo’.
1+	; A symbol named ‘1+’
	; (not ‘+1’, which is an integer).
\+1	; A symbol named ‘+1’
	; (not a very readable name).
\(*\ 1\ 2\)	; A symbol named ‘(* 1 2)’ (a worse name).
+*/_~!@\$%^&=:<>{}	; A symbol named ‘+*/_~!@\$%^&=:<>{}’.
	; These characters need not be escaped.

As an exception to the rule that a symbol’s name serves as its printed representation, ‘##’ is the printed representation for an interned symbol whose name is an empty string. Furthermore, ‘#:foo’ is the printed representation for an uninterned symbol whose name is *foo*. (Normally, the Lisp reader interns all symbols; see Section 9.3 [Creating Symbols], page 135.)

2.4.5 Sequence Types

A sequence is a Lisp object that represents an ordered set of elements. There are two kinds of sequence in Emacs Lisp: *lists* and *arrays*.

Lists are the most commonly-used sequences. A list can hold elements of any type, and its length can be easily changed by adding or removing elements. See the next subsection for more about lists.

Arrays are fixed-length sequences. They are further subdivided into strings, vectors, char-tables and bool-vectors. Vectors can hold elements of any type, whereas string elements must be characters, and bool-vector elements must be `t` or `nil`. Char-tables are like vectors except that they are indexed by any valid character code. The characters in a string can have text properties like characters in a buffer (see Section 33.19 [Text Properties], page 917), but vectors do not support text properties, even when their elements happen to be characters.

Lists, strings and the other array types also share important similarities. For example, all have a length *l*, and all have elements which can be indexed from zero to *l* minus one. Several functions, called sequence functions, accept any kind of sequence. For example, the function `length` reports the length of any kind of sequence. See Chapter 6 [Sequences Arrays Vectors], page 102.

It is generally impossible to read the same sequence twice, since sequences are always created anew upon reading. If you read the read syntax for a sequence twice, you get two sequences with equal contents. There is one exception: the empty list () always stands for the same object, `nil`.

2.4.6 Cons Cell and List Types

A *cons cell* is an object that consists of two slots, called the CAR slot and the CDR slot. Each slot can *hold* any Lisp object. We also say that the CAR of this cons cell is whatever object its CAR slot currently holds, and likewise for the CDR.

A *list* is a series of cons cells, linked together so that the CDR slot of each cons cell holds either the next cons cell or the empty list. The empty list is actually the symbol `nil`. See Chapter 5 [Lists], page 77, for details. Because most cons cells are used as part of lists, we refer to any structure made out of cons cells as a *list structure*.

A note to C programmers: a Lisp list thus works as a *linked list* built up of cons cells. Because pointers in Lisp are implicit, we do not distinguish between a cons cell slot holding a value versus pointing to the value.

Because cons cells are so central to Lisp, we also have a word for an object which is not a cons cell. These objects are called *atoms*.

The read syntax and printed representation for lists are identical, and consist of a left parenthesis, an arbitrary number of elements, and a right parenthesis. Here are examples of lists:

<code>(A 2 "A")</code>	; A list of three elements.
<code>()</code>	; A list of no elements (the empty list).
<code>nil</code>	; A list of no elements (the empty list).
<code>("A ()")</code>	; A list of one element: the string "A ()".
<code>(A ())</code>	; A list of two elements: A and the empty list.
<code>(A nil)</code>	; Equivalent to the previous.
<code>((A B C))</code>	; A list of one element ; (which is a list of three elements).

Upon reading, each object inside the parentheses becomes an element of the list. That is, a cons cell is made for each element. The CAR slot of the cons cell holds the element, and its CDR slot refers to the next cons cell of the list, which holds the next element in the list. The CDR slot of the last cons cell is set to hold `nil`.

The names CAR and CDR derive from the history of Lisp. The original Lisp implementation ran on an IBM 704 computer which divided words into two parts, the address and the decrement; CAR was an instruction to extract the contents of the address part of a register, and CDR an instruction to extract the contents of the decrement. By contrast, cons cells are named for the function `cons` that creates them, which in turn was named for its purpose, the construction of cells.

2.4.6.1 Drawing Lists as Box Diagrams

A list can be illustrated by a diagram in which the cons cells are shown as pairs of boxes, like dominoes. (The Lisp reader cannot read such an illustration; unlike the textual notation, which can be understood by both humans and computers, the box illustrations can be understood only by humans.) This picture represents the three-element list (`rose violet buttercup`):

In this diagram, each box represents a slot that can hold or refer to any Lisp object. Each pair of boxes represents a cons cell. Each arrow represents a reference to a Lisp object, either an atom or another cons cell.

In this example, the first box, which holds the CAR of the first cons cell, refers to or holds `rose` (a symbol). The second box, holding the CDR of the first cons cell, refers to the next pair of boxes, the second cons cell. The CAR of the second cons cell is `violet`, and its CDR is the third cons cell. The CDR of the third (and last) cons cell is `nil`.

Here is another diagram of the same list, (*rose violet buttercup*), sketched in a different manner:

A list with no elements in it is the *empty list*; it is identical to the symbol `nil`. In other words, `nil` is both a symbol and a list.

Here is the list `(A ())`, or equivalently `(A nil)`, depicted with boxes and arrows:

Here is a more complex illustration, showing the three-element list, ((pine needles) oak maple), the first element of which is a two-element list:

The same list represented in the second box notation looks like this:

2.4.6.2 Dotted Pair Notation

Dotted pair notation is a general syntax for cons cells that represents the CAR and CDR explicitly. In this syntax, `(a . b)` stands for a cons cell whose CAR is the object `a` and whose CDR is the object `b`. Dotted pair notation is more general than list syntax because the CDR does not have to be a list. However, it is more cumbersome in cases where list syntax would work. In dotted pair notation, the list `'(1 2 3)` is written as `'(1 . (2 . (3 . nil)))`. For nil-terminated lists, you can use either notation, but list notation is usually clearer and more convenient. When printing a list, the dotted pair notation is only used if the CDR of a cons cell is not a list.

Here's an example using boxes to illustrate dotted pair notation. This example shows the pair `(rose . violet)`:

You can combine dotted pair notation with list notation to represent conveniently a chain of cons cells with a non-nil final CDR. You write a dot after the last element of the list, followed by the CDR of the final cons cell. For example, `(rose violet . buttercup)` is equivalent to `(rose . (violet . buttercup))`. The object looks like this:

The syntax `(rose . violet . buttercup)` is invalid because there is nothing that it could mean. If anything, it would say to put `buttercup` in the CDR of a cons cell whose CDR is already used for `violet`.

The list `(rose violet)` is equivalent to `(rose . (violet))`, and looks like this:

Similarly, the three-element list `(rose violet buttercup)` is equivalent to `(rose . (violet . (buttercup)))`.

2.4.6.3 Association List Type

An *association list* or *alist* is a specially-constructed list whose elements are cons cells. In each element, the CAR is considered a *key*, and the CDR is considered an *associated value*. (In some cases, the associated value is stored in the CAR of the CDR.) Association lists are often used as stacks, since it is easy to add or remove associations at the front of the list.

For example,

```
(setq alist-of-colors
      '((rose . red) (lily . white) (buttercup . yellow)))
```

sets the variable `alist-of-colors` to an alist of three elements. In the first element, `rose` is the key and `red` is the value.

See Section 5.8 [Association Lists], page 95, for a further explanation of alists and for functions that work on alists. See Chapter 8 [Hash Tables], page 127, for another kind of lookup table, which is much faster for handling a large number of keys.

2.4.7 Array Type

An *array* is composed of an arbitrary number of slots for holding or referring to other Lisp objects, arranged in a contiguous block of memory. Accessing any element of an array takes approximately the same amount of time. In contrast, accessing an element of a list requires time proportional to the position of the element in the list. (Elements at the end of a list take longer to access than elements at the beginning of a list.)

Emacs defines four types of array: strings, vectors, bool-vectors, and char-tables.

A string is an array of characters and a vector is an array of arbitrary objects. A bool-vector can hold only `t` or `nil`. These kinds of array may have any length up to the largest fixnum, subject to system architecture limits and available memory. Char-tables are sparse arrays indexed by any valid character code; they can hold arbitrary objects.

The first element of an array has index zero, the second element has index 1, and so on. This is called *zero-origin* indexing. For example, an array of four elements has indices 0, 1, 2, and 3. The largest possible index value is one less than the length of the array. Once an array is created, its length is fixed.

All Emacs Lisp arrays are one-dimensional. (Most other programming languages support multidimensional arrays, but they are not essential; you can get the same effect with nested one-dimensional arrays.) Each type of array has its own read syntax; see the following sections for details.

The array type is a subset of the sequence type, and contains the string type, the vector type, the bool-vector type, and the char-table type.

2.4.8 String Type

A *string* is an array of characters. Strings are used for many purposes in Emacs, as can be expected in a text editor; for example, as the names of Lisp symbols, as messages for the user, and to represent text extracted from buffers. Strings in Lisp are constants: evaluation of a string returns the same string.

See Chapter 4 [Strings and Characters], page 54, for functions that operate on strings.

2.4.8.1 Syntax for Strings

The read syntax for a string is a double-quote, an arbitrary number of characters, and another double-quote, "like this". To include a double-quote in a string, precede it with a backslash; thus, "\'" is a string containing just one double-quote character. Likewise, you can include a backslash by preceding it with another backslash, like this: "this \\ is a single embedded backslash".

Since a string is an array of characters, you can specify the string characters using the read syntax of characters, but without the leading question mark. This is useful for including in string constants characters that don't stand for themselves. Thus, control characters can be specified as escape sequences that start with a backslash; for example, "foo\r" yields 'foo' followed by the carriage return character. See Section 2.4.3.1 [Basic Char Syntax], page 11, for escape sequences of other control characters. Similarly, you can use the special read syntax for control characters (see Section 2.4.3.3 [Ctl-Char Syntax], page 13), as in "foo\tbar", which produces a tab character embedded within a string. You can also use the escape sequences for non-ASCII characters described in Section 2.4.3.2 [General Escape Syntax], page 12, as in "\N{LATIN SMALL LETTER A WITH GRAVE}" and "\u00e0" (however, see a caveat with non-ASCII characters in Section 2.4.8.2 [Non-ASCII in Strings], page 20).

The newline character is not special in the read syntax for strings; if you write a new line between the double-quotes, it becomes a character in the string. But an escaped newline—one that is preceded by '\n'—does not become part of the string; i.e., the Lisp reader ignores an escaped newline while reading a string. An escaped space '\ ' is likewise ignored.

```
"It is useful to include newlines
in documentation strings,
but the newline is \
ignored if escaped."
⇒ "It is useful to include newlines
in documentation strings,
but the newline is ignored if escaped."
```

2.4.8.2 Non-ASCII Characters in Strings

There are two text representations for non-ASCII characters in Emacs strings: multibyte and unibyte (see Section 34.1 [Text Representations], page 963). Roughly speaking, unibyte strings store raw bytes, while multibyte strings store human-readable text. Each character in a unibyte string is a byte, i.e., its value is between 0 and 255. By contrast, each character in a multibyte string may have a value between 0 to 4194303 (see Section 2.4.3 [Character Type], page 11). In both cases, characters above 127 are non-ASCII.

You can include a non-ASCII character in a string constant by writing it literally. If the string constant is read from a multibyte source, such as a multibyte buffer or string, or a file that would be visited as multibyte, then Emacs reads each non-ASCII character as a multibyte character and automatically makes the string a multibyte string. If the string constant is read from a unibyte source, then Emacs reads the non-ASCII character as unibyte, and makes the string unibyte.

Instead of writing a character literally into a multibyte string, you can write it as its character code using an escape sequence. See Section 2.4.3.2 [General Escape Syntax], page 12, for details about escape sequences.

If you use any Unicode-style escape sequence ‘\uNNNN’ or ‘\U00NNNNNN’ in a string constant (even for an ASCII character), Emacs automatically assumes that it is multibyte.

You can also use hexadecimal escape sequences (‘\xn’) and octal escape sequences (‘\n’) in string constants. **But beware:** If a string constant contains octal escape sequences or one- or two-digit hexadecimal escape sequences, and these escape sequences all specify unibyte characters (i.e., codepoints less than 256), and there are no other literal non-ASCII characters or Unicode-style escape sequences in the string, then Emacs automatically assumes that it is a unibyte string. That is to say, it assumes that all non-ASCII characters occurring in the string are 8-bit raw bytes.

In hexadecimal and octal escape sequences, the escaped character code may contain a variable number of digits, so the first subsequent character which is not a valid hexadecimal or octal digit terminates the escape sequence. If the next character in a string could be interpreted as a hexadecimal or octal digit, write ‘\ ’ (backslash and space) to terminate the escape sequence. For example, ‘\xe0\ ’ represents one character, ‘a’ with grave accent. ‘\ ’ in a string constant is just like backslash-newline; it does not contribute any character to the string, but it does terminate any preceding hex escape.

2.4.8.3 Nonprinting Characters in Strings

You can use the same backslash escape-sequences in a string constant as in character literals (but do not use the question mark that begins a character constant). For example, you can write a string containing the nonprinting characters tab and C-a, with commas and spaces between them, like this: “\t, \C-a”. See Section 2.4.3 [Character Type], page 11, and its subsections for a description of the various kinds of read syntax for characters.

However, not all of the characters you can write with backslash escape-sequences are valid in strings. The only control characters that a string can hold are the ASCII control characters. Strings do not distinguish case in ASCII control characters.

Properly speaking, strings cannot hold meta characters; but when a string is to be used as a key sequence, there is a special convention that provides a way to represent meta versions of ASCII characters in a string. If you use the ‘\M-’ syntax to indicate a meta character in a string constant, this sets the 2⁷ bit of the character in the string. If the string is used in `define-key` or `lookup-key`, this numeric code is translated into the equivalent meta character. See Section 2.4.3 [Character Type], page 11.

Strings cannot hold characters that have the hyper, super, or alt modifiers.

2.4.8.4 Text Properties in Strings

A string can hold properties for the characters it contains, in addition to the characters themselves. This enables programs that copy text between strings and buffers to copy the text's properties with no special effort. See Section 33.19 [Text Properties], page 917, for an explanation of what text properties mean. Strings with text properties use a special read and print syntax:

```
#"characters" property-data...)
```

where *property-data* consists of zero or more elements, in groups of three as follows:

```
beg end plist
```

The elements *beg* and *end* are integers, and together specify a range of indices in the string; *plist* is the property list for that range. For example,

```
#"foo bar" 0 3 (face bold) 3 4 nil 4 7 (face italic))
```

represents a string whose textual contents are ‘foo bar’, in which the first three characters have a `face` property with value `bold`, and the last three have a `face` property with value `italic`. (The fourth character has no text properties, so its property list is `nil`. It is not actually necessary to mention ranges with `nil` as the property list, since any characters not mentioned in any range will default to having no properties.)

2.4.9 Vector Type

A *vector* is a one-dimensional array of elements of any type. It takes a constant amount of time to access any element of a vector. (In a list, the access time of an element is proportional to the distance of the element from the beginning of the list.)

The printed representation of a vector consists of a left square bracket, the elements, and a right square bracket. This is also the read syntax. Like numbers and strings, vectors are considered constants for evaluation.

```
[1 "two" (three)]      ; A vector of three elements.  
⇒ [1 "two" (three)]
```

See Section 6.4 [Vectors], page 117, for functions that work with vectors.

2.4.10 Char-Table Type

A *char-table* is a one-dimensional array of elements of any type, indexed by character codes. Char-tables have certain extra features to make them more useful for many jobs that involve assigning information to character codes—for example, a char-table can have a parent to inherit from, a default value, and a small number of extra slots to use for special purposes. A char-table can also specify a single value for a whole character set.

The printed representation of a char-table is like a vector except that there is an extra ‘#^’ at the beginning.¹

See Section 6.6 [Char-Tables], page 119, for special functions to operate on char-tables. Uses of char-tables include:

- Case tables (see Section 4.10 [Case Tables], page 74).
- Character category tables (see Section 36.8 [Categories], page 1036).

¹ You may also encounter ‘#^^’, used for sub-char-tables.

- Display tables (see Section 41.23.2 [Display Tables], page 1243).
- Syntax tables (see Chapter 36 [Syntax Tables], page 1022).

2.4.11 Bool-Vector Type

A *bool-vector* is a one-dimensional array whose elements must be `t` or `nil`.

The printed representation of a bool-vector is like a string, except that it begins with ‘`#&`’ followed by the length. The string constant that follows actually specifies the contents of the bool-vector as a bitmap—each character in the string contains 8 bits, which specify the next 8 elements of the bool-vector (1 stands for `t`, and 0 for `nil`). The least significant bits of the character correspond to the lowest indices in the bool-vector.

```
(make-bool-vector 3 t)
  ⇒ #&3"^\G"
(make-bool-vector 3 nil)
  ⇒ #&3"^\@"
```

These results make sense, because the binary code for ‘C-g’ is 111 and ‘C-@’ is the character with code 0.

If the length is not a multiple of 8, the printed representation shows extra elements, but these extras really make no difference. For instance, in the next example, the two bool-vectors are equal, because only the first 3 bits are used:

```
(equal #&3"\377" #&3"\007")
  ⇒ t
```

2.4.12 Hash Table Type

A hash table is a very fast kind of lookup table, somewhat like an alist in that it maps keys to corresponding values, but much faster. The printed representation of a hash table specifies its properties and contents, like this:

```
(make-hash-table)
  ⇒ #s(hash-table size 65 test eql rehash-size 1.5
           rehash-threshold 0.8125 data ())
```

See Chapter 8 [Hash Tables], page 127, for more information about hash tables.

2.4.13 Function Type

Lisp functions are executable code, just like functions in other programming languages. In Lisp, unlike most languages, functions are also Lisp objects. A non-compiled function in Lisp is a lambda expression: that is, a list whose first element is the symbol `lambda` (see Section 13.2 [Lambda Expressions], page 232).

In most programming languages, it is impossible to have a function without a name. In Lisp, a function has no intrinsic name. A lambda expression can be called as a function even though it has no name; to emphasize this, we also call it an *anonymous function* (see Section 13.7 [Anonymous Functions], page 243). A named function in Lisp is just a symbol with a valid function in its function cell (see Section 13.4 [Defining Functions], page 237).

Most of the time, functions are called when their names are written in Lisp expressions in Lisp programs. However, you can construct or obtain a function object at run time and then call it with the primitive functions `funcall` and `apply`. See Section 13.5 [Calling Functions], page 239.

2.4.14 Macro Type

A *Lisp macro* is a user-defined construct that extends the Lisp language. It is represented as an object much like a function, but with different argument-passing semantics. A Lisp macro has the form of a list whose first element is the symbol `macro` and whose CDR is a Lisp function object, including the `lambda` symbol.

Lisp macro objects are usually defined with the built-in `defmacro` macro, but any list that begins with `macro` is a macro as far as Emacs is concerned. See Chapter 14 [Macros], page 268, for an explanation of how to write a macro.

Warning: Lisp macros and keyboard macros (see Section 22.16 [Keyboard Macros], page 478) are entirely different things. When we use the word “macro” without qualification, we mean a Lisp macro, not a keyboard macro.

2.4.15 Primitive Function Type

A *primitive function* is a function callable from Lisp but written in the C programming language. Primitive functions are also called *subrs* or *built-in functions*. (The word “subr” is derived from “subroutine”.) Most primitive functions evaluate all their arguments when they are called. A primitive function that does not evaluate all its arguments is called a *special form* (see Section 10.1.7 [Special Forms], page 149).

It does not matter to the caller of a function whether the function is primitive. However, this does matter if you try to redefine a primitive with a function written in Lisp. The reason is that the primitive function may be called directly from C code. Calls to the redefined function from Lisp will use the new definition, but calls from C code may still use the built-in definition. Therefore, **we discourage redefinition of primitive functions**.

The term *function* refers to all Emacs functions, whether written in Lisp or C. See Section 2.4.13 [Function Type], page 23, for information about the functions written in Lisp.

Primitive functions have no read syntax and print in hash notation with the name of the subroutine.

```
(symbol-function 'car)           ; Access the function cell
                                ;   of the symbol.
⇒ #<subr car>
(subrp (symbol-function 'car))  ; Is this a primitive function?
⇒ t                           ; Yes.
```

2.4.16 Byte-Code Function Type

Byte-code function objects are produced by byte-compiling Lisp code (see Chapter 17 [Byte Compilation], page 316). Internally, a byte-code function object is much like a vector; however, the evaluator handles this data type specially when it appears in a function call. See Section 17.7 [Byte-Code Objects], page 323.

The printed representation and read syntax for a byte-code function object is like that for a vector, with an additional ‘#’ before the opening '['.

2.4.17 Record Type

A *record* is much like a `vector`. However, the first element is used to hold its type as returned by `type-of`. The purpose of records is to allow programmers to create objects with new types that are not built into Emacs.

See Chapter 7 [Records], page 125, for functions that work with records.

2.4.18 Type Descriptors

A *type descriptor* is a `record` which holds information about a type. Slot 1 in the record must be a symbol naming the type, and `type-of` relies on this to return the type of `record` objects. No other type descriptor slot is used by Emacs; they are free for use by Lisp extensions.

An example of a type descriptor is any instance of `cl-structure-class`.

2.4.19 Autoload Type

An *autoload object* is a list whose first element is the symbol `autoload`. It is stored as the function definition of a symbol, where it serves as a placeholder for the real definition. The autoload object says that the real definition is found in a file of Lisp code that should be loaded when necessary. It contains the name of the file, plus some other information about the real definition.

After the file has been loaded, the symbol should have a new function definition that is not an autoload object. The new definition is then called as if it had been there to begin with. From the user's point of view, the function call works as expected, using the function definition in the loaded file.

An autoload object is usually created with the function `autoload`, which stores the object in the function cell of a symbol. See Section 16.5 [Autoload], page 304, for more details.

2.4.20 Finalizer Type

A *finalizer object* helps Lisp code clean up after objects that are no longer needed. A finalizer holds a Lisp function object. When a finalizer object becomes unreachable after a garbage collection pass, Emacs calls the finalizer's associated function object. When deciding whether a finalizer is reachable, Emacs does not count references from finalizer objects themselves, allowing you to use finalizers without having to worry about accidentally capturing references to finalized objects themselves.

Errors in finalizers are printed to `*Messages*`. Emacs runs a given finalizer object's associated function exactly once, even if that function fails.

`make-finalizer` function

[Function]

Make a finalizer that will run *function*. *function* will be called after garbage collection when the returned finalizer object becomes unreachable. If the finalizer object is reachable only through references from finalizer objects, it does not count as reachable for the purpose of deciding whether to run *function*. *function* will be run once per finalizer object.

2.5 Editing Types

The types in the previous section are used for general programming purposes, and most of them are common to most Lisp dialects. Emacs Lisp provides several additional data types for purposes connected with editing.

2.5.1 Buffer Type

A *buffer* is an object that holds text that can be edited (see Chapter 28 [Buffers], page 671). Most buffers hold the contents of a disk file (see Chapter 26 [Files], page 608) so they can be edited, but some are used for other purposes. Most buffers are also meant to be seen by the user, and therefore displayed, at some time, in a window (see Chapter 29 [Windows], page 690). But a buffer need not be displayed in any window. Each buffer has a designated position called *point* (see Chapter 31 [Positions], page 853); most editing commands act on the contents of the current buffer in the neighborhood of point. At any time, one buffer is the *current buffer*.

The contents of a buffer are much like a string, but buffers are not used like strings in Emacs Lisp, and the available operations are different. For example, you can insert text efficiently into an existing buffer, altering the buffer's contents, whereas inserting text into a string requires concatenating substrings, and the result is an entirely new string object.

Many of the standard Emacs functions manipulate or test the characters in the current buffer; a whole chapter in this manual is devoted to describing these functions (see Chapter 33 [Text], page 878).

Several other data structures are associated with each buffer:

- a local syntax table (see Chapter 36 [Syntax Tables], page 1022);
- a local keymap (see Chapter 23 [Keymaps], page 480); and,
- a list of buffer-local variable bindings (see Section 12.11 [Buffer-Local Variables], page 207).
- overlays (see Section 41.9 [Overlays], page 1150).
- text properties for the text in the buffer (see Section 33.19 [Text Properties], page 917).

The local keymap and variable list contain entries that individually override global bindings or values. These are used to customize the behavior of programs in different buffers, without actually changing the programs.

A buffer may be *indirect*, which means it shares the text of another buffer, but presents it differently. See Section 28.11 [Indirect Buffers], page 687.

Buffers have no read syntax. They print in hash notation, showing the buffer name.

```
(current-buffer)
⇒ #<buffer objects.texi>
```

2.5.2 Marker Type

A *marker* denotes a position in a specific buffer. Markers therefore have two components: one for the buffer, and one for the position. Changes in the buffer's text automatically relocate the position value as necessary to ensure that the marker always points between the same two characters in the buffer.

Markers have no read syntax. They print in hash notation, giving the current character position and the name of the buffer.

```
(point-marker)
⇒ #<marker at 10779 in objects.texi>
```

See Chapter 32 [Markers], page 869, for information on how to test, create, copy, and move markers.

2.5.3 Window Type

A *window* describes the portion of the screen that Emacs uses to display buffers. Every live window (see Section 29.1 [Basic Windows], page 690) has one associated buffer, whose contents appear in that window. By contrast, a given buffer may appear in one window, no window, or several windows. Windows are grouped on the screen into frames; each window belongs to one and only one frame. See Section 2.5.4 [Frame Type], page 27.

Though many windows may exist simultaneously, at any time one window is designated the *selected window* (see Section 29.3 [Selecting Windows], page 696). This is the window where the cursor is (usually) displayed when Emacs is ready for a command. The selected window usually displays the current buffer (see Section 28.2 [Current Buffer], page 671), but this is not necessarily the case.

Windows have no read syntax. They print in hash notation, giving the window number and the name of the buffer being displayed. The window numbers exist to identify windows uniquely, since the buffer displayed in any given window can change frequently.

```
(selected-window)
⇒ #<window 1 on objects.texi>
```

See Chapter 29 [Windows], page 690, for a description of the functions that work on windows.

2.5.4 Frame Type

A *frame* is a screen area that contains one or more Emacs windows; we also use the term “frame” to refer to the Lisp object that Emacs uses to refer to the screen area.

Frames have no read syntax. They print in hash notation, giving the frame’s title, plus its address in core (useful to identify the frame uniquely).

```
(selected-frame)
⇒ #<frame emacs@psilocin.gnu.org 0xdac80>
```

See Chapter 30 [Frames], page 785, for a description of the functions that work on frames.

2.5.5 Terminal Type

A *terminal* is a device capable of displaying one or more Emacs frames (see Section 2.5.4 [Frame Type], page 27).

Terminals have no read syntax. They print in hash notation giving the terminal’s ordinal number and its TTY device file name.

```
(get-device-terminal nil)
⇒ #<terminal 1 on /dev/tty>
```

2.5.6 Window Configuration Type

A *window configuration* stores information about the positions, sizes, and contents of the windows in a frame, so you can recreate the same arrangement of windows later.

Window configurations do not have a read syntax; their print syntax looks like ‘#<window-configuration>’. See Section 29.26 [Window Configurations], page 774, for a description of several functions related to window configurations.

2.5.7 Frame Configuration Type

A *frame configuration* stores information about the positions, sizes, and contents of the windows in all frames. It is not a primitive type—it is actually a list whose CAR is `frame-configuration` and whose CDR is an alist. Each alist element describes one frame, which appears as the CAR of that element.

See Section 30.13 [Frame Configurations], page 831, for a description of several functions related to frame configurations.

2.5.8 Process Type

The word *process* usually means a running program. Emacs itself runs in a process of this sort. However, in Emacs Lisp, a process is a Lisp object that designates a subprocess created by the Emacs process. Programs such as shells, GDB, ftp, and compilers, running in subprocesses of Emacs, extend the capabilities of Emacs. An Emacs subprocess takes textual input from Emacs and returns textual output to Emacs for further manipulation. Emacs can also send signals to the subprocess.

Process objects have no read syntax. They print in hash notation, giving the name of the process:

```
(process-list)
⇒ (#<process shell>)
```

See Chapter 40 [Processes], page 1078, for information about functions that create, delete, return information about, send input or signals to, and receive output from processes.

2.5.9 Thread Type

A *thread* in Emacs represents a separate thread of Emacs Lisp execution. It runs its own Lisp program, has its own current buffer, and can have subprocesses locked to it, i.e. subprocesses whose output only this thread can accept. See Chapter 39 [Threads], page 1073.

Thread objects have no read syntax. They print in hash notation, giving the name of the thread (if it has been given a name) or its address in core:

```
(all-threads)
⇒ (#<thread 0176fc40>)
```

2.5.10 Mutex Type

A *mutex* is an exclusive lock that threads can own and disown, in order to synchronize between them. See Section 39.2 [Mutexes], page 1075.

Mutex objects have no read syntax. They print in hash notation, giving the name of the mutex (if it has been given a name) or its address in core:

```
(make-mutex "my-mutex")
⇒ #<mutex my-mutex>
(make-mutex)
⇒ #<mutex 01c7e4e0>
```

2.5.11 Condition Variable Type

A *condition variable* is a device for a more complex thread synchronization than the one supported by a mutex. A thread can wait on a condition variable, to be woken up when some other thread notifies the condition.

Condition variable objects have no read syntax. They print in hash notation, giving the name of the condition variable (if it has been given a name) or its address in core:

```
(make-condition-variable (make-mutex))
⇒ #<condvar 01c45ae8>
```

2.5.12 Stream Type

A *stream* is an object that can be used as a source or sink for characters—either to supply characters for input or to accept them as output. Many different types can be used this way: markers, buffers, strings, and functions. Most often, input streams (character sources) obtain characters from the keyboard, a buffer, or a file, and output streams (character sinks) send characters to a buffer, such as a *Help* buffer, or to the echo area.

The object `nil`, in addition to its other meanings, may be used as a stream. It stands for the value of the variable `standard-input` or `standard-output`. Also, the object `t` as a stream specifies input using the minibuffer (see Chapter 21 [Minibuffers], page 385) or output in the echo area (see Section 41.4 [The Echo Area], page 1131).

Streams have no special printed representation or read syntax, and print as whatever primitive type they are.

See Chapter 20 [Read and Print], page 371, for a description of functions related to streams, including parsing and printing functions.

2.5.13 Keymap Type

A *keymap* maps keys typed by the user to commands. This mapping controls how the user’s command input is executed. A keymap is actually a list whose CAR is the symbol `keymap`.

See Chapter 23 [Keymaps], page 480, for information about creating keymaps, handling prefix keys, local as well as global keymaps, and changing key bindings.

2.5.14 Overlay Type

An *overlay* specifies properties that apply to a part of a buffer. Each overlay applies to a specified range of the buffer, and contains a property list (a list whose elements are alternating property names and values). Overlay properties are used to present parts of the buffer temporarily in a different display style. Overlays have no read syntax, and print in hash notation, giving the buffer name and range of positions.

See Section 41.9 [Overlays], page 1150, for information on how you can create and use overlays.

2.5.15 Font Type

A *font* specifies how to display text on a graphical terminal. There are actually three separate font types—*font objects*, *font specs*, and *font entities*—each of which has slightly different properties. None of them have a read syntax; their print syntax looks like ‘#<font-object>’, ‘#<font-spec>’, and ‘#<font-entity>’ respectively. See Section 41.12.12 [Low-Level Font], page 1184, for a description of these Lisp objects.

2.5.16 Xwidget Type

An *xwidget* is a special display element, such as a web browser, that can be embedded inside a buffer. Each window that displays an xwidget will also have an *xwidget view*, which on X-Windows corresponds to a single X window used to display the widget.

Neither of these objects are readable; their print syntaxes look like ‘#<xwidget>’ and ‘#<xwidget-view>’, respectively. See Section 41.19 [Xwidgets], page 1228, for a more detailed description of xwidgets.

2.6 Read Syntax for Circular Objects

To represent shared or circular structures within a complex of Lisp objects, you can use the reader constructs ‘#n=’ and ‘#n#’.

Use #n= before an object to label it for later reference; subsequently, you can use #n# to refer the same object in another place. Here, n is some integer. For example, here is how to make a list in which the first element recurs as the third element:

```
(#1=(a) b #1#)
```

This differs from ordinary syntax such as this

```
((a) b (a))
```

which would result in a list whose first and third elements look alike but are not the same Lisp object. This shows the difference:

```
(prog1 nil
  (setq x'(#1=(a) b #1#)))
(eq (nth 0 x) (nth 2 x))
⇒ t
(setq x'((a) b (a)))
(eq (nth 0 x) (nth 2 x))
⇒ nil
```

You can also use the same syntax to make a circular structure, which appears as an element within itself. Here is an example:

```
#1=(a #1#)
```

This makes a list whose second element is the list itself. Here’s how you can see that it really works:

```
(prog1 nil
  (setq x '#1=(a #1#)))
(eq x (cadr x))
⇒ t
```

The Lisp printer can produce this syntax to record circular and shared structure in a Lisp object, if you bind the variable `print-circle` to a non-nil value. See Section 20.6 [Output Variables], page 380.

2.7 Type Predicates

The Emacs Lisp interpreter itself does not perform type checking on the actual arguments passed to functions when they are called. It could not do so, since function arguments in Lisp do not have declared data types, as they do in other programming languages. It is therefore up to the individual function to test whether each actual argument belongs to a type that the function can use.

All built-in functions do check the types of their actual arguments when appropriate, and signal a `wrong-type-argument` error if an argument is of the wrong type. For example, here is what happens if you pass an argument to `+` that it cannot handle:

```
(+ 2 'a)
[error] Wrong type argument: number-or-marker-p, a
```

If you want your program to handle different types differently, you must do explicit type checking. The most common way to check the type of an object is to call a *type predicate* function. Emacs has a type predicate for each type, as well as some predicates for combinations of types.

A type predicate function takes one argument; it returns `t` if the argument belongs to the appropriate type, and `nil` otherwise. Following a general Lisp convention for predicate functions, most type predicates' names end with '`p`'.

Here is an example which uses the predicates `listp` to check for a list and `symbolp` to check for a symbol.

```
(defun add-on (x)
  (cond ((symbolp x)
          ;; If X is a symbol, put it on LIST.
          (setq list (cons x list)))
        ((listp x)
          ;; If X is a list, add its elements to LIST.
          (setq list (append x list)))
        (t
          ;; We handle only symbols and lists.
          (error "Invalid argument %s in add-on" x))))
```

Here is a table of predefined type predicates, in alphabetical order, with references to further information.

`atom` See Section 5.2 [List-related Predicates], page 78.

`arrayp` See Section 6.3 [Array Functions], page 116.

`bignumP` See Section 3.3 [Predicates on Numbers], page 41.

`bool-vector-p`
See Section 6.7 [Bool-Vectors], page 121.

`booleanp` See Section 1.3.2 [nil and t], page 2.

`bufferp` See Section 28.1 [Buffer Basics], page 671.

`byte-code-function-p`
See Section 2.4.16 [Byte-Code Type], page 24.

`compiled-function-p`
See Section 2.4.16 [Byte-Code Type], page 24.

`case-table-p`
See Section 4.10 [Case Tables], page 74.

`char-or-string-p`
See Section 4.2 [Predicates for Strings], page 55.

char-table-p

See Section 6.6 [Char-Tables], page 119.

commandp See Section 22.3 [Interactive Call], page 432.**condition-variable-p**

See Section 39.3 [Condition Variables], page 1075.

consp See Section 5.2 [List-related Predicates], page 78.**custom-variable-p**

symbolp**syntax-table-p**

See Chapter 36 [Syntax Tables], page 1022.

threadp

See Section 39.1 [Basic Thread Functions], page 1073.

vectorp**wholenump**

See Section 3.3 [Predicates on Numbers], page 41.

window-configuration-p

See Section 29.26 [Window Configurations], page 774.

window-live-p

See Section 29.8 [Deleting Windows], page 711.

windowp

See Section 29.1 [Basic Windows], page 690.

The most general way to check the type of an object is to call the function `type-of`. Recall that each object belongs to one and only one primitive type; `type-of` tells you which one (see Chapter 2 [Lisp Data Types], page 8). But `type-of` knows nothing about non-primitive types. In most cases, it is more convenient to use type predicates than `type-of`.

type-of object

[Function]

This function returns a symbol naming the primitive type of *object*. The value is one of the symbols `bool-vector`, `buffer`, `char-table`, `compiled-function`, `condition-variable`, `cons`, `finalizer`, `float`, `font-entity`, `font-object`, `font-spec`, `frame`, `hash-table`, `integer`, `marker`, `mutex`, `overlay`, `process`, `string`, `subr`, `symbol`, `thread`, `vector`, `window`, or `window-configuration`. However, if *object* is a record, the type specified by its first slot is returned; Chapter 7 [Records], page 125.

```
(type-of 1)
        ⇒ integer
(type-of 'nil)
        ⇒ symbol
(type-of '())
        ; () is nil.
        ⇒ symbol
(type-of '(x))
        ⇒ cons
(type-of (record 'foo))
        ⇒ foo
```

2.8 Equality Predicates

Here we describe functions that test for equality between two objects. Other functions test equality of contents between objects of specific types, e.g., strings. For these predicates, see the appropriate chapter describing the data type.

eq *object1 object2* [Function]

This function returns `t` if *object1* and *object2* are the same object, and `nil` otherwise.

If *object1* and *object2* are symbols with the same name, they are normally the same object—but see Section 9.3 [Creating Symbols], page 135, for exceptions. For other non-numeric types (e.g., lists, vectors, strings), two arguments with the same contents or elements are not necessarily `eq` to each other: they are `eq` only if they are the same object, meaning that a change in the contents of one will be reflected by the same change in the contents of the other.

If *object1* and *object2* are numbers with differing types or values, then they cannot be the same object and `eq` returns `nil`. If they are fixnums with the same value, then they are the same object and `eq` returns `t`. If they were computed separately but happen to have the same value and the same non-fixnum numeric type, then they might or might not be the same object, and `eq` returns `t` or `nil` depending on whether the Lisp interpreter created one object or two.

```
(eq 'foo 'foo)
⇒ t

(eq ?A ?A)
⇒ t

(eq 3.0 3.0)
⇒ t or nil
;; Equal floats may or may not be the same object.

(eq (make-string 3 ?A) (make-string 3 ?A))
⇒ nil

(eq "asdf" "asdf")
⇒ t or nil
;; Equal string constants or may not be the same object.

(eq '(1 (2 (3))) '(1 (2 (3))))
⇒ nil

(setq foo '(1 (2 (3))))
⇒ (1 (2 (3)))
(eq foo foo)
⇒ t
(eq foo '(1 (2 (3))))
⇒ nil
```

```
(eq [(1 2) 3] [(1 2) 3])
⇒ nil

(equal (point-marker) (point-marker))
⇒ nil
```

The `make-symbol` function returns an uninterned symbol, distinct from the symbol that is used if you write the name in a Lisp expression. Distinct symbols with the same name are not `eq`. See Section 9.3 [Creating Symbols], page 135.

```
(eq (make-symbol "foo") 'foo)
⇒ nil
```

The Emacs Lisp byte compiler may collapse identical literal objects, such as literal strings, into references to the same object, with the effect that the byte-compiled code will compare such objects as `eq`, while the interpreted version of the same code will not. Therefore, your code should never rely on objects with the same literal contents being either `eq` or not `eq`, it should instead use functions that compare object contents such as `equal`, described below. Similarly, your code should not modify literal objects (e.g., put text properties on literal strings), since doing that might affect other literal objects of the same contents, if the byte compiler collapses them.

`equal object1 object2` [Function]

This function returns `t` if `object1` and `object2` have equal components, and `nil` otherwise. Whereas `eq` tests if its arguments are the same object, `equal` looks inside nonidentical arguments to see if their elements or contents are the same. So, if two objects are `eq`, they are `equal`, but the converse is not always true.

```
(equal 'foo 'foo)
⇒ t

(equal 456 456)
⇒ t

(equal "asdf" "asdf")
⇒ t
(eq "asdf" "asdf")
⇒ nil

(equal '(1 (2 (3))) '(1 (2 (3))))
⇒ t
(eq '(1 (2 (3))) '(1 (2 (3))))
⇒ nil

(equal [(1 2) 3] [(1 2) 3])
⇒ t
(eq [(1 2) 3] [(1 2) 3])
⇒ nil

(equal (point-marker) (point-marker))
⇒ t
```

```
(eq (point-marker) (point-marker))
⇒ nil
```

Comparison of strings is case-sensitive, but does not take account of text properties—it compares only the characters in the strings. See Section 33.19 [Text Properties], page 917. Use `equal-including-properties` to also compare text properties. For technical reasons, a unibyte string and a multibyte string are `equal` if and only if they contain the same sequence of character codes and all these codes are in the range 0 through 127 (ASCII).

```
(equal "asdf" "ASDF")
⇒ nil
```

The `equal` function recursively compares the contents of objects if they are integers, strings, markers, vectors, bool-vectors, byte-code function objects, char-tables, records, or font objects. Other objects are considered `equal` only if they are `eq`. For example, two distinct buffers are never considered `equal`, even if their textual contents are the same.

For `equal`, equality is defined recursively; for example, given two cons cells `x` and `y`, `(equal x y)` returns `t` if and only if both the expressions below return `t`:

```
(equal (car x) (car y))
(equal (cdr x) (cdr y))
```

Comparing circular lists may therefore cause deep recursion that leads to an error, and this may result in counterintuitive behavior such as `(equal a b)` returning `t` whereas `(equal b a)` signals an error.

`equal-including-properties object1 object2` [Function]

This function behaves like `equal` in all cases but also requires that for two strings to be equal, they have the same text properties.

```
(equal "asdf" (propertize "asdf" 'asdf t))
⇒ t
(equal-including-properties "asdf"
                           (propertize "asdf" 'asdf t))
⇒ nil
```

2.9 Mutability

Some Lisp objects should never change. For example, the Lisp expression `"aaa"` yields a string, but you should not change its contents. And some objects cannot be changed; for example, although you can create a new number by calculating one, Lisp provides no operation to change the value of an existing number.

Other Lisp objects are *mutable*: it is safe to change their values via destructive operations involving side effects. For example, an existing marker can be changed by moving the marker to point to somewhere else.

Although numbers never change and all markers are mutable, some types have members some of which are mutable and others not. These types include conses, vectors, and strings. For example, although `"cons"` and `(symbol-name 'cons)` both yield strings that should not

be changed, (`(copy-sequence "cons")`) and (`(make-string 3 ?a)`) both yield mutable strings that can be changed via later calls to `aset`.

A mutable object stops being mutable if it is part of an expression that is evaluated. For example:

```
(let* ((x (list 0.5))
       (y (eval (list 'quote x))))
  (setcar x 1.5) ;; The program should not do this.
  y)
```

Although the list (0.5) was mutable when it was created, it should not have been changed via `setcar` because it was given to `eval`. The reverse does not occur: an object that should not be changed never becomes mutable afterwards.

If a program attempts to change objects that should not be changed, the resulting behavior is undefined: the Lisp interpreter might signal an error, or it might crash or behave unpredictably in other ways.²

When similar constants occur as parts of a program, the Lisp interpreter might save time or space by reusing existing constants or their components. For example, (`(eq "abc" "abc")`) returns `t` if the interpreter creates only one instance of the string literal "abc", and returns `nil` if it creates two instances. Lisp programs should be written so that they work regardless of whether this optimization is in use.

² This is the behavior specified for languages like Common Lisp and C for constants, and this differs from languages like JavaScript and Python where an interpreter is required to signal an error if a program attempts to change an immutable object. Ideally the Emacs Lisp interpreter will evolve in latter direction.

3 Numbers

GNU Emacs supports two numeric data types: *integers* and *floating-point numbers*. Integers are whole numbers such as -3 , 0 , 7 , 13 , and 511 . Floating-point numbers are numbers with fractional parts, such as -4.5 , 0.0 , and 2.71828 . They can also be expressed in exponential notation: ‘ $1.5\text{e}2$ ’ is the same as ‘ 150.0 ’; here, ‘ $\text{e}2$ ’ stands for ten to the second power, and that is multiplied by 1.5 . Integer computations are exact. Floating-point computations often involve rounding errors, as the numbers have a fixed amount of precision.

3.1 Integer Basics

The Lisp reader reads an integer as a nonempty sequence of decimal digits with optional initial sign and optional final period.

<code>1</code>	; The integer 1.
<code>1.</code>	; The integer 1.
<code>+1</code>	; Also the integer 1.
<code>-1</code>	; The integer -1 .
<code>0</code>	; The integer 0.
<code>-0</code>	; The integer 0.

The syntax for integers in bases other than 10 consists of ‘#’ followed by a radix indication followed by one or more digits. The radix indications are ‘`b`’ for binary, ‘`o`’ for octal, ‘`x`’ for hex, and ‘`radixr`’ for radix `radix`. Thus, ‘`#binteger`’ reads `integer` in binary, and ‘`#radixrinteger`’ reads `integer` in radix `radix`. Allowed values of `radix` run from 2 to 36, and allowed digits are the first `radix` characters taken from ‘`0`’–‘`9`’, ‘`A`’–‘`Z`’. Letter case is ignored and there is no initial sign or final period. For example:

```
#b101100 ⇒ 44
#o54 ⇒ 44
#x2c ⇒ 44
#24r1k ⇒ 44
```

To understand how various functions work on integers, especially the bitwise operators (see Section 3.8 [Bitwise Operations], page 48), it is often helpful to view the numbers in their binary form.

In binary, the decimal integer 5 looks like this:

```
...000101
```

(The ellipsis ‘...’ stands for a conceptually infinite number of bits that match the leading bit; here, an infinite number of 0 bits. Later examples also use this ‘...’ notation.)

The integer -1 looks like this:

```
...111111
```

-1 is represented as all ones. (This is called *two’s complement* notation.)

Subtracting 4 from -1 returns the negative integer -5 . In binary, the decimal integer 4 is 100. Consequently, -5 looks like this:

```
...111011
```

Many of the functions described in this chapter accept markers for arguments in place of numbers. (See Chapter 32 [Markers], page 869.) Since the actual arguments to such

functions may be either numbers or markers, we often give these arguments the name *number-or-marker*. When the argument value is a marker, its position value is used and its buffer is ignored.

In Emacs Lisp, text characters are represented by integers. Any integer between zero and the value of `(max-char)`, inclusive, is considered to be valid as a character. See Section 34.5 [Character Codes], page 967.

Integers in Emacs Lisp are not limited to the machine word size. Under the hood, though, there are two kinds of integers: smaller ones, called *fixnums*, and larger ones, called *bignums*. Although Emacs Lisp code ordinarily should not depend on whether an integer is a fixnum or a bignum, older Emacs versions support only fixnums, some functions in Emacs still accept only fixnums, and older Emacs Lisp code may have trouble when given bignums. For example, while older Emacs Lisp code could safely compare integers for numeric equality with `eq`, the presence of bignums means that equality predicates like `eql` and `=` should now be used to compare integers.

The range of values for bignums is limited by the amount of main memory, by machine characteristics such as the size of the word used to represent a bignum’s exponent, and by the `integer-width` variable. These limits are typically much more generous than the limits for fixnums. A bignum is never numerically equal to a fixnum; Emacs always represents an integer in fixnum range as a fixnum, not a bignum.

The range of values for a fixnum depends on the machine. The minimum range is $-536,870,912$ to $536,870,911$ (30 bits; i.e., -2^{29} to $2^{29} - 1$), but many machines provide a wider range.

`most-positive-fixnum`

[Variable]

The value of this variable is the greatest “small” integer that Emacs Lisp can handle. Typical values are $2^{29} - 1$ on 32-bit and $2^{61} - 1$ on 64-bit platforms.

`most-negative-fixnum`

[Variable]

The value of this variable is the numerically least “small” integer that Emacs Lisp can handle. It is negative. Typical values are -2^{29} on 32-bit and -2^{61} on 64-bit platforms.

`integer-width`

[Variable]

The value of this variable is a nonnegative integer that controls whether Emacs signals a range error when a large integer would be calculated. Integers with absolute values less than 2^n , where n is this variable’s value, do not signal a range error. Attempts to create larger integers typically signal a range error, although there might be no signal if a larger integer can be created cheaply. Setting this variable to a large number can be costly if a computation creates huge integers.

3.2 Floating-Point Basics

Floating-point numbers are useful for representing numbers that are not integral. The range of floating-point numbers is the same as the range of the C data type `double` on the machine you are using. On almost all computers supported by Emacs, this is IEEE binary64 floating point format, which is standardized by IEEE Std 754-2019 and is discussed further in David Goldberg’s paper “What Every Computer Scientist Should Know About Floating-Point Arithmetic (<https://docs.oracle.com/cd/E19957-01/806-3568/>

`ncg_goldberg.html`”). On modern platforms, floating-point operations follow the IEEE-754 standard closely; however, results are not always rounded correctly on some systems, notably 32-bit x86.

On some old computer systems, Emacs may not use IEEE floating-point. We know of one such system on which Emacs runs correctly, but does not follow IEEE-754: the VAX running NetBSD using GCC 10.4.0, where the VAX ‘D_Floating’ format is used instead. IBM System/370-derived mainframes and their XL/C compiler are also capable of utilizing a hexadecimal floating point format, but Emacs has not yet been built in such a configuration.

The read syntax for floating-point numbers requires either a decimal point, an exponent, or both. Optional signs ('+' or '-') precede the number and its exponent. For example, '1500.0', '+15e2', '15.0e+2', '+1500000e-3', and '.15e4' are five ways of writing a floating-point number whose value is 1500. They are all equivalent. Like Common Lisp, Emacs Lisp requires at least one digit after a decimal point in a floating-point number that does not have an exponent; '1500.' is an integer, not a floating-point number.

Emacs Lisp treats `-0.0` as numerically equal to ordinary zero with respect to numeric comparisons like `=`. This follows the IEEE floating-point standard, which says `-0.0` and `0.0` are numerically equal even though other operations can distinguish them.

The IEEE floating-point standard supports positive infinity and negative infinity as floating-point values. It also provides for a class of values called NaN, or “not a number”; numerical functions return such values in cases where there is no correct answer. For example, $(/ 0.0 0.0)$ returns a NaN. A NaN is never numerically equal to any value, not even to itself. NaNs carry a sign and a significand, and non-numeric functions treat two NaNs as equal when their signs and significands agree. Significands of NaNs are machine-dependent, as are the digits in their string representation.

NaNs are not available on systems which do not use IEEE floating-point arithmetic; if the read syntax for a NaN is used on a VAX, for example, the reader signals an error.

When NaNs and signed zeros are involved, non-numeric functions like `eql`, `equal`, `sxhash-eql`, `sxhash-equal` and `gethash` determine whether values are indistinguishable, not whether they are numerically equal. For example, when `x` and `y` are the same NaN, `(equal x y)` returns `t` whereas `(= x y)` uses numeric comparison and returns `nil`; conversely, `(equal 0.0 -0.0)` returns `nil` whereas `(= 0.0 -0.0)` returns `t`.

Here are read syntaxes for these special floating-point values:

infinity ‘1.0e+INF’ and ‘-1.0e+INF’

not-a-number

'0.0e+NaN' and '-0.0e+NaN'

The following functions are specialized for handling floating-point numbers:

isnan x

Function

This predicate returns `t` if its floating-point argument is a NaN, `nil` otherwise.

frexp x

Function

This function returns a cons cell (*s . e*), where *s* and *e* are respectively the significand and exponent of the floating-point number *x*.

If x is finite, then s is a floating-point number between 0.5 (inclusive) and 1.0 (exclusive), e is an integer, and $x = s2^e$. If x is zero or infinity, then s is the same as x . If x is a NaN, then s is also a NaN. If x is zero, then e is 0.

ldexp $s\ e$ [Function]

Given a numeric significand s and an integer exponent e , this function returns the floating point number $s2^e$.

copysign $x1\ x2$ [Function]

This function copies the sign of $x2$ to the value of $x1$, and returns the result. $x1$ and $x2$ must be floating point.

logb x [Function]

This function returns the binary exponent of x . More precisely, if x is finite and nonzero, the value is the logarithm base 2 of $|x|$, rounded down to an integer. If x is zero or infinite, the value is infinity; if x is a NaN, the value is a NaN.

```
(logb 10)
    ⇒ 3
(logb 10.0e20)
    ⇒ 69
(logb 0)
    ⇒ -1.0e+INF
```

3.3 Type Predicates for Numbers

The functions in this section test for numbers, or for a specific type of number. The functions **integerp** and **floatp** can take any type of Lisp object as argument (they would not be of much use otherwise), but the **zerop** predicate requires a number as its argument. See also **integer-or-marker-p** and **number-or-marker-p**, in Section 32.2 [Predicates on Markers], page 870.

bignump $object$ [Function]

This predicate tests whether its argument is a large integer, and returns **t** if so, **nil** otherwise. Unlike small integers, large integers can be **=** or **eql** even if they are not **eq**.

fixnump $object$ [Function]

This predicate tests whether its argument is a small integer, and returns **t** if so, **nil** otherwise. Small integers can be compared with **eq**.

floatp $object$ [Function]

This predicate tests whether its argument is floating point and returns **t** if so, **nil** otherwise.

integerp $object$ [Function]

This predicate tests whether its argument is an integer, and returns **t** if so, **nil** otherwise.

numberp $object$ [Function]

This predicate tests whether its argument is a number (either integer or floating point), and returns **t** if so, **nil** otherwise.

natnump object [Function]

This predicate (whose name comes from the phrase “natural number”) tests to see whether its argument is a nonnegative integer, and returns `t` if so, `nil` otherwise. 0 is considered non-negative.

`wholenump` is a synonym for `natnump`.

zerop number [Function]

This predicate tests whether its argument is zero, and returns `t` if so, `nil` otherwise. The argument must be a number.

`(zerop x)` is equivalent to `(= x 0)`.

3.4 Comparison of Numbers

To test numbers for numerical equality, you should normally use `=` instead of non-numeric comparison predicates like `eq`, `eql` and `equal`. Distinct floating-point and large integer objects can be numerically equal. If you use `eq` to compare them, you test whether they are the same *object*; if you use `eql` or `equal`, you test whether their values are *indistinguishable*. In contrast, `=` uses numeric comparison, and sometimes returns `t` when a non-numeric comparison would return `nil` and vice versa. See Section 3.2 [Float Basics], page 39.

In Emacs Lisp, if two fixnums are numerically equal, they are the same Lisp object. That is, `eq` is equivalent to `=` on fixnums. It is sometimes convenient to use `eq` for comparing an unknown value with a fixnum, because `eq` does not report an error if the unknown value is not a number—it accepts arguments of any type. By contrast, `=` signals an error if the arguments are not numbers or markers. However, it is better programming practice to use `=` if you can, even for comparing integers.

Sometimes it is useful to compare numbers with `eql` or `equal`, which treat two numbers as equal if they have the same data type (both integers, or both floating point) and the same value. By contrast, `=` can treat an integer and a floating-point number as equal. See Section 2.8 [Equality Predicates], page 34.

There is another wrinkle: because floating-point arithmetic is not exact, it is often a bad idea to check for equality of floating-point values. Usually it is better to test for approximate equality. Here’s a function to do this:

```
(defvar fuzz-factor 1.0e-6)
(defun approx-equal (x y)
  (or (= x y)
      (< (/ (abs (- x y))
            (max (abs x) (abs y)))
          fuzz-factor)))
```

`= number-or-marker &rest number-or-markers` [Function]

This function tests whether all its arguments are numerically equal, and returns `t` if so, `nil` otherwise.

eql value1 value2 [Function]

This function acts like `eq` except when both arguments are numbers. It compares numbers by type and numeric value, so that `(eql 1.0 1)` returns `nil`, but `(eql 1.0 1.0)` and `(eql 1 1)` both return `t`. This can be used to compare large integers as well

as small ones. Floating-point values with the same sign, exponent and fraction are `eq1`. This differs from numeric comparison: (`eq1 0.0 -0.0`) returns `nil` and (`eq1 0.0e+NaN 0.0e+NaN`) returns `t`, whereas `=` does the opposite.

/= *number-or-marker1 number-or-marker2* [Function]

This function tests whether its arguments are numerically equal, and returns `t` if they are not, and `nil` if they are.

< *number-or-marker &rest number-or-markers* [Function]

This function tests whether each argument is strictly less than the following argument. It returns `t` if so, `nil` otherwise.

<= *number-or-marker &rest number-or-markers* [Function]

This function tests whether each argument is less than or equal to the following argument. It returns `t` if so, `nil` otherwise.

> *number-or-marker &rest number-or-markers* [Function]

This function tests whether each argument is strictly greater than the following argument. It returns `t` if so, `nil` otherwise.

>= *number-or-marker &rest number-or-markers* [Function]

This function tests whether each argument is greater than or equal to the following argument. It returns `t` if so, `nil` otherwise.

max *number-or-marker &rest numbers-or-markers* [Function]

This function returns the largest of its arguments.

```
(max 20)
    ⇒ 20
(max 1 2.5)
    ⇒ 2.5
(max 1 3 2.5)
    ⇒ 3
```

min *number-or-marker &rest numbers-or-markers* [Function]

This function returns the smallest of its arguments.

```
(min -4 1)
    ⇒ -4
```

abs *number* [Function]

This function returns the absolute value of *number*.

3.5 Numeric Conversions

To convert an integer to floating point, use the function `float`.

float *number* [Function]

This returns *number* converted to floating point. If *number* is already floating point, `float` returns it unchanged.

There are four functions to convert floating-point numbers to integers; they differ in how they round. All accept an argument *number* and an optional argument *divisor*. Both arguments may be integers or floating-point numbers. *divisor* may also be `nil`. If *divisor* is `nil` or omitted, these functions convert *number* to an integer, or return it unchanged if it already is an integer. If *divisor* is non-`nil`, they divide *number* by *divisor* and convert the result to an integer. If *divisor* is zero (whether integer or floating point), Emacs signals an `arith-error` error.

truncate *number* &**optional divisor**

[Function]

This returns *number*, converted to an integer by rounding towards zero.

```
(truncate 1.2)
⇒ 1
(truncate 1.7)
⇒ 1
(truncate -1.2)
⇒ -1
(truncate -1.7)
⇒ -1
```

floor *number* &**optional divisor**

[Function]

This returns *number*, converted to an integer by rounding downward (towards negative infinity).

If *divisor* is specified, this uses the kind of division operation that corresponds to `mod`, rounding downward.

```
(floor 1.2)
⇒ 1
(floor 1.7)
⇒ 1
(floor -1.2)
⇒ -2
(floor -1.7)
⇒ -2
(floor 5.99 3)
⇒ 1
```

ceiling *number* &**optional divisor**

[Function]

This returns *number*, converted to an integer by rounding upward (towards positive infinity).

```
(ceiling 1.2)
⇒ 2
(ceiling 1.7)
⇒ 2
(ceiling -1.2)
⇒ -1
(ceiling -1.7)
⇒ -1
```

round *number &optional divisor* [Function]

This returns *number*, converted to an integer by rounding towards the nearest integer. Rounding a value equidistant between two integers returns the even integer.

```
(round 1.2)
⇒ 1
(round 1.7)
⇒ 2
(round -1.2)
⇒ -1
(round -1.7)
⇒ -2
```

3.6 Arithmetic Operations

Emacs Lisp provides the traditional four arithmetic operations (addition, subtraction, multiplication, and division), as well as remainder and modulus functions, and functions to add or subtract 1. Except for %, each of these functions accepts both integer and floating-point arguments, and returns a floating-point number if any argument is floating point.

1+ *number-or-marker* [Function]

This function returns *number-or-marker* plus 1. For example,

```
(setq foo 4)
⇒ 4
(1+ foo)
⇒ 5
```

This function is not analogous to the C operator ++—it does not increment a variable. It just computes a sum. Thus, if we continue,

```
foo
⇒ 4
```

If you want to increment the variable, you must use `setq`, like this:

```
(setq foo (1+ foo))
⇒ 5
```

1- *number-or-marker* [Function]

This function returns *number-or-marker* minus 1.

+ *&rest numbers-or-markers* [Function]

This function adds its arguments together. When given no arguments, + returns 0.

```
(+)
⇒ 0
(+ 1)
⇒ 1
(+ 1 2 3 4)
⇒ 10
```

- **&optional** *number-or-marker* **&rest** *more-numbers-or-markers* [Function]

The `-` function serves two purposes: negation and subtraction. When `-` has a single argument, the value is the negative of the argument. When there are multiple arguments, `-` subtracts each of the *more-numbers-or-markers* from *number-or-marker*, cumulatively. If there are no arguments, the result is 0.

```
(- 10 1 2 3 4)
⇒ 0
(- 10)
⇒ -10
(-)
⇒ 0
```

* **&rest** *numbers-or-markers* [Function]

This function multiplies its arguments together, and returns the product. When given no arguments, `*` returns 1.

```
(*)
⇒ 1
(* 1)
⇒ 1
(* 1 2 3 4)
⇒ 24
```

/ *number* **&rest** *divisors* [Function]

With one or more *divisors*, this function divides *number* by each divisor in *divisors* in turn, and returns the quotient. With no *divisors*, this function returns $1/\text{number}$, i.e., the multiplicative inverse of *number*. Each argument may be a number or a marker.

If all the arguments are integers, the result is an integer, obtained by rounding the quotient towards zero after each division.

```
(/ 6 2)
⇒ 3
(/ 5 2)
⇒ 2
(/ 5.0 2)
⇒ 2.5
(/ 5 2.0)
⇒ 2.5
(/ 5.0 2.0)
⇒ 2.5
(/ 4.0)
⇒ 0.25
(/ 4)
⇒ 0
(/ 25 3 2)
⇒ 4
(/ -17 6)
⇒ -2
```

If you divide an integer by the integer 0, Emacs signals an **arith-error** error (see Section 11.7.3 [Errors], page 179). On systems using IEEE-754 floating-point, floating-point division of a nonzero number by zero yields either positive or negative infinity (see Section 3.2 [Float Basics], page 39); otherwise, an **arith-error** is signaled as usual.

% *dividend divisor* [Function]

This function returns the integer remainder after division of *dividend* by *divisor*. The arguments must be integers or markers.

For any two integers *dividend* and *divisor*,

```
(+ (% dividend divisor)
    (* (/ dividend divisor) divisor))
```

always equals *dividend* if *divisor* is nonzero.

```
(% 9 4)
  ⇒ 1
(% -9 4)
  ⇒ -1
(% 9 -4)
  ⇒ 1
(% -9 -4)
  ⇒ -1
```

mod *dividend divisor* [Function]

This function returns the value of *dividend* modulo *divisor*; in other words, the remainder after division of *dividend* by *divisor*, but with the same sign as *divisor*. The arguments must be numbers or markers.

Unlike %, mod permits floating-point arguments; it rounds the quotient downward (towards minus infinity) to an integer, and uses that quotient to compute the remainder. If *divisor* is zero, mod signals an **arith-error** error if both arguments are integers, and returns a NaN otherwise.

```
(mod 9 4)
  ⇒ 1
(mod -9 4)
  ⇒ 3
(mod 9 -4)
  ⇒ -3
(mod -9 -4)
  ⇒ -1
(mod 5.5 2.5)
  ⇒ .5
```

For any two numbers *dividend* and *divisor*,

```
(+ (mod dividend divisor)
    (* (floor dividend divisor) divisor))
```

always equals *dividend*, subject to rounding error if either argument is floating point and to an **arith-error** if *dividend* is an integer and *divisor* is 0. For floor, see Section 3.5 [Numeric Conversions], page 43.

3.7 Rounding Operations

The functions `ffloor`, `fceiling`, `fround`, and `ftruncate` take a floating-point argument and return a floating-point result whose value is a nearby integer. `ffloor` returns the nearest integer below; `fceiling`, the nearest integer above; `ftruncate`, the nearest integer in the direction towards zero; `fround`, the nearest integer.

ffloor *float*

[Function]

This function rounds *float* to the next lower integral value, and returns that value as a floating-point number.

fceiling *float*

[Function]

This function rounds *float* to the next higher integral value, and returns that value as a floating-point number.

ftruncate *float*

[Function]

This function rounds *float* towards zero to an integral value, and returns that value as a floating-point number.

fround *float*

[Function]

This function rounds *float* to the nearest integral value, and returns that value as a floating-point number. Rounding a value equidistant between two integers returns the even integer.

3.8 Bitwise Operations on Integers

In a computer, an integer is represented as a binary number, a sequence of *bits* (digits which are either zero or one). Conceptually the bit sequence is infinite on the left, with the most-significant bits being all zeros or all ones. A bitwise operation acts on the individual bits of such a sequence. For example, *shifting* moves the whole sequence left or right one or more places, reproducing the same pattern moved over.

The bitwise operations in Emacs Lisp apply only to integers.

ash *integer1 count*

[Function]

`ash` (*arithmetic shift*) shifts the bits in *integer1* to the left *count* places, or to the right if *count* is negative. Left shifts introduce zero bits on the right; right shifts discard the rightmost bits. Considered as an integer operation, `ash` multiplies *integer1* by 2^{count} , and then converts the result to an integer by rounding downward, toward minus infinity.

Here are examples of `ash`, shifting a pattern of bits one place to the left and to the right. These examples show only the low-order bits of the binary pattern; leading bits all agree with the highest-order bit shown. As you can see, shifting left by one is equivalent to multiplying by two, whereas shifting right by one is equivalent to dividing by two and then rounding toward minus infinity.

```
(ash 7 1) ⇒ 14
;; Decimal 7 becomes decimal 14.
...000111
      ⇒
...001110
```

```
(ash 7 -1) => 3
...000111
      =>
...000011

(ash -7 1) => -14
...111001
      =>
...110010

(ash -7 -1) => -4
...111001
      =>
...111100
```

Here are examples of shifting left or right by two bits:

	; binary values
(ash 5 2)	; 5 = ...000101
⇒ 20	; = ...010100
(ash -5 2)	; -5 = ...111011
⇒ -20	; = ...101100
(ash 5 -2)	; = ...000001
⇒ 1	; = ...000001
(ash -5 -2)	; = ...111110
⇒ -2	; = ...111110

`lsh integer1 count`

[Function]

`lsh`, which is an abbreviation for *logical shift*, shifts the bits in `integer1` to the left `count` places, or to the right if `count` is negative, bringing zeros into the vacated bits. If `count` is negative, then `integer1` must be either a fixnum or a positive bignum, and `lsh` treats a negative fixnum as if it were unsigned by subtracting twice `most-negative-fixnum` before shifting, producing a nonnegative result. This quirky behavior dates back to when Emacs supported only fixnums; nowadays `ash` is a better choice.

As `lsh` behaves like `ash` except when `integer1` and `count1` are both negative, the following examples focus on these exceptional cases. These examples assume 30-bit fixnums.

	; binary values
(ash -7 -1)	; -7 = ...111111111111111111111111111111001
⇒ -4	; = ...111111111111111111111111111111100
(lsh -7 -1)	⇒ 536870908 ; = ...011111111111111111111111111111100
(ash -5 -2)	; -5 = ...1111111111111111111111111111111011
⇒ -2	; = ...1111111111111111111111111111111110
(lsh -5 -2)	⇒ 268435454 ; = ...0011111111111111111111111111111110

`logand &rest ints-or-markers`

[Function]

This function returns the bitwise AND of the arguments: the *n*th bit is 1 in the result if, and only if, the *n*th bit is 1 in all the arguments.

For example, using 4-bit binary numbers, the bitwise AND of 13 and 12 is 12: 1101 combined with 1100 produces 1100. In both the binary numbers, the leftmost two

bits are both 1 so the leftmost two bits of the returned value are both 1. However, for the rightmost two bits, each is 0 in at least one of the arguments, so the rightmost two bits of the returned value are both 0.

Therefore,

```
(logand 13 12)
⇒ 12
```

If `logand` is not passed any argument, it returns a value of -1 . This number is an identity element for `logand` because its binary representation consists entirely of ones. If `logand` is passed just one argument, it returns that argument.

```
;      binary values

(logand 14 13) ; 14 = ...001110
; 13 = ...001101
⇒ 12 ; 12 = ...001100

(logand 14 13 4) ; 14 = ...001110
; 13 = ...001101
; 4 = ...000100
⇒ 4 ; 4 = ...000100

(logand)
⇒ -1 ; -1 = ...111111
```

`logior &rest ints-or-markers`

[Function]

This function returns the bitwise inclusive OR of its arguments: the n th bit is 1 in the result if, and only if, the n th bit is 1 in at least one of the arguments. If there are no arguments, the result is 0, which is an identity element for this operation. If `logior` is passed just one argument, it returns that argument.

```
;      binary values

(logior 12 5) ; 12 = ...001100
; 5 = ...000101
⇒ 13 ; 13 = ...001101

(logior 12 5 7) ; 12 = ...001100
; 5 = ...000101
; 7 = ...000111
⇒ 15 ; 15 = ...001111
```

`logxor &rest ints-or-markers`

[Function]

This function returns the bitwise exclusive OR of its arguments: the n th bit is 1 in the result if, and only if, the n th bit is 1 in an odd number of the arguments. If there are no arguments, the result is 0, which is an identity element for this operation. If `logxor` is passed just one argument, it returns that argument.

```
;      binary values

(logxor 12 5) ; 12 = ...001100
; 5 = ...000101
⇒ 9 ; 9 = ...001001

(logxor 12 5 7) ; 12 = ...001100
; 5 = ...000101
; 7 = ...000111
⇒ 14 ; 14 = ...001110
```

lognot integer

[Function]

This function returns the bitwise complement of its argument: the n th bit is one in the result if, and only if, the n th bit is zero in *integer*, and vice-versa. The result equals $-1 - \text{integer}$.

```
(lognot 5)
  ⇒ -6
;; 5 = ...000101
;; becomes
;; -6 = ...111010
```

logcount integer

[Function]

This function returns the *Hamming weight* of *integer*: the number of ones in the binary representation of *integer*. If *integer* is negative, it returns the number of zero bits in its two's complement binary representation. The result is always nonnegative.

```
(logcount 43)      ; 43 = ...000101011
  ⇒ 4
(logcount -43)     ; -43 = ...111010101
  ⇒ 3
```

3.9 Standard Mathematical Functions

These mathematical functions allow integers as well as floating-point numbers as arguments.

sin arg

[Function]

cos arg

[Function]

tan arg

[Function]

These are the basic trigonometric functions, with argument *arg* measured in radians.

asin arg

[Function]

The value of **(asin arg)** is a number between $-\pi/2$ and $\pi/2$ (inclusive) whose sine is *arg*. If *arg* is out of range (outside $[-1, 1]$), **asin** returns a NaN.

acos arg

[Function]

The value of **(acos arg)** is a number between 0 and π (inclusive) whose cosine is *arg*. If *arg* is out of range (outside $[-1, 1]$), **acos** returns a NaN.

atan y &optional x

[Function]

The value of **(atan y)** is a number between $-\pi/2$ and $\pi/2$ (exclusive) whose tangent is *y*. If the optional second argument *x* is given, the value of **(atan y x)** is the angle in radians between the vector **[x, y]** and the X axis.

exp arg

[Function]

This is the exponential function; it returns e to the power *arg*.

log arg &optional base

[Function]

This function returns the logarithm of *arg*, with base *base*. If you don't specify *base*, the natural base e is used. If *arg* or *base* is negative, **log** returns a NaN.

expt *x y*

[Function]

This function returns *x* raised to power *y*. If both arguments are integers and *y* is nonnegative, the result is an integer; in this case, overflow signals an error, so watch out. If *x* is a finite negative number and *y* is a finite non-integer, **expt** returns a NaN.

sqrt *arg*

[Function]

This returns the square root of *arg*. If *arg* is finite and less than zero, **sqrt** returns a NaN.

In addition, Emacs defines the following common mathematical constants:

float-e

[Variable]

The mathematical constant *e* (2.71828...).

float-pi

[Variable]

The mathematical constant *pi* (3.14159...).

3.10 Random Numbers

A deterministic computer program cannot generate true random numbers. For most purposes, *pseudo-random numbers* suffice. A series of pseudo-random numbers is generated in a deterministic fashion. The numbers are not truly random, but they have certain properties that mimic a random series. For example, all possible values occur equally often in a pseudo-random series.

Pseudo-random numbers are generated from a *seed value*. Starting from any given seed, the **random** function always generates the same sequence of numbers. By default, Emacs initializes the random seed at startup, in such a way that the sequence of values of **random** (with overwhelming likelihood) differs in each Emacs run. The random seed is typically initialized from system entropy; however, on obsolescent platforms lacking entropy pools, the seed is taken from less-random volatile data such as the current time.

Sometimes you want the random number sequence to be repeatable. For example, when debugging a program whose behavior depends on the random number sequence, it is helpful to get the same behavior in each program run. To make the sequence repeat, execute (**random ""**). This sets the seed to a constant value for your particular Emacs executable (though it may differ for other Emacs builds). You can use other strings to choose various seed values.

random &*optional limit*

[Function]

This function returns a pseudo-random integer. Repeated calls return a series of pseudo-random integers.

If *limit* is a positive integer, the value is chosen to be nonnegative and less than *limit*. Otherwise, the value might be any fixnum, i.e., any integer from **most-negative-fixnum** through **most-positive-fixnum** (see Section 3.1 [Integer Basics], page 38).

If *limit* is a string, it means to choose a new seed based on the string's contents. This causes later calls to **random** to return a reproducible sequence of results.

If *limit* is **t**, it means to choose a new seed as if Emacs were restarting. This causes later calls to **random** to return an unpredictable sequence of results.

If you need a random nonce for cryptographic purposes, using `random` is typically not the best approach, for several reasons:

- Although you can use `(random t)` to consult system entropy, doing so can adversely affect other parts of your program that benefit from reproducible results.
- The system-dependent pseudo-random number generator (PRNG) used by `random` is not necessarily suitable for cryptography.
- A call to `(random t)` does not give direct access to system entropy; the entropy is passed through the system-dependent PRNG, thus possibly biasing the results.
- On typical platforms the random seed contains only 32 bits, which is typically narrower than an Emacs fixnum, and is not nearly enough for cryptographic purposes.
- A `(random t)` call leaves information about the nonce scattered about Emacs's internal state, increasing the size of the internal attack surface.
- On obsolescent platforms lacking entropy pools, `(random t)` is seeded from a cryptographically weak source.

4 Strings and Characters

A string in Emacs Lisp is an array that contains an ordered sequence of characters. Strings are used as names of symbols, buffers, and files; to send messages to users; to hold text being copied between buffers; and for many other purposes. Because strings are so important, Emacs Lisp has many functions expressly for manipulating them. Emacs Lisp programs use strings more often than individual characters.

See Section 22.7.17 [Strings of Events], page 459, for special considerations for strings of keyboard character events.

4.1 String and Character Basics

A character is a Lisp object which represents a single character of text. In Emacs Lisp, characters are simply integers; whether an integer is a character or not is determined only by how it is used. See Section 34.5 [Character Codes], page 967, for details about character representation in Emacs.

A string is a fixed sequence of characters. It is a type of sequence called an *array*, meaning that its length is fixed and cannot be altered once it is created (see Chapter 6 [Sequences Arrays Vectors], page 102). Unlike in C, Emacs Lisp strings are *not* terminated by a distinguished character code.

Since strings are arrays, and therefore sequences as well, you can operate on them with the general array and sequence functions documented in Chapter 6 [Sequences Arrays Vectors], page 102. For example, you can access individual characters in a string using the function `aref` (see Section 6.3 [Array Functions], page 116).

There are two text representations for non-ASCII characters in Emacs strings (and in buffers): unibyte and multibyte. For most Lisp programming, you don't need to be concerned with these two representations. See Section 34.1 [Text Representations], page 963, for details.

Sometimes key sequences are represented as unibyte strings. When a unibyte string is a key sequence, string elements in the range 128 to 255 represent meta characters (which are large integers) rather than character codes in the range 128 to 255. Strings cannot hold characters that have the hyper, super or alt modifiers; they can hold ASCII control characters, but no other control characters. They do not distinguish case in ASCII control characters. If you want to store such characters in a sequence, such as a key sequence, you must use a vector instead of a string. See Section 2.4.3 [Character Type], page 11, for more information about keyboard input characters.

Strings are useful for holding regular expressions. You can also match regular expressions against strings with `string-match` (see Section 35.4 [Regexp Search], page 1008). The functions `match-string` (see Section 35.6.2 [Simple Match Data], page 1013) and `replace-match` (see Section 35.6.1 [Replacing Match], page 1012) are useful for decomposing and modifying strings after matching regular expressions against them.

Like a buffer, a string can contain text properties for the characters in it, as well as the characters themselves. See Section 33.19 [Text Properties], page 917. All the Lisp primitives that copy text from strings to buffers or other strings also copy the properties of the characters being copied.

See Chapter 33 [Text], page 878, for information about functions that display strings or copy them into buffers. See Section 2.4.3 [Character Type], page 11, and Section 2.4.8 [String

Type], page 20, for information about the syntax of characters and strings. See Chapter 34 [Non-ASCII Characters], page 963, for functions to convert between text representations and to encode and decode character codes. Also, note that `length` should *not* be used for computing the width of a string on display; use `string-width` (see Section 41.10 [Size of Displayed Text], page 1157) instead.

4.2 Predicates for Strings

For more information about general sequence and array predicates, see Chapter 6 [Sequences Arrays Vectors], page 102, and Section 6.2 [Arrays], page 115.

stringp *object* [Function]

This function returns `t` if *object* is a string, `nil` otherwise.

string-or-null-p *object* [Function]

This function returns `t` if *object* is a string or `nil`. It returns `nil` otherwise.

char-or-string-p *object* [Function]

This function returns `t` if *object* is a string or a character (i.e., an integer), `nil` otherwise.

4.3 Creating Strings

The following functions create strings, either from scratch, or by putting strings together, or by taking them apart. (For functions that create strings based on the modified contents of other strings, like `string-replace` and `replace-regexp-in-string`, see Section 35.7 [Search and Replace], page 1016.)

make-string *count character &optional multibyte* [Function]

This function returns a string made up of *count* repetitions of *character*. If *count* is negative, an error is signaled.

```
(make-string 5 ?x)
⇒ "xxxxx"
(make-string 0 ?x)
⇒ ""
```

Normally, if *character* is an ASCII character, the result is a unibyte string. But if the optional argument *multibyte* is non-`nil`, the function will produce a multibyte string instead. This is useful when you later need to concatenate the result with non-ASCII strings or replace some of its characters with non-ASCII characters.

Other functions to compare with this one include `make-vector` (see Section 6.4 [Vectors], page 117) and `make-list` (see Section 5.4 [Building Lists], page 82).

string &rest characters [Function]

This returns a string containing the characters *characters*.

```
(string ?a ?b ?c)
⇒ "abc"
```

substring *string* &**optional** *start end* [Function]

This function returns a new string which consists of those characters from *string* in the range from (and including) the character at the index *start* up to (but excluding) the character at the index *end*. The first character is at index zero. With one argument, this function just copies *string*.

```
(substring "abcdefg" 0 3)
⇒ "abc"
```

In the above example, the index for ‘a’ is 0, the index for ‘b’ is 1, and the index for ‘c’ is 2. The index 3—which is the fourth character in the string—marks the character position up to which the substring is copied. Thus, ‘abc’ is copied from the string “abcdefg”.

A negative number counts from the end of the string, so that -1 signifies the index of the last character of the string. For example:

```
(substring "abcdefg" -3 -1)
⇒ "ef"
```

In this example, the index for ‘e’ is -3 , the index for ‘f’ is -2 , and the index for ‘g’ is -1 . Therefore, ‘e’ and ‘f’ are included, and ‘g’ is excluded.

When **nil** is used for *end*, it stands for the length of the string. Thus,

```
(substring "abcdefg" -3 nil)
⇒ "efg"
```

Omitting the argument *end* is equivalent to specifying **nil**. It follows that **(substring string 0)** returns a copy of all of *string*.

```
(substring "abcdefg" 0)
⇒ "abcdefg"
```

But we recommend **copy-sequence** for this purpose (see Section 6.1 [Sequence Functions], page 102).

If the characters copied from *string* have text properties, the properties are copied into the new string also. See Section 33.19 [Text Properties], page 917.

substring also accepts a vector for the first argument. For example:

```
(substring [a b (c) "d"] 1 3)
⇒ [b (c)]
```

A **wrong-type-argument** error is signaled if *start* is not an integer or if *end* is neither an integer nor **nil**. An **args-out-of-range** error is signaled if *start* indicates a character following *end*, or if either integer is out of range for *string*.

Contrast this function with **buffer-substring** (see Section 33.2 [Buffer Contents], page 879), which returns a string containing a portion of the text in the current buffer. The beginning of a string is at index 0, but the beginning of a buffer is at index 1.

substring-no-properties *string* &**optional** *start end* [Function]

This works like **substring** but discards all text properties from the value. Also, *start* may be omitted or **nil**, which is equivalent to 0. Thus, **(substring-no-properties string)** returns a copy of *string*, with all text properties removed.

concat &rest sequences

[Function]

This function returns a string consisting of the characters in the arguments passed to it (along with their text properties, if any). The arguments may be strings, lists of numbers, or vectors of numbers; they are not themselves changed. If `concat` receives no arguments, it returns an empty string.

```
(concat "abc" "-def")
      ⇒ "abc-def"
(concat "abc" (list 120 121) [122])
      ⇒ "abcxyz"
;; nil is an empty sequence.
(concat "abc" nil "-def")
      ⇒ "abc-def"
(concat "The " "quick brown " "fox.")
      ⇒ "The quick brown fox."
(concat)
      ⇒ ""
```

This function does not always allocate a new string. Callers are advised not rely on the result being a new string nor on it being `eq` to an existing string.

In particular, mutating the returned value may inadvertently change another string, alter a constant string in the program, or even raise an error. To obtain a string that you can safely mutate, use `copy-sequence` on the result.

For information about other concatenation functions, see the description of `mapconcat` in Section 13.6 [Mapping Functions], page 241, `vconcat` in Section 6.5 [Vector Functions], page 118, and `append` in Section 5.4 [Building Lists], page 82. For concatenating individual command-line arguments into a string to be used as a shell command, see Section 40.2 [Shell Arguments], page 1080.

split-string string &optional separators omit-nulls trim

[Function]

This function splits *string* into substrings based on the regular expression *separators* (see Section 35.3 [Regular Expressions], page 995). Each match for *separators* defines a splitting point; the substrings between splitting points are made into a list, which is returned.

If *separators* is `nil` (or omitted), the default is the value of `split-string-default-separators` and the function behaves as if *omit-nulls* were `t`.

If *omit-nulls* is `nil` (or omitted), the result contains null strings whenever there are two consecutive matches for *separators*, or a match is adjacent to the beginning or end of *string*. If *omit-nulls* is `t`, these null strings are omitted from the result.

If the optional argument *trim* is non-`nil`, it should be a regular expression to match text to trim from the beginning and end of each substring. If trimming makes the substring empty, it is treated as null.

If you need to split a string into a list of individual command-line arguments suitable for `call-process` or `start-process`, see Section 40.2 [Shell Arguments], page 1080.

Examples:

```
(split-string " two words ")
      ⇒ ("two" "words")
```

The result is not ("" "two" "words" ""), which would rarely be useful. If you need such a result, use an explicit value for *separators*:

```
(split-string " two words "
             split-string-default-separators)
⇒ ("" "two" "words" "")

(split-string "Soup is good food" "o")
⇒ ("S" "up is g" "" "d f" "" "d")
(split-string "Soup is good food" "o" t)
⇒ ("S" "up is g" "d f" "d")
(split-string "Soup is good food" "o+")
⇒ ("S" "up is g" "d f" "d")
```

Empty matches do count, except that `split-string` will not look for a final empty match when it already reached the end of the string using a non-empty match or when *string* is empty:

```
(split-string "aoob" "o*")
⇒ ("" "a" "" "b" "")
(split-string "ooaboo" "o*")
⇒ ("" "" "a" "b" "")
(split-string "") ""
⇒ ("")
```

However, when *separators* can match the empty string, *omit-nulls* is usually `t`, so that the subtleties in the three previous examples are rarely relevant:

```
(split-string "Soup is good food" "o*" t)
⇒ ("S" "u" "p" " " "i" "s" " " "g" "d" " " "f" "d")
(split-string "Nice doggy!" "" t)
⇒ ("N" "i" "c" "e" " " "d" "o" "g" "g" "y" "!")
(split-string "" "" t)
⇒ nil
```

Somewhat odd, but predictable, behavior can occur for certain “non-greedy” values of *separators* that can prefer empty matches over non-empty matches. Again, such values rarely occur in practice:

```
(split-string "ooo" "o*" t)
⇒ nil
(split-string "ooo" "\\\|o+" t)
⇒ ("o" "o" "o")
```

split-string-default-separators [Variable]
 The default value of *separators* for `split-string`. Its usual value is "[\f\t\n\r\v]+".

string-clean-whitespace string [Function]
 Clean up the whitespace in *string* by collapsing stretches of whitespace to a single space character, as well as removing all whitespace from the start and the end of *string*.

string-trim-left *string* &optional *regexp* [Function]

Remove the leading text that matches *regexp* from *string*. *regexp* defaults to ‘[
 \t\n\r]+’.

string-trim-right *string* &optional *regexp* [Function]

Remove the trailing text that matches *regexp* from *string*. *regexp* defaults to ‘[
 \t\n\r]+’.

string-trim *string* &optional *trim-left* *trim-right* [Function]

Remove the leading text that matches *trim-left* and trailing text that matches *trim-right* from *string*. Both regexps default to ‘[\t\n\r]+’.

string-fill *string* *length* [Function]

Attempt to Word-wrap *string* so that no lines are longer than *length*. Filling is done on whitespace boundaries only. If there are individual words that are longer than *length*, these will not be shortened.

string-limit *string* *length* &optional *end* *coding-system* [Function]

If *string* is shorter than *length* characters, *string* is returned as is. Otherwise, return a substring of *string* consisting of the first *length* characters. If the optional *end* parameter is given, return a string of the *length* last characters instead.

If *coding-system* is non-nil, *string* will be encoded before limiting, and the result will be a unibyte string that’s shorter than *length* bytes. If *string* contains characters that are encoded into several bytes (for instance, when using utf-8), the resulting unibyte string is never truncated in the middle of a character representation.

This function measures the string length in characters or bytes, and thus is generally inappropriate if you need to shorten strings for display purposes; use **truncate-string-to-width** or **window-text-pixel-size** or **string-glyph-split** instead (see Section 41.10 [Size of Displayed Text], page 1157).

string-lines *string* &optional *omit-nulls* *keep-newlines* [Function]

Split *string* into a list of strings on newline boundaries. If the optional argument *omit-nulls* is non-nil, remove empty lines from the results. If the optional argument *keep-newlines* is non-nil, don’t remove the trailing newlines from the result strings.

string-pad *string* *length* &optional *padding* *start* [Function]

Pad *string* to be of the given *length* using *padding* as the padding character. *padding* defaults to the space character. If *string* is longer than *length*, no padding is done. If *start* is nil or omitted, the padding is appended to the characters of *string*, and if it’s non-nil, the padding is prepended to *string*’s characters.

string-chop-newline *string* [Function]

Remove the final newline, if any, from *string*.

4.4 Modifying Strings

You can alter the contents of a mutable string via operations described in this section. See Section 2.9 [Mutability], page 36.

The most basic way to alter the contents of an existing string is with `aset` (see Section 6.3 [Array Functions], page 116). (`aset string idx char`) stores `char` into `string` at character index `idx`. It will automatically convert a pure-ASCII `string` to a multibyte string (see Section 34.1 [Text Representations], page 963) if needed, but we recommend to always make sure `string` is multibyte (e.g., by using `string-to-multibyte`, see Section 34.3 [Converting Representations], page 965), if `char` is a non-ASCII character, not a raw byte.

A more powerful function is `store-substring`:

`store-substring string idx obj` [Function]

This function alters part of the contents of the specified `string`, by storing `obj` starting at character index `idx`. The argument `obj` may be either a character (in which case the function behaves exactly as `aset`) or a (smaller) string. If `obj` is a multibyte string, we recommend to make sure `string` is also multibyte, even if it's pure-ASCII.

Since it is impossible to change the number of characters in an existing string, it is an error if `obj` consists of more characters than would fit in `string` starting at character index `idx`.

To clear out a string that contained a password, use `clear-string`:

`clear-string string` [Function]

This makes `string` a unibyte string and clears its contents to zeros. It may also change `string`'s length.

4.5 Comparison of Characters and Strings

`char-equal character1 character2` [Function]

This function returns `t` if the arguments represent the same character, `nil` otherwise. This function ignores differences in case if `case-fold-search` is non-`nil`.

```
(char-equal ?x ?x)
  ⇒ t
(let ((case-fold-search nil))
  (char-equal ?x ?X))
  ⇒ nil
```

`string= string1 string2` [Function]

This function returns `t` if the characters of the two strings match exactly. Symbols are also allowed as arguments, in which case the symbol names are used. Case is always significant, regardless of `case-fold-search`.

This function is equivalent to `equal` for comparing two strings (see Section 2.8 [Equality Predicates], page 34). In particular, the text properties of the two strings are ignored; use `equal-including-properties` if you need to distinguish between strings that differ only in their text properties. However, unlike `equal`, if either argument is not a string or symbol, `string=` signals an error.

```
(string= "abc" "abc")
  ⇒ t
(string= "abc" "ABC")
  ⇒ nil
```

```
(string= "ab" "ABC")
⇒ nil
```

A unibyte and a multibyte string are equal in the sense of `string=` if and only if they contain the same sequence of character codes all being in the range 0–127 (ASCII). See Section 34.1 [Text Representations], page 963.

`string-equal string1 string2` [Function]
`string-equal` is another name for `string=`.

`string-equal-ignore-case string1 string2` [Function]
`string-equal-ignore-case` compares strings ignoring case differences, like `char-equal` when `case-fold-search` is `t`.

`string-collate-equalp string1 string2 &optional locale ignore-case` [Function]
This function returns `t` if `string1` and `string2` are equal with respect to the collation rules of the specified `locale`, which defaults to your current system locale. A collation rule is not only determined by the lexicographic order of the characters contained in `string1` and `string2`, but also by further rules about relations between these characters. Usually, it is defined by the locale environment with which Emacs is running and by the Standard C library against which Emacs was linked¹.

For example, characters with different code points but the same meaning, like different grave accent Unicode characters, might, in some locales, be considered as equal:

```
(string-collate-equalp (string ?\uFF40) (string ?\u1FEF))
⇒ t
```

The optional argument `locale`, a string, overrides the setting of your current locale identifier for collation. The value is system dependent; a `locale "en_US.UTF-8"` is applicable on POSIX systems, while it would be, e.g., `"enu_USA.1252"` on MS-Windows systems.

If `ignore-case` is `non-nil`, characters are compared case-insensitively, by converting them to lower-case. However, if the underlying system library doesn't provide locale-specific collation rules, this function falls back to `string-equal`, in which case the `ignore-case` argument is ignored, and the comparison will always be case-sensitive.

To emulate Unicode-compliant collation on MS-Windows systems, bind `w32-collate-ignore-punctuation` to a `non-nil` value, since the codeset part of the locale cannot be "UTF-8" on MS-Windows.

If your system does not support a locale environment, this function behaves like `string-equal`.

Do *not* use this function to compare file names for equality, as filesystems generally don't honor linguistic equivalence of strings that collation implements.

`string< string1 string2` [Function]

This function compares two strings a character at a time. It scans both the strings at the same time to find the first pair of corresponding characters that do not match. If

¹ For more information about collation rules and their locale dependencies, see The Unicode Collation Algorithm (<https://unicode.org/reports/tr10/>). Some Standard C libraries, such as the GNU C Library (a.k.a. `glibc`) implement large portions of the Unicode Collation Algorithm and use the associated locale data, Common Locale Data Repository, or CLDR.

the lesser character of these two is the character from *string1*, then *string1* is less, and this function returns `t`. If the lesser character is the one from *string2*, then *string1* is greater, and this function returns `nil`. If the two strings match entirely, the value is `nil`.

Pairs of characters are compared according to their character codes. Keep in mind that lower case letters have higher numeric values in the ASCII character set than their upper case counterparts; digits and many punctuation characters have a lower numeric value than upper case letters. An ASCII character is less than any non-ASCII character; a unibyte non-ASCII character is always less than any multibyte non-ASCII character (see Section 34.1 [Text Representations], page 963).

```
(string< "abc" "abd")
⇒ t
(string< "abd" "abc")
⇒ nil
(string< "123" "abc")
⇒ t
```

When the strings have different lengths, and they match up to the length of *string1*, then the result is `t`. If they match up to the length of *string2*, the result is `nil`. A string of no characters is less than any other string.

```
(string< "" "abc")
⇒ t
(string< "ab" "abc")
⇒ t
(string< "abc" "")
⇒ nil
(string< "abc" "ab")
⇒ nil
(string< "" "")
⇒ nil
```

Symbols are also allowed as arguments, in which case their print names are compared.

string-lessp *string1* *string2* [Function]
`string-lessp` is another name for `string<`.

string-greaterp *string1* *string2* [Function]
This function returns the result of comparing *string1* and *string2* in the opposite order, i.e., it is equivalent to calling `(string-lessp string2 string1)`.

string-collate-lessp *string1* *string2* &**optional** *locale* *ignore-case* [Function]
This function returns `t` if *string1* is less than *string2* in collation order of the specified *locale*, which defaults to your current system locale. A collation order is not only determined by the lexicographic order of the characters contained in *string1* and *string2*, but also by further rules about relations between these characters. Usually, it is defined by the locale environment with which Emacs is running, and by the Standard C library against which Emacs was linked.

For example, punctuation and whitespace characters might be ignored for sorting (see Section 6.1 [Sequence Functions], page 102):

```
(sort (list "11" "12" "1 1" "1 2" "1.1" "1.2") 'string-collate-lessp)
      ⇒ ("11" "1 1" "1.1" "12" "1 2" "1.2")
```

This behavior is system-dependent; e.g., punctuation and whitespace are never ignored on Cygwin, regardless of locale.

The optional argument *locale*, a string, overrides the setting of your current locale identifier for collation. The value is system dependent; a *locale* "en_US.UTF-8" is applicable on POSIX systems, while it would be, e.g., "enu_USA.1252" on MS-Windows systems. The *locale* value of "POSIX" or "C" lets `string-collate-lessp` behave like `string-lessp`:

```
(sort (list "11" "12" "1 1" "1 2" "1.1" "1.2")
      (lambda (s1 s2) (string-collate-lessp s1 s2 "POSIX")))
      ⇒ ("1 1" "1 2" "1.1" "1.2" "11" "12")
```

If *ignore-case* is non-*nil*, characters are compared case-insensitively, by converting them to lower-case. However, if the underlying system library doesn't provide locale-specific collation rules, this function falls back to `string-lessp`, in which case the *ignore-case* argument is ignored, and the comparison will always be case-sensitive.

To emulate Unicode-compliant collation on MS-Windows systems, bind `w32-collate-ignore-punctuation` to a non-*nil* value, since the codeset part of the locale cannot be "UTF-8" on MS-Windows.

If your system does not support a locale environment, this function behaves like `string-lessp`.

string-version-lessp *string1* *string2* [Function]

This function compares strings lexicographically, except it treats sequences of numerical characters as if they comprised a base-ten number, and then compares the numbers. So 'foo2.png' is "smaller" than 'foo12.png' according to this predicate, even if '12' is lexicographically "smaller" than '2'.

string-prefix-p *string1* *string2* &**optional** *ignore-case* [Function]

This function returns non-*nil* if *string1* is a prefix of *string2*; i.e., if *string2* starts with *string1*. If the optional argument *ignore-case* is non-*nil*, the comparison ignores case differences.

string-suffix-p *suffix* *string* &**optional** *ignore-case* [Function]

This function returns non-*nil* if *suffix* is a suffix of *string*; i.e., if *string* ends with *suffix*. If the optional argument *ignore-case* is non-*nil*, the comparison ignores case differences.

string-search *needle* *haystack* &**optional** *start-pos* [Function]

Return the position of the first instance of *needle* in *haystack*, both of which are strings. If *start-pos* is non-*nil*, start searching from that position in *haystack*. Return *nil* if no match was found. This function only considers the characters in the strings when doing the comparison; text properties are ignored. Matching is always case-sensitive.

compare-strings *string1* *start1* *end1* *string2* *start2* *end2* &**optional** *ignore-case* [Function]

This function compares a specified part of *string1* with a specified part of *string2*. The specified part of *string1* runs from index *start1* (inclusive) up to index *end1*

(exclusive); `nil` for `start1` means the start of the string, while `nil` for `end1` means the length of the string. Likewise, the specified part of `string2` runs from index `start2` up to index `end2`.

The strings are compared by the numeric values of their characters. For instance, `str1` is considered less than `str2` if its first differing character has a smaller numeric value. If `ignore-case` is non-`nil`, characters are converted to upper-case, using the current buffer's case-table (see Section 4.10 [Case Tables], page 74), before comparing them. Unibyte strings are converted to multibyte for comparison (see Section 34.1 [Text Representations], page 963), so that a unibyte string and its conversion to multibyte are always regarded as equal.

If the specified portions of the two strings match, the value is `t`. Otherwise, the value is an integer which indicates how many leading characters agree, and which string is less. Its absolute value is one plus the number of characters that agree at the beginning of the two strings. The sign is negative if `string1` (or its specified portion) is less.

string-distance *string1* *string2* &optional *bytecompare* [Function]

This function returns the Levenshtein distance between the source string `string1` and the target string `string2`. The Levenshtein distance is the number of single-character changes—deletions, insertions, or replacements—required to transform the source string into the target string; it is one possible definition of the edit distance between strings.

Letter-case of the strings is significant for the computed distance, but their text properties are ignored. If the optional argument `bytecompare` is non-`nil`, the function calculates the distance in terms of bytes instead of characters. The byte-wise comparison uses the internal Emacs representation of characters, so it will produce inaccurate results for multibyte strings that include raw bytes (see Section 34.1 [Text Representations], page 963); make the strings unibyte by encoding them (see Section 34.10.7 [Explicit Encoding], page 988) if you need accurate results with raw bytes.

assoc-string *key* *alist* &optional *case-fold* [Function]

This function works like `assoc`, except that `key` must be a string or symbol, and comparison is done using `compare-strings`. Symbols are converted to strings before testing. If `case-fold` is non-`nil`, `key` and the elements of `alist` are converted to upper-case before comparison. Unlike `assoc`, this function can also match elements of the alist that are strings or symbols rather than conses. In particular, `alist` can be a list of strings or symbols rather than an actual alist. See Section 5.8 [Association Lists], page 95.

See also the function `compare-buffer-substrings` in Section 33.3 [Comparing Text], page 882, for a way to compare text in buffers. The function `string-match`, which matches a regular expression against a string, can be used for a kind of string comparison; see Section 35.4 [Regexp Search], page 1008.

4.6 Conversion of Characters and Strings

This section describes functions for converting between characters, strings and integers. `format` (see Section 4.7 [Formatting Strings], page 66) and `prin1-to-string` (see Section 20.5 [Output Functions], page 377) can also convert Lisp objects into strings.

read-from-string (see Section 20.3 [Input Functions], page 374) can convert a string representation of a Lisp object into an object. The functions **string-to-multibyte** and **string-to-unibyte** convert the text representation of a string (see Section 34.3 [Converting Representations], page 965).

See Chapter 25 [Documentation], page 595, for functions that produce textual descriptions of text characters and general input events (**single-key-description** and **text-char-description**). These are used primarily for making help messages.

number-to-string *number* [Function]

This function returns a string consisting of the printed base-ten representation of *number*. The returned value starts with a minus sign if the argument is negative.

```
(number-to-string 256)
  ⇒ "256"
(number-to-string -23)
  ⇒ "-23"
(number-to-string -23.5)
  ⇒ "-23.5"
```

int-to-string is a semi-obsolete alias for this function.

See also the function **format** in Section 4.7 [Formatting Strings], page 66.

string-to-number *string* &**optional** *base* [Function]

This function returns the numeric value of the characters in *string*. If *base* is non-*nil*, it must be an integer between 2 and 16 (inclusive), and integers are converted in that base. If *base* is *nil*, then base ten is used. Floating-point conversion only works in base ten; we have not implemented other radices for floating-point numbers, because that would be much more work and does not seem useful.

The parsing skips spaces and tabs at the beginning of *string*, then reads as much of *string* as it can interpret as a number in the given base. (On some systems it ignores other whitespace at the beginning, not just spaces and tabs.) If *string* cannot be interpreted as a number, this function returns 0.

```
(string-to-number "256")
  ⇒ 256
(string-to-number "25 is a perfect square.")
  ⇒ 25
(string-to-number "X256")
  ⇒ 0
(string-to-number "-4.5")
  ⇒ -4.5
(string-to-number "1e5")
  ⇒ 100000.0
```

string-to-int is an obsolete alias for this function.

char-to-string *character* [Function]

This function returns a new string containing one character, *character*. This function is semi-obsolete because the function **string** is more general. See Section 4.3 [Creating Strings], page 55.

string-to-char *string*

[Function]

This function returns the first character in *string*. This is mostly identical to (`aref string 0`), except that it returns 0 if the string is empty. (The value is also 0 when the first character of *string* is the null character, ASCII code 0.) This function may be eliminated in the future if it does not seem useful enough to retain.

Here are some other functions that can convert to or from a string:

concat This function converts a vector or a list into a string. See Section 4.3 [Creating Strings], page 55.

vconcat This function converts a string into a vector. See Section 6.5 [Vector Functions], page 118.

append This function converts a string into a list. See Section 5.4 [Building Lists], page 82.

byte-to-string

This function converts a byte of character data into a unibyte string. See Section 34.3 [Converting Representations], page 965.

4.7 Formatting Strings

Formatting means constructing a string by substituting computed values at various places in a constant string. This constant string controls how the other values are printed, as well as where they appear; it is called a *format string*.

Formatting is often useful for computing messages to be displayed. In fact, the functions `message` and `error` provide the same formatting feature described here; they differ from `format-message` only in how they use the result of formatting.

format *string &rest objects*

[Function]

This function returns a string equal to *string*, replacing any format specifications with encodings of the corresponding *objects*. The arguments *objects* are the computed values to be formatted.

The characters in *string*, other than the format specifications, are copied directly into the output, including their text properties, if any. Any text properties of the format specifications are copied to the produced string representations of the argument *objects*.

The output string need not be newly-allocated. For example, if `x` is the string "foo", the expressions (`eq x (format x)`) and (`eq x (format "%s" x)`) might both yield `t`.

format-message *string &rest objects*

[Function]

This function acts like `format`, except it also converts any grave accents (`) and apostrophes (') in *string* as per the value of `text-quoting-style`.

Typically grave accent and apostrophe in the format translate to matching curved quotes, e.g., "Missing ‘%s’" might result in "Missing ‘foo’". See Section 25.4 [Text Quoting Style], page 600, for how to influence or inhibit this translation.

A format specification is a sequence of characters beginning with a ‘%’. Thus, if there is a ‘%d’ in *string*, the **format** function replaces it with the printed representation of one of the values to be formatted (one of the arguments *objects*). For example:

```
(format "The value of fill-column is %d." fill-column)
⇒ "The value of fill-column is 72."
```

Since **format** interprets ‘%’ characters as format specifications, you should *never* pass an arbitrary string as the first argument. This is particularly true when the string is generated by some Lisp code. Unless the string is *known* to never include any ‘%’ characters, pass “%s”, described below, as the first argument, and the string as the second, like this:

```
(format "%s" arbitrary-string)
```

Certain format specifications require values of particular types. If you supply a value that doesn’t fit the requirements, an error is signaled.

Here is a table of valid format specifications:

‘%s’	Replace the specification with the printed representation of the object, made without quoting (that is, using princ , not prin1 —see Section 20.5 [Output Functions], page 377). Thus, strings are represented by their contents alone, with no “” characters, and symbols appear without ‘\’ characters. If the object is a string, its text properties are copied into the output. The text properties of the ‘%s’ itself are also copied, but those of the object take priority.
‘%S’	Replace the specification with the printed representation of the object, made with quoting (that is, using prin1 —see Section 20.5 [Output Functions], page 377). Thus, strings are enclosed in “” characters, and ‘\’ characters appear where necessary before special characters.
‘%o’	Replace the specification with the base-eight representation of an integer. Negative integers are formatted in a platform-dependent way. The object can also be a floating-point number that is formatted as an integer, dropping any fraction.
‘%d’	Replace the specification with the base-ten representation of a signed integer. The object can also be a floating-point number that is formatted as an integer, dropping any fraction.
‘%x’	Replace the specification with the base-sixteen representation of an integer. Negative integers are formatted in a platform-dependent way. ‘%x’ uses lower case and ‘%X’ uses upper case. The object can also be a floating-point number that is formatted as an integer, dropping any fraction.
‘%X’	Replace the specification with the base-sixteen representation of an integer. Negative integers are formatted in a platform-dependent way. ‘%x’ uses lower case and ‘%X’ uses upper case. The object can also be a floating-point number that is formatted as an integer, dropping any fraction.
‘%c’	Replace the specification with the character which is the value given.
‘%e’	Replace the specification with the exponential notation for a floating-point number.
‘%f’	Replace the specification with the decimal-point notation for a floating-point number.
‘%g’	Replace the specification with notation for a floating-point number, using either exponential notation or decimal-point notation. The exponential notation is

used if the exponent would be less than -4 or greater than or equal to the precision (default: 6). By default, trailing zeros are removed from the fractional portion of the result and a decimal-point character appears only if it is followed by a digit.

`'%%'` Replace the specification with a single ‘%’. This format specification is unusual in that its only form is plain ‘%%’ and that it does not use a value. For example, `(format "%% %d" 30)` returns “% 30”.

Any other format character results in an ‘**Invalid format operation**’ error.

Here are several examples, which assume the typical `text-quoting-style` settings:

```
(format "The octal value of %d is %o,
        and the hex value is %x." 18 18 18)
⇒ "The octal value of 18 is 22,
        and the hex value is 12."

(format-message
  "The name of this buffer is '%s'." (buffer-name))
⇒ "The name of this buffer is 'strings.texi'.

(format-message
  "The buffer object prints as `'%s'." (current-buffer))
⇒ "The buffer object prints as 'strings.texi'."
```

By default, format specifications correspond to successive values from *objects*. Thus, the first format specification in *string* uses the first such value, the second format specification uses the second such value, and so on. Any extra format specifications (those for which there are no corresponding values) cause an error. Any extra values to be formatted are ignored.

A format specification can have a *field number*, which is a decimal number immediately after the initial ‘%’, followed by a literal dollar sign ‘\$’. It causes the format specification to convert the argument with the given number instead of the next argument. Field numbers start at 1. A format can contain either numbered or unnumbered format specifications but not both, except that ‘%%’ can be mixed with numbered specifications.

```
(format "%2$s, %3$s, %%, %1$s" "x" "y" "z")
⇒ "y, z, %, x"
```

After the ‘%’ and any field number, you can put certain *flag characters*.

The flag ‘+’ inserts a plus sign before a nonnegative number, so that it always has a sign. A space character as flag inserts a space before a nonnegative number. (Otherwise, nonnegative numbers start with the first digit.) These flags are useful for ensuring that nonnegative and negative numbers use the same number of columns. They are ignored except for ‘%d’, ‘%e’, ‘%f’, ‘%g’, and if both flags are used, ‘+’ takes precedence.

The flag ‘#’ specifies an alternate form which depends on the format in use. For ‘%o’, it ensures that the result begins with a ‘0’. For ‘%x’ and ‘%X’, it prefixes nonzero results with ‘0x’ or ‘0X’. For ‘%e’ and ‘%f’, the ‘#’ flag means include a decimal point even if the precision is zero. For ‘%g’, it always includes a decimal point, and also forces any trailing zeros after the decimal point to be left in place where they would otherwise be removed.

The flag ‘0’ ensures that the padding consists of ‘0’ characters instead of spaces. This flag is ignored for non-numerical specification characters like ‘%s’, ‘%S’ and ‘%c’. These specification characters accept the ‘0’ flag, but still pad with *spaces*.

The flag ‘-’ causes any padding inserted by the width, if specified, to be inserted on the right rather than the left. If both ‘-’ and ‘0’ are present, the ‘0’ flag is ignored.

```
(format "%06d is padded on the left with zeros" 123)
⇒ "000123 is padded on the left with zeros"

(format "%-6d' is padded on the right" 123)
⇒ "'123      is padded on the right"

(format "The word '%-7s' actually has %d letters in it."
       "foo" (length "foo"))
⇒ "The word 'foo      ' actually has 3 letters in it."
```

A specification can have a *width*, which is a decimal number that appears after any field number and flags. If the printed representation of the object contains fewer characters than this width, **format** extends it with padding. Any padding introduced by the width normally consists of spaces inserted on the left:

```
(format "%5d is padded on the left with spaces" 123)
⇒ "   123 is padded on the left with spaces"
```

If the width is too small, **format** does not truncate the object’s printed representation. Thus, you can use a width to specify a minimum spacing between columns with no risk of losing information. In the following two examples, ‘%7s’ specifies a minimum width of 7. In the first case, the string inserted in place of ‘%7s’ has only 3 letters, and needs 4 blank spaces as padding. In the second case, the string “specification” is 13 letters wide but is not truncated.

```
(format "The word '%7s' has %d letters in it."
       "foo" (length "foo"))
⇒ "The word '      foo' has 3 letters in it."
(format "The word '%7s' has %d letters in it."
       "specification" (length "specification"))
⇒ "The word 'specification' has 13 letters in it."
```

All the specification characters allow an optional *precision* after the field number, flags and width, if present. The precision is a decimal-point ‘.’ followed by a digit-string. For the floating-point specifications (‘%e’ and ‘%f’), the precision specifies how many digits following the decimal point to show; if zero, the decimal-point itself is also omitted. For ‘%g’, the precision specifies how many significant digits to show (significant digits are the first digit before the decimal point and all the digits after it). If the precision of %g is zero or unspecified, it is treated as 1. For ‘%s’ and ‘%S’, the precision truncates the string to the given width, so ‘%.3s’ shows only the first three characters of the representation for *object*. For other specification characters, the effect of precision is what the local library functions of the **printf** family produce.

If you plan to use **read** later on the formatted string to retrieve a copy of the formatted value, use a specification that lets **read** reconstruct the value. To format numbers in this reversible way you can use ‘%s’ and ‘%S’, to format just integers you can also use ‘%d’, and to

format just nonnegative integers you can also use ‘# $x\%$ x ’ and ‘# $o\%$ o ’. Other formats may be problematic; for example, ‘%d’ and ‘%g’ can mishandle NaNs and can lose precision and type, and ‘# $x\%$ x ’ and ‘# $o\%$ o ’ can mishandle negative integers. See Section 20.3 [Input Functions], page 374.

The functions described in this section accept a fixed set of specification characters. The next section describes a function `format-spec` which can accept custom specification characters, such as ‘%a’ or ‘%z’.

4.8 Custom Format Strings

Sometimes it is useful to allow users and Lisp programs alike to control how certain text is generated via custom format control strings. For example, a format string could control how to display someone’s forename, surname, and email address. Using the function `format` described in the previous section, the format string could be something like “%s %s <%s>”. This approach quickly becomes impractical, however, as it can be unclear which specification character corresponds to which piece of information.

A more convenient format string for such cases would be something like “%f %l <%e>”, where each specification character carries more semantic information and can easily be rearranged relative to other specification characters, making such format strings more easily customizable by the user.

The function `format-spec` described in this section performs a similar function to `format`, except it operates on format control strings that use arbitrary specification characters.

`format-spec template spec-alist &optional ignore-missing split` [Function]

This function returns a string produced from the format string *template* according to conversions specified in *spec-alist*, which is an alist (see Section 5.8 [Association Lists], page 95) of the form (*letter* . *replacement*). Each specification **%letter** in *template* will be replaced by *replacement* when formatting the resulting string.

The characters in *template*, other than the format specifications, are copied directly into the output, including their text properties, if any. Any text properties of the format specifications are copied to their replacements.

Using an alist to specify conversions gives rise to some useful properties:

- If *spec-alist* contains more unique *letter* keys than there are unique specification characters in *template*, the unused keys are simply ignored.
- If *spec-alist* contains more than one association with the same *letter*, the closest one to the start of the list is used.
- If *template* contains the same specification character more than once, then the same *replacement* found in *spec-alist* is used as a basis for all of that character’s substitutions.
- The order of specifications in *template* need not correspond to the order of associations in *spec-alist*.

REPLACEMENT can also be a function taking no arguments, and returning a string to be used for the replacement. It will only be called when the corresponding LETTER is used in the TEMPLATE. This is useful, for example, to avoid prompting for input unless it is needed.

The optional argument *ignore-missing* indicates how to handle specification characters in *template* that are not found in *spec-alist*. If it is `nil` or omitted, the function signals an error; if it is `ignore`, those format specifications are left verbatim in the output, including their text properties, if any; if it is `delete`, those format specifications are removed from the output; any other non-`nil` value is handled like `ignore`, but any occurrences of ‘`%%`’ are also left verbatim in the output.

If the optional argument *split* is non-`nil`, instead of returning a single string, `format-spec` will split the result into a list of strings, based on where the substitutions were performed. For instance:

```
(format-spec "foo %b bar" '((?b . "zot")) nil t)
⇒ ("foo" "zot" "bar")
```

The syntax of format specifications accepted by `format-spec` is similar, but not identical, to that accepted by `format`. In both cases, a format specification is a sequence of characters beginning with ‘%’ and ending with an alphabetic letter such as ‘s’.

Unlike `format`, which assigns specific meanings to a fixed set of specification characters, `format-spec` accepts arbitrary specification characters and treats them all equally. For example:

```
(setq my-site-info
      (list (cons ?s system-name)
            (cons ?t (symbol-name system-type))
            (cons ?c system-configuration)
            (cons ?v emacs-version)
            (cons ?e invocation-name)
            (cons ?p (number-to-string (emacs-pid)))
            (cons ?a user-mail-address)
            (cons ?n user-full-name)))

(format-spec "%e %v (%c)" my-site-info)
⇒ "emacs 27.1 (x86_64-pc-linux-gnu)"

(format-spec "%n <%a>" my-site-info)
⇒ "Emacs Developers <emacs-devel@gnu.org>"
```

A format specification can include any number of the following flag characters immediately after the ‘%’ to modify aspects of the substitution.

- ‘0’ This flag causes any padding specified by the width to consist of ‘0’ characters instead of spaces.
- ‘-’ This flag causes any padding specified by the width to be inserted on the right rather than the left.
- ‘<’ This flag causes the substitution to be truncated on the left to the given width and precision, if specified.
- ‘>’ This flag causes the substitution to be truncated on the right to the given width and precision, if specified.

‘`^`’ This flag converts the substituted text to upper case (see Section 4.9 [Case Conversion], page 72).

‘`_`’ (underscore)

This flag converts the substituted text to lower case (see Section 4.9 [Case Conversion], page 72).

The result of using contradictory flags (for instance, both upper and lower case) is undefined.

As is the case with `format`, a format specification can include a width, which is a decimal number that appears after any flags, and a precision, which is a decimal-point ‘`.`’ followed by a decimal number that appears after any flags and width.

If a substitution contains fewer characters than its specified width, it is padded on the left:

```
(format-spec "%8a is padded on the left with spaces"
             '((?a . "alpha")))
⇒ "    alpha is padded on the left with spaces"
```

If a substitution contains more characters than its specified precision, it is truncated on the right:

```
(format-spec "%.2a is truncated on the right"
             '((?a . "alpha")))
⇒ "al is truncated on the right"
```

Here is a more complicated example that combines several aforementioned features:

```
(setq my-battery-info
      (list (cons ?p "73")      ; Percentage
            (cons ?L "Battery") ; Status
            (cons ?t "2:23")     ; Remaining time
            (cons ?c "24330")   ; Capacity
            (cons ?r "10.6"))   ; Rate of discharge

(format-spec "%>^-3L : %3p%% (%05t left)" my-battery-info)
⇒ "BAT : 73% (02:23 left)"

(format-spec "%>^-3L : %3p%% (%05t left)"
            (cons (cons ?L "AC")
                  my-battery-info))
⇒ "AC : 73% (02:23 left)"
```

As the examples in this section illustrate, `format-spec` is often used for selectively formatting an assortment of different pieces of information. This is useful in programs that provide user-customizable format strings, as the user can choose to format with a regular syntax and in any desired order only a subset of the information that the program makes available.

4.9 Case Conversion in Lisp

The character case functions change the case of single characters or of the contents of strings. The functions normally convert only alphabetic characters (the letters ‘A’ through ‘Z’ and ‘a’

through ‘z’, as well as non-ASCII letters); other characters are not altered. You can specify a different case conversion mapping by specifying a case table (see Section 4.10 [Case Tables], page 74).

These functions do not modify the strings that are passed to them as arguments.

The examples below use the characters ‘X’ and ‘x’ which have ASCII codes 88 and 120 respectively.

`downcase string-or-char`

[Function]

This function converts *string-or-char*, which should be either a character or a string, to lower case.

When *string-or-char* is a string, this function returns a new string in which each letter in the argument that is upper case is converted to lower case. When *string-or-char* is a character, this function returns the corresponding lower case character (an integer); if the original character is lower case, or is not a letter, the return value is equal to the original character.

```
(downcase "The cat in the hat")
⇒ "the cat in the hat"
```

```
(downcase ?X)
⇒ 120
```

`upcase string-or-char`

[Function]

This function converts *string-or-char*, which should be either a character or a string, to upper case.

When *string-or-char* is a string, this function returns a new string in which each letter in the argument that is lower case is converted to upper case. When *string-or-char* is a character, this function returns the corresponding upper case character (an integer); if the original character is upper case, or is not a letter, the return value is equal to the original character.

```
(upcase "The cat in the hat")
⇒ "THE CAT IN THE HAT"
```

```
(upcase ?x)
⇒ 88
```

`capitalize string-or-char`

[Function]

This function capitalizes strings or characters. If *string-or-char* is a string, the function returns a new string whose contents are a copy of *string-or-char* in which each word has been capitalized. This means that the first character of each word is converted to upper case, and the rest are converted to lower case.

The definition of a word is any sequence of consecutive characters that are assigned to the word constituent syntax class in the current syntax table (see Section 36.2.1 [Syntax Class Table], page 1023).

When *string-or-char* is a character, this function does the same thing as `upcase`.

```
(capitalize "The cat in the hat")
⇒ "The Cat In The Hat"
```

```
(capitalize "THE 77TH-HATTED CAT")
⇒ "The 77th-Hatted Cat"
```

```
(capitalize ?x)
⇒ 88
```

upcase-initials *string-or-char* [Function]

If *string-or-char* is a string, this function capitalizes the initials of the words in *string-or-char*, without altering any letters other than the initials. It returns a new string whose contents are a copy of *string-or-char*, in which each word has had its initial letter converted to upper case.

The definition of a word is any sequence of consecutive characters that are assigned to the word constituent syntax class in the current syntax table (see Section 36.2.1 [Syntax Class Table], page 1023).

When the argument to **upcase-initials** is a character, **upcase-initials** has the same result as **upcase**.

```
(upcase-initials "The CAT in the hAt")
⇒ "The CAT In The HAt"
```

Note that case conversion is not a one-to-one mapping of codepoints and length of the result may differ from length of the argument. Furthermore, because passing a character forces return type to be a character, functions are unable to perform proper substitution and result may differ compared to treating a one-character string. For example:

```
(upcase "fi") ; note: single character, ligature "fi"
⇒ "FI"
(upcase ?fi)
⇒ 64257 ; i.e. ?fi
```

To avoid this, a character must first be converted into a string, using **string** function, before being passed to one of the casing functions. Of course, no assumptions on the length of the result may be made.

Mapping for such special cases are taken from **special-uppercase**, **special-lowercase** and **special-titlecase**. See Section 34.6 [Character Properties], page 968.

See Section 4.5 [Text Comparison], page 60, for functions that compare strings; some of them ignore case differences, or can optionally ignore case differences.

4.10 The Case Table

You can customize case conversion by installing a special *case table*. A case table specifies the mapping between upper case and lower case letters. It affects both the case conversion functions for Lisp objects (see the previous section) and those that apply to text in the buffer (see Section 33.18 [Case Changes], page 916). Each buffer has a case table; there is also a standard case table which is used to initialize the case table of new buffers.

A case table is a char-table (see Section 6.6 [Char-Tables], page 119) whose subtype is **case-table**. This char-table maps each character into the corresponding lower case character. It has three extra slots, which hold related tables:

upcase The upcase table maps each character into the corresponding upper case character.

canonicalize

The canonicalize table maps all of a set of case-related characters into a particular member of that set.

equivalences

The equivalences table maps each one of a set of case-related characters into the next character in that set.

In simple cases, all you need to specify is the mapping to lower-case; the three related tables will be calculated automatically from that one.

For some languages, upper and lower case letters are not in one-to-one correspondence. There may be two different lower case letters with the same upper case equivalent. In these cases, you need to specify the maps for both lower case and upper case.

The extra table *canonicalize* maps each character to a canonical equivalent; any two characters that are related by case-conversion have the same canonical equivalent character. For example, since ‘a’ and ‘A’ are related by case-conversion, they should have the same canonical equivalent character (which should be either ‘a’ for both of them, or ‘A’ for both of them).

The extra table *equivalences* is a map that cyclically permutes each equivalence class (of characters with the same canonical equivalent). (For ordinary ASCII, this would map ‘a’ into ‘A’ and ‘A’ into ‘a’, and likewise for each set of equivalent characters.)

When constructing a case table, you can provide *nil* for *canonicalize*; then Emacs fills in this slot from the lower case and upper case mappings. You can also provide *nil* for *equivalences*; then Emacs fills in this slot from *canonicalize*. In a case table that is actually in use, those components are non-*nil*. Do not try to specify *equivalences* without also specifying *canonicalize*.

Here are the functions for working with case tables:

case-table-p *object* [Function]

This predicate returns non-*nil* if *object* is a valid case table.

set-standard-case-table *table* [Function]

This function makes *table* the standard case table, so that it will be used in any buffers created subsequently.

standard-case-table [Function]

This returns the standard case table.

current-case-table [Function]

This function returns the current buffer’s case table.

set-case-table *table* [Function]

This sets the current buffer’s case table to *table*.

with-case-table *table body...* [Macro]

The **with-case-table** macro saves the current case table, makes *table* the current case table, evaluates the *body* forms, and finally restores the case table. The return

value is the value of the last form in *body*. The case table is restored even in case of an abnormal exit via `throw` or error (see Section 11.7 [Nonlocal Exits], page 177).

Some language environments modify the case conversions of ASCII characters; for example, in the Turkish language environment, the ASCII capital I is downcased into a Turkish dotless i ('ı'). This can interfere with code that requires ordinary ASCII case conversion, such as implementations of ASCII-based network protocols. In that case, use the `with-case-table` macro with the variable `ascii-case-table`, which stores the unmodified case table for the ASCII character set.

ascii-case-table [Variable]

The case table for the ASCII character set. This should not be modified by any language environment settings.

The following three functions are convenient subroutines for packages that define non-ASCII character sets. They modify the specified case table *case-table*; they also modify the standard syntax table. See Chapter 36 [Syntax Tables], page 1022. Normally you would use these functions to change the standard case table.

set-case-syntax-pair *uc lc case-table* [Function]

This function specifies a pair of corresponding letters, one upper case and one lower case.

set-case-syntax-delims *l r case-table* [Function]

This function makes characters *l* and *r* a matching pair of case-invariant delimiters.

set-case-syntax *char syntax case-table* [Function]

This function makes *char* case-invariant, with syntax *syntax*.

describe-buffer-case-table [Command]

This command displays a description of the contents of the current buffer's case table.

5 Lists

A *list* represents a sequence of zero or more elements (which may be any Lisp objects). The important difference between lists and vectors is that two or more lists can share part of their structure; in addition, you can insert or delete elements in a list without copying the whole list.

5.1 Lists and Cons Cells

Lists in Lisp are not a primitive data type; they are built up from *cons cells* (see Section 2.4.6 [Cons Cell Type], page 16). A cons cell is a data object that represents an ordered pair. That is, it has two slots, and each slot *holds*, or *refers to*, some Lisp object. One slot is known as the CAR, and the other is known as the CDR. (These names are traditional; see Section 2.4.6 [Cons Cell Type], page 16.) CDR is pronounced “could-er”.

We say that “the CAR of this cons cell is” whatever object its CAR slot currently holds, and likewise for the CDR.

A list is a series of cons cells chained together, so that each cell refers to the next one. There is one cons cell for each element of the list. By convention, the CARs of the cons cells hold the elements of the list, and the CDRs are used to chain the list (this asymmetry between CAR and CDR is entirely a matter of convention; at the level of cons cells, the CAR and CDR slots have similar properties). Hence, the CDR slot of each cons cell in a list refers to the following cons cell.

Also by convention, the CDR of the last cons cell in a list is `nil`. We call such a `nil`-terminated structure a *proper list*¹. In Emacs Lisp, the symbol `nil` is both a symbol and a list with no elements. For convenience, the symbol `nil` is considered to have `nil` as its CDR (and also as its CAR).

Hence, the CDR of a proper list is always a proper list. The CDR of a nonempty proper list is a proper list containing all the elements except the first.

If the CDR of a list’s last cons cell is some value other than `nil`, we call the structure a *dotted list*, since its printed representation would use dotted pair notation (see Section 2.4.6.2 [Dotted Pair Notation], page 18). There is one other possibility: some cons cell’s CDR could point to one of the previous cons cells in the list. We call that structure a *circular list*.

For some purposes, it does not matter whether a list is proper, circular or dotted. If a program doesn’t look far enough down the list to see the CDR of the final cons cell, it won’t care. However, some functions that operate on lists demand proper lists and signal errors if given a dotted list. Most functions that try to find the end of a list enter infinite loops if given a circular list. You can use the function `proper-list-p`, described in the next section (see Section 5.2 [List-related Predicates], page 78), to determine whether a list is a proper one.

Because most cons cells are used as part of lists, we refer to any structure made out of cons cells as a *list structure*.

¹ It is sometimes also referred to as a *true list*, but we generally do not use this terminology in this manual.

5.2 Predicates on Lists

The following predicates test whether a Lisp object is an atom, whether it is a cons cell or is a list, or whether it is the distinguished object `nil`. (Many of these predicates can be defined in terms of the others, but they are used so often that it is worth having them.)

consp *object* [Function]

This function returns `t` if *object* is a cons cell, `nil` otherwise. `nil` is not a cons cell, although it *is* a list.

atom *object* [Function]

This function returns `t` if *object* is an atom, `nil` otherwise. All objects except cons cells are atoms. The symbol `nil` is an atom and is also a list; it is the only Lisp object that is both.

```
(atom object) ≡ (not (consp object))
```

listp *object* [Function]

This function returns `t` if *object* is a cons cell or `nil`. Otherwise, it returns `nil`.

```
(listp '(1))
      ⇒ t
(listp '())
      ⇒ t
```

nlistp *object* [Function]

This function is the opposite of `listp`: it returns `t` if *object* is not a list. Otherwise, it returns `nil`.

```
(listp object) ≡ (not (nlistp object))
```

null *object* [Function]

This function returns `t` if *object* is `nil`, and returns `nil` otherwise. This function is identical to `not`, but as a matter of clarity we use `not` when *object* is considered a truth value (see `not` in Section 11.3 [Combining Conditions], page 162) and `null` otherwise.

```
(null '(1))
      ⇒ nil
(null '())
      ⇒ t
```

proper-list-p *object* [Function]

This function returns the length of *object* if it is a proper list, `nil` otherwise (see Section 5.1 [Cons Cells], page 77). In addition to satisfying `listp`, a proper list is neither circular nor dotted.

```
(proper-list-p '(a b c))
      ⇒ 3
(proper-list-p '(a b . c))
      ⇒ nil
```

5.3 Accessing Elements of Lists

`car cons-cell`

[Function]

This function returns the value referred to by the first slot of the cons cell *cons-cell*. In other words, it returns the CAR of *cons-cell*.

As a special case, if *cons-cell* is `nil`, this function returns `nil`. Therefore, any list is a valid argument. An error is signaled if the argument is not a cons cell or `nil`.

```
(car '(a b c))
  ⇒ a
(car '())
  ⇒ nil
```

`cdr cons-cell`

[Function]

This function returns the value referred to by the second slot of the cons cell *cons-cell*. In other words, it returns the CDR of *cons-cell*.

As a special case, if *cons-cell* is `nil`, this function returns `nil`; therefore, any list is a valid argument. An error is signaled if the argument is not a cons cell or `nil`.

```
(cdr '(a b c))
  ⇒ (b c)
(cdr '())
  ⇒ nil
```

`car-safe object`

[Function]

This function lets you take the CAR of a cons cell while avoiding errors for other data types. It returns the CAR of *object* if *object* is a cons cell, `nil` otherwise. This is in contrast to `car`, which signals an error if *object* is not a list.

```
(car-safe object)
≡
(let ((x object))
  (if (consp x)
      (car x)
      nil))
```

`cdr-safe object`

[Function]

This function lets you take the CDR of a cons cell while avoiding errors for other data types. It returns the CDR of *object* if *object* is a cons cell, `nil` otherwise. This is in contrast to `cdr`, which signals an error if *object* is not a list.

```
(cdr-safe object)
≡
(let ((x object))
  (if (consp x)
      (cdr x)
      nil))
```

`pop listname`

[Macro]

This macro provides a convenient way to examine the CAR of a list, and take it off the list, all at once. It operates on the list stored in *listname*. It removes the first element from the list, saves the CDR into *listname*, then returns the removed element.

In the simplest case, *listname* is an unquoted symbol naming a list; in that case, this macro is equivalent to (prog1 (car *listname*) (setq *listname* (cdr *listname*))).

```
x
⇒ (a b c)
(pop x)
⇒ a
x
⇒ (b c)
```

More generally, *listname* can be a generalized variable. In that case, this macro saves into *listname* using **setf**. See Section 12.17 [Generalized Variables], page 224.

For the **push** macro, which adds an element to a list, See Section 5.5 [List Variables], page 85.

nth *n* *list* [Function]

This function returns the *n*th element of *list*. Elements are numbered starting with zero, so the CAR of *list* is element number zero. If the length of *list* is *n* or less, the value is **nil**.

```
(nth 2 '(1 2 3 4))
⇒ 3
(nth 10 '(1 2 3 4))
⇒ nil

(nth n x) ≡ (car (nthcdr n x))
```

The function **elt** is similar, but applies to any kind of sequence. For historical reasons, it takes its arguments in the opposite order. See Section 6.1 [Sequence Functions], page 102.

nthcdr *n* *list* [Function]

This function returns the *n*th CDR of *list*. In other words, it skips past the first *n* links of *list* and returns what follows.

If *n* is zero, **nthcdr** returns all of *list*. If the length of *list* is *n* or less, **nthcdr** returns **nil**.

```
(nthcdr 1 '(1 2 3 4))
⇒ (2 3 4)
(nthcdr 10 '(1 2 3 4))
⇒ nil
(nthcdr 0 '(1 2 3 4))
⇒ (1 2 3 4)
```

take *n* *list* [Function]

This function returns the *n* first elements of *list*. Essentially, it returns the part of *list* that **nthcdr** skips.

take returns *list* if shorter than *n* elements; it returns **nil** if *n* is zero or negative.

```
(take 3 '(a b c d))
⇒ (a b c)
```

```
(take 10 '(a b c d))
  ⇒ (a b c d)
(take 0 '(a b c d))
  ⇒ nil
```

ntake *n list*

[Function]

This is a version of **take** that works by destructively modifying the list structure of the argument. That makes it faster, but the original value of *list* may be lost.

ntake returns *list* unmodified if shorter than *n* elements; it returns **nil** if *n* is zero or negative. Otherwise, it returns *list* truncated to its first *n* elements.

This means that it is usually a good idea to use the return value and not just rely on the truncation effect unless *n* is known to be positive.

last *list &optional n*

[Function]

This function returns the last link of *list*. The **car** of this link is the list's last element. If *list* is null, **nil** is returned. If *n* is non-nil, the *n*th-to-last link is returned instead, or the whole of *list* if *n* is bigger than *list*'s length.

safe-length *list*

[Function]

This function returns the length of *list*, with no risk of either an error or an infinite loop. It generally returns the number of distinct cons cells in the list. However, for circular lists, the value is just an upper bound; it is often too large.

If *list* is not **nil** or a cons cell, **safe-length** returns 0.

The most common way to compute the length of a list, when you are not worried that it may be circular, is with **length**. See Section 6.1 [Sequence Functions], page 102.

caar *cons-cell*

[Function]

This is the same as **(car (car cons-cell))**.

cadr *cons-cell*

[Function]

This is the same as **(car (cdr cons-cell))** or **(nth 1 cons-cell)**.

cdar *cons-cell*

[Function]

This is the same as **(cdr (car cons-cell))**.

cddr *cons-cell*

[Function]

This is the same as **(cdr (cdr cons-cell))** or **(nthcdr 2 cons-cell)**.

In addition to the above, 24 additional compositions of **car** and **cdr** are defined as **cxxxr** and **cxxxxr**, where each *x* is either a or d. **cadr**, **caddr**, and **cadddr** pick out the second, third or fourth elements of a list, respectively. **cl-lib** provides the same under the names **cl-second**, **cl-third**, and **cl-fourth**. See Section “List Functions” in *Common Lisp Extensions*.

butlast *x &optional n*

[Function]

This function returns the list *x* with the last element, or the last *n* elements, removed. If *n* is greater than zero it makes a copy of the list so as not to damage the original list. In general, **(append (butlast x n) (last x n))** will return a list equal to *x*.

nbutlast *x* &**optional** *n* [Function]

This is a version of **butlast** that works by destructively modifying the **cdr** of the appropriate element, rather than making a copy of the list.

5.4 Building Cons Cells and Lists

Many functions build lists, as lists reside at the very heart of Lisp. **cons** is the fundamental list-building function; however, it is interesting to note that **list** is used more times in the source code for Emacs than **cons**.

cons *object1 object2* [Function]

This function is the most basic function for building new list structure. It creates a new cons cell, making *object1* the CAR, and *object2* the CDR. It then returns the new cons cell. The arguments *object1* and *object2* may be any Lisp objects, but most often *object2* is a list.

```
(cons 1 '(2))
      ⇒ (1 2)
(cons 1 '())
      ⇒ (1)
(cons 1 2)
      ⇒ (1 . 2)
```

cons is often used to add a single element to the front of a list. This is called *consing the element onto the list*.² For example:

```
(setq list (cons newelt list))
```

Note that there is no conflict between the variable named **list** used in this example and the function named **list** described below; any symbol can serve both purposes.

list &**rest** *objects* [Function]

This function creates a list with *objects* as its elements. The resulting list is always **nil**-terminated. If no *objects* are given, the empty list is returned.

```
(list 1 2 3 4 5)
      ⇒ (1 2 3 4 5)
(list 1 2 '(3 4 5) 'foo)
      ⇒ (1 2 (3 4 5) foo)
(list)
      ⇒ nil
```

make-list *length object* [Function]

This function creates a list of *length* elements, in which each element is *object*. Compare **make-list** with **make-string** (see Section 4.3 [Creating Strings], page 55).

```
(make-list 3 'pigs)
      ⇒ (pigs pigs pigs)
```

² There is no strictly equivalent way to add an element to the end of a list. You can use (**append** *listname* (**list** *newelt*)), which creates a whole new list by copying *listname* and adding *newelt* to its end. Or you can use (**nconc** *listname* (**list** *newelt*)), which modifies *listname* by following all the CDRs and then replacing the terminating **nil**. Compare this to adding an element to the beginning of a list with **cons**, which neither copies nor modifies the list.

```
(make-list 0 'pigs)
⇒ nil
(setq l (make-list 3 '(a b)))
⇒ ((a b) (a b) (a b))
(eq (car l) (cadr l))
⇒ t
```

append &rest sequences

[Function]

This function returns a list containing all the elements of *sequences*. The *sequences* may be lists, vectors, bool-vectors, or strings, but the last one should usually be a list. All arguments except the last one are copied, so none of the arguments is altered. (See `nconc` in Section 5.6.3 [Rearrangement], page 90, for a way to join lists with no copying.)

More generally, the final argument to `append` may be any Lisp object. The final argument is not copied or converted; it becomes the CDR of the last cons cell in the new list. If the final argument is itself a list, then its elements become in effect elements of the result list. If the final element is not a list, the result is a dotted list since its final CDR is not `nil` as required in a proper list (see Section 5.1 [Cons Cells], page 77).

Here is an example of using `append`:

```
(setq trees '(pine oak))
⇒ (pine oak)
(setq more-trees (append '(maple birch) trees))
⇒ (maple birch pine oak)

trees
⇒ (pine oak)
more-trees
⇒ (maple birch pine oak)
(eq trees (cdr (cdr more-trees)))
⇒ t
```

You can see how `append` works by looking at a box diagram. The variable `trees` is set to the list `(pine oak)` and then the variable `more-trees` is set to the list `(maple birch pine oak)`. However, the variable `trees` continues to refer to the original list:

An empty sequence contributes nothing to the value returned by `append`. As a consequence of this, a final `nil` argument forces a copy of the previous argument:

```
trees
⇒ (pine oak)
(setq wood (append trees nil))
⇒ (pine oak)
```

```

wood
  ⇒ (pine oak)
(eq wood trees)
  ⇒ nil

```

This once was the usual way to copy a list, before the function `copy-sequence` was invented. See Chapter 6 [Sequences Arrays Vectors], page 102.

Here we show the use of vectors and strings as arguments to `append`:

```

(append [a b] "cd" nil)
  ⇒ (a b 99 100)

```

With the help of `apply` (see Section 13.5 [Calling Functions], page 239), we can append all the lists in a list of lists:

```

(apply 'append '((a b c) nil (x y z) nil))
  ⇒ (a b c x y z)

```

If no sequences are given, `nil` is returned:

```

(append)
  ⇒ nil

```

Here are some examples where the final argument is not a list:

```

(append '(x y) 'z)
  ⇒ (x y . z)
(append '(x y) [z])
  ⇒ (x y . [z])

```

The second example shows that when the final argument is a sequence but not a list, the sequence's elements do not become elements of the resulting list. Instead, the sequence becomes the final CDR, like any other non-list final argument.

`copy-tree tree &optional vecp`

[Function]

This function returns a copy of the tree `tree`. If `tree` is a cons cell, this makes a new cons cell with the same CAR and CDR, then recursively copies the CAR and CDR in the same way.

Normally, when `tree` is anything other than a cons cell, `copy-tree` simply returns `tree`. However, if `vecp` is non-`nil`, it copies vectors too (and operates recursively on their elements).

`flatten-tree tree`

[Function]

This function returns a “flattened” copy of `tree`, that is, a list containing all the non-`nil` terminal nodes, or leaves, of the tree of cons cells rooted at `tree`. Leaves in the returned list are in the same order as in `tree`.

```

(flatten-tree '(1 (2 . 3) nil (4 5 (6)) 7))
  ⇒ (1 2 3 4 5 6 7)

```

`ensure-list object`

[Function]

This function returns `object` as a list. If `object` is already a list, the function returns it; otherwise, the function returns a one-element list containing `object`.

This is usually useful if you have a variable that may or may not be a list, and you can then say, for instance:

```
(dolist (elem (ensure-list foo))
  (princ elem))
```

number-sequence from &optional to separation [Function]

This function returns a list of numbers starting with *from* and incrementing by *separation*, and ending at or just before *to*. *separation* can be positive or negative and defaults to 1. If *to* is **nil** or numerically equal to *from*, the value is the one-element list (*from*). If *to* is less than *from* with a positive *separation*, or greater than *from* with a negative *separation*, the value is **nil** because those arguments specify an empty sequence.

If *separation* is 0 and *to* is neither **nil** nor numerically equal to *from*, **number-sequence** signals an error, since those arguments specify an infinite sequence.

All arguments are numbers. Floating-point arguments can be tricky, because floating-point arithmetic is inexact. For instance, depending on the machine, it may quite well happen that (**number-sequence** 0.4 0.6 0.2) returns the one element list (0.4), whereas (**number-sequence** 0.4 0.8 0.2) returns a list with three elements. The *n*th element of the list is computed by the exact formula (+ *from* (* *n* *separation*)). Thus, if one wants to make sure that *to* is included in the list, one can pass an expression of this exact type for *to*. Alternatively, one can replace *to* with a slightly larger value (or a slightly more negative value if *separation* is negative).

Some examples:

```
(number-sequence 4 9)
  ⇒ (4 5 6 7 8 9)
(number-sequence 9 4 -1)
  ⇒ (9 8 7 6 5 4)
(number-sequence 9 4 -2)
  ⇒ (9 7 5)
(number-sequence 8)
  ⇒ (8)
(number-sequence 8 5)
  ⇒ nil
(number-sequence 5 8 -1)
  ⇒ nil
(number-sequence 1.5 6 2)
  ⇒ (1.5 3.5 5.5)
```

5.5 Modifying List Variables

These functions, and one macro, provide convenient ways to modify a list which is stored in a variable.

push element listname [Macro]

This macro creates a new list whose CAR is *element* and whose CDR is the list specified by *listname*, and saves that list in *listname*. In the simplest case,

listname is an unquoted symbol naming a list, and this macro is equivalent to
`(setq listname (cons element listname))`.

```
(setq l '(a b))
      ⇒ (a b)
(push 'c l)
      ⇒ (c a b)
l
      ⇒ (c a b)
```

More generally, *listname* can be a generalized variable. In that case, this macro does the equivalent of `(setf listname (cons element listname))`. See Section 12.17 [Generalized Variables], page 224.

For the `pop` macro, which removes the first element from a list, See Section 5.3 [List Elements], page 79.

Two functions modify lists that are the values of variables.

add-to-list symbol element &optional append compare-fn [Function]

This function sets the variable *symbol* by consing *element* onto the old value, if *element* is not already a member of that value. It returns the resulting list, whether updated or not. The value of *symbol* had better be a list already before the call. `add-to-list` uses *compare-fn* to compare *element* against existing list members; if *compare-fn* is `nil`, it uses `equal`.

Normally, if *element* is added, it is added to the front of *symbol*, but if the optional argument *append* is non-`nil`, it is added at the end.

The argument *symbol* is not implicitly quoted; `add-to-list` is an ordinary function, like `set` and unlike `setq`. Quote the argument yourself if that is what you want.

Do not use this function when *symbol* refers to a lexical variable.

Here's a scenario showing how to use `add-to-list`:

```
(setq foo '(a b))
      ⇒ (a b)

(add-to-list 'foo 'c)      ;; Add c.
      ⇒ (c a b)

(add-to-list 'foo 'b)      ;; No effect.
      ⇒ (c a b)

foo                      ;; foo was changed.
      ⇒ (c a b)
```

An equivalent expression for `(add-to-list 'var value)` is this:

```
(if (member value var)
    var
  (setq var (cons value var)))
```

add-to-ordered-list symbol element &optional order [Function]

This function sets the variable *symbol* by inserting *element* into the old value, which must be a list, at the position specified by *order*. If *element* is already a member of the list, its position in the list is adjusted according to *order*. Membership is tested using `eq`. This function returns the resulting list, whether updated or not.

The *order* is typically a number (integer or float), and the elements of the list are sorted in non-decreasing numerical order.

order may also be omitted or `nil`. Then the numeric order of *element* stays unchanged if it already has one; otherwise, *element* has no numeric order. Elements without a numeric list order are placed at the end of the list, in no particular order.

Any other value for *order* removes the numeric order of *element* if it already has one; otherwise, it is equivalent to `nil`.

The argument *symbol* is not implicitly quoted; `add-to-ordered-list` is an ordinary function, like `set` and unlike `setq`. Quote the argument yourself if necessary.

The ordering information is stored in a hash table on *symbol*'s `list-order` property. *symbol* cannot refer to a lexical variable.

Here's a scenario showing how to use `add-to-ordered-list`:

```
(setq foo '())
⇒ nil

(add-to-ordered-list 'foo 'a 1)      ;; Add a.
⇒ (a)

(add-to-ordered-list 'foo 'c 3)      ;; Add c.
⇒ (a c)

(add-to-ordered-list 'foo 'b 2)      ;; Add b.
⇒ (a b c)

(add-to-ordered-list 'foo 'b 4)      ;; Move b.
⇒ (a c b)

(add-to-ordered-list 'foo 'd)        ;; Append d.
⇒ (a c b d)

(add-to-ordered-list 'foo 'e)        ;; Add e.
⇒ (a c b e d)

foo                                ;; foo was changed.
⇒ (a c b e d)
```

5.6 Modifying Existing List Structure

You can modify the CAR and CDR contents of a cons cell with the primitives `setcar` and `setcdr`. These are destructive operations because they change existing list structure.

Destructive operations should be applied only to mutable lists, that is, lists constructed via `cons`, `list` or similar operations. Lists created by quoting are part of the program and should not be changed by destructive operations. See Section 2.9 [Mutability], page 36.

Common Lisp note: Common Lisp uses functions `rplaca` and `rplacd` to alter list structure; they change structure the same way as `setcar` and `setcdr`, but the Common Lisp functions return the cons cell while `setcar` and `setcdr` return the new CAR or CDR.

5.6.1 Altering List Elements with `setcar`

Changing the CAR of a cons cell is done with `setcar`. When used on a list, `setcar` replaces one element of a list with a different element.

`setcar cons object`

[Function]

This function stores *object* as the new CAR of *cons*, replacing its previous CAR. In other words, it changes the CAR slot of *cons* to refer to *object*. It returns the value *object*. For example:

```
(setq x (list 1 2))
      ⇒ (1 2)
(setcar x 4)
      ⇒ 4
x
      ⇒ (4 2)
```

When a cons cell is part of the shared structure of several lists, storing a new CAR into the cons changes one element of each of these lists. Here is an example:

```
; ; Create two lists that are partly shared.
(setq x1 (list 'a 'b 'c))
      ⇒ (a b c)
(setq x2 (cons 'z (cdr x1)))
      ⇒ (z b c)

; ; Replace the CAR of a shared link.
(setcar (cdr x1) 'foo)
      ⇒ foo
x1
      ⇒ (a foo c)
x2
      ⇒ (z foo c)

; ; Replace the CAR of a link that is not shared.
(setcar x1 'baz)
      ⇒ baz
x1
      ⇒ (baz foo c)
x2
      ⇒ (z foo c)
```

; Both lists are changed.

; Only one list is changed.

Here is a graphical depiction of the shared structure of the two lists in the variables `x1` and `x2`, showing why replacing `b` changes them both:

Here is an alternative form of box diagram, showing the same relationship:

5.6.2 Altering the CDR of a List

The lowest-level primitive for modifying a CDR is `setcdr`:

`setcdr cons object` [Function]

This function stores `object` as the new CDR of `cons`, replacing its previous CDR. In other words, it changes the CDR slot of `cons` to refer to `object`. It returns the value `object`.

Here is an example of replacing the CDR of a list with a different list. All but the first element of the list are removed in favor of a different sequence of elements. The first element is unchanged, because it resides in the CAR of the list, and is not reached via the CDR.

```

(setq x (list 1 2 3))
      => (1 2 3)
(setcdr x '(4))
      => (4)
x
      => (1 4)
  
```

You can delete elements from the middle of a list by altering the CDRS of the cons cells in the list. For example, here we delete the second element, b, from the list (a b c), by changing the CDR of the first cons cell:

```
(setq x1 (list 'a 'b 'c))
  ⇒ (a b c)
(setcdr x1 (cdr (cdr x1)))
  ⇒ (c)
x1
  ⇒ (a c)
```

Here is the result in box notation:

The second cons cell, which previously held the element b, still exists and its CAR is still b, but it no longer forms part of this list.

It is equally easy to insert a new element by changing CDRs:

```
(setq x1 (list 'a 'b 'c))
  ⇒ (a b c)
(setcdr x1 (cons 'd (cdr x1)))
  ⇒ (d b c)
x1
  ⇒ (a d b c)
```

Here is this result in box notation:

5.6.3 Functions that Rearrange Lists

Here are some functions that rearrange lists destructively by modifying the CDRS of their component cons cells. These functions are destructive because they chew up the original lists passed to them as arguments, relinking their cons cells to form a new list that is the returned value.

The function `delq` in the following section is another example of destructive list manipulation.

nconc &rest lists

[Function]

This function returns a list containing all the elements of *lists*. Unlike `append` (see Section 5.4 [Building Lists], page 82), the *lists* are *not* copied. Instead, the last CDR of each of the *lists* is changed to refer to the following list. The last of the *lists* is not altered. For example:

```
(setq x (list 1 2 3))
      ⇒ (1 2 3)
(nconc x '(4 5))
      ⇒ (1 2 3 4 5)
x
      ⇒ (1 2 3 4 5)
```

Since the last argument of `nconc` is not itself modified, it is reasonable to use a constant list, such as `'(4 5)`, as in the above example. For the same reason, the last argument need not be a list:

```
(setq x (list 1 2 3))
      ⇒ (1 2 3)
(nconc x 'z)
      ⇒ (1 2 3 . z)
x
      ⇒ (1 2 3 . z)
```

However, the other arguments (all but the last) should be mutable lists.

A common pitfall is to use a constant list as a non-last argument to `nconc`. If you do this, the resulting behavior is undefined (see Section 10.1.1 [Self-Evaluating Forms], page 146). It is possible that your program will change each time you run it! Here is what might happen (though this is not guaranteed to happen):

```
(defun add-foo (x) ; We want this function to add
  (nconc '(foo) x)) ;   foo to the front of its arg.

(symbol-function 'add-foo)
      ⇒ (lambda (x) (nconc '(foo) x))

(setq xx (add-foo '(1 2))) ; It seems to work.
      ⇒ (foo 1 2)
(setq xy (add-foo '(3 4))) ; What happened?
      ⇒ (foo 1 2 3 4)
(eq xx xy)
      ⇒ t

(symbol-function 'add-foo)
      ⇒ (lambda (x) (nconc '(foo 1 2 3 4) x))
```

5.7 Using Lists as Sets

A list can represent an unordered mathematical set—simply consider a value an element of a set if it appears in the list, and ignore the order of the list. To form the union of two sets, use `append` (as long as you don't mind having duplicate elements). You can remove equal duplicates using `delete-dups` or `seq-uniq`. Other useful functions for sets include `memq` and `delq`, and their equal versions, `member` and `delete`.

Common Lisp note: Common Lisp has functions `union` (which avoids duplicate elements) and `intersection` for set operations. In Emacs Lisp, variants of these facilities are provided by the `cl-lib` library. See Section “Lists as Sets” in *Common Lisp Extensions*.

`memq object list`

[Function]

This function tests to see whether `object` is a member of `list`. If it is, `memq` returns a list starting with the first occurrence of `object`. Otherwise, it returns `nil`. The letter ‘`q`’ in `memq` says that it uses `eq` to compare `object` against the elements of the list. For example:

```
(memq 'b '(a b c b a))
      ⇒ (b c b a)
(memq '(2) '((1) (2))) ; The two (2)s need not be eq.
      ⇒ Unspecified; might be nil or ((2)).
```

`delq object list`

[Function]

This function destructively removes all elements `eq` to `object` from `list`, and returns the resulting list. The letter ‘`q`’ in `delq` says that it uses `eq` to compare `object` against the elements of the list, like `memq` and `remq`.

Typically, when you invoke `delq`, you should use the return value by assigning it to the variable which held the original list. The reason for this is explained below.

The `delq` function deletes elements from the front of the list by simply advancing down the list, and returning a sublist that starts after those elements. For example:

```
(delq 'a '(a b c)) ≡ (cdr '(a b c))
```

When an element to be deleted appears in the middle of the list, removing it involves changing the CDRs (see Section 5.6.2 [Setcdr], page 89).

```
(setq sample-list (list 'a 'b 'c '(4)))
      ⇒ (a b c (4))
(delq 'a sample-list)
      ⇒ (b c (4))
sample-list
      ⇒ (a b c (4))
(delq 'c sample-list)
      ⇒ (a b (4))
sample-list
      ⇒ (a b (4))
```

Note that `(delq 'c sample-list)` modifies `sample-list` to splice out the third element, but `(delq 'a sample-list)` does not splice anything—it just returns a shorter list. Don’t assume that a variable which formerly held the argument `list` now has fewer elements, or that it still holds the original list! Instead, save the result of `delq` and use that. Most often we store the result back into the variable that held the original list:

```
(setq flowers (delq 'rose flowers))
```

In the following example, the `(list 4)` that `delq` attempts to match and the `(4)` in the `sample-list` are equal but not `eq`:

```
(delq (list 4) sample-list)
      ⇒ (a c (4))
```

If you want to delete elements that are `equal` to a given value, use `delete` (see below).

remq *object list*

[Function]

This function returns a copy of *list*, with all elements removed which are `eq` to *object*. The letter ‘q’ in `remq` says that it uses `eq` to compare *object* against the elements of *list*.

```
(setq sample-list (list 'a 'b 'c 'a 'b 'c))
      ⇒ (a b c a b c)
(remq 'a sample-list)
      ⇒ (b c b c)
sample-list
      ⇒ (a b c a b c)
```

memql *object list*

[Function]

The function `memql` tests to see whether *object* is a member of *list*, comparing members with *object* using `eq1`, so floating-point elements are compared by value. If *object* is a member, `memql` returns a list starting with its first occurrence in *list*. Otherwise, it returns `nil`.

Compare this with `memq`:

```
(memql 1.2 '(1.1 1.2 1.3)) ; 1.2 and 1.2 are eq1.
      ⇒ (1.2 1.3)
(memq 1.2 '(1.1 1.2 1.3)) ; The two 1.2s need not be eq.
      ⇒ Unspecified; might be nil or (1.2 1.3).
```

The following three functions are like `memq`, `delq` and `remq`, but use `equal` rather than `eq` to compare elements. See Section 2.8 [Equality Predicates], page 34.

member *object list*

[Function]

The function `member` tests to see whether *object* is a member of *list*, comparing members with *object* using `equal`. If *object* is a member, `member` returns a list starting with its first occurrence in *list*. Otherwise, it returns `nil`.

Compare this with `memq`:

```
(member '(2) '((1) (2))) ; (2) and (2) are equal.
      ⇒ ((2))
(memq '(2) '((1) (2))) ; The two (2)s need not be eq.
      ⇒ Unspecified; might be nil or (2).
;; Two strings with the same contents are equal.
(member "foo" '("foo" "bar"))
      ⇒ ("foo" "bar")
```

delete *object sequence*

[Function]

This function removes all elements `equal` to *object* from *sequence*, and returns the resulting sequence.

If *sequence* is a list, `delete` is to `delq` as `member` is to `memq`: it uses `equal` to compare elements with *object*, like `member`; when it finds an element that matches, it cuts the element out just as `delq` would. As with `delq`, you should typically use the return value by assigning it to the variable which held the original list.

If `sequence` is a vector or string, `delete` returns a copy of `sequence` with all elements equal to `object` removed.

For example:

```
(setq l (list '(2) '(1) '(2)))
(delete '(2) l)
⇒ ((1))
l
⇒ ((2) (1))
;; If you want to change l reliably,
;; write (setq l (delete '(2) l)).
(setq l (list '(2) '(1) '(2)))
(delete '(1) l)
⇒ ((2) (2))
l
⇒ ((2) (2))
;; In this case, it makes no difference whether you set l,
;; but you should do so for the sake of the other case.
(delete '(2) [(2) (1) (2)])
⇒ [(1)]
```

`remove object sequence`

[Function]

This function is the non-destructive counterpart of `delete`. It returns a copy of `sequence`, a list, vector, or string, with elements equal to `object` removed. For example:

```
(remove '(2) '((2) (1) (2)))
⇒ ((1))
(remove '(2) [(2) (1) (2)])
⇒ [(1)]
```

Common Lisp note: The functions `member`, `delete` and `remove` in GNU Emacs Lisp are derived from Maclisp, not Common Lisp. The Common Lisp versions do not use `equal` to compare elements.

`member-ignore-case object list`

[Function]

This function is like `member`, except that `object` should be a string and that it ignores differences in letter-case and text representation: upper-case and lower-case letters are treated as equal, and unibyte strings are converted to multibyte prior to comparison.

`delete-dups list`

[Function]

This function destructively removes all `equal` duplicates from `list`, stores the result in `list` and returns it. Of several `equal` occurrences of an element in `list`, `delete-dups` keeps the first one. See `seq-uniq` for non-destructive operation (see Section 6.1 [Sequence Functions], page 102).

See also the function `add-to-list`, in Section 5.5 [List Variables], page 85, for a way to add an element to a list stored in a variable and used as a set.

5.8 Association Lists

An *association list*, or *alist* for short, records a mapping from keys to values. It is a list of cons cells called *associations*: the CAR of each cons cell is the *key*, and the CDR is the *associated value*.³

Here is an example of an alist. The key `pine` is associated with the value `cones`; the key `oak` is associated with `acorns`; and the key `maple` is associated with `seeds`.

```
((pine . cones)
  (oak . acorns)
  (maple . seeds))
```

Both the values and the keys in an alist may be any Lisp objects. For example, in the following alist, the symbol `a` is associated with the number `1`, and the string "`b`" is associated with the *list* `(2 3)`, which is the CDR of the alist element:

```
((a . 1) ("b" 2 3))
```

Sometimes it is better to design an alist to store the associated value in the CAR of the CDR of the element. Here is an example of such an alist:

```
((rose red) (lily white) (buttercup yellow))
```

Here we regard `red` as the value associated with `rose`. One advantage of this kind of alist is that you can store other related information—even a list of other items—in the CDR of the CDR. One disadvantage is that you cannot use `rassq` (see below) to find the element containing a given value. When neither of these considerations is important, the choice is a matter of taste, as long as you are consistent about it for any given alist.

The same alist shown above could be regarded as having the associated value in the CDR of the element; the value associated with `rose` would be the list `(red)`.

Association lists are often used to record information that you might otherwise keep on a stack, since new associations may be added easily to the front of the list. When searching an association list for an association with a given key, the first one found is returned, if there is more than one.

In Emacs Lisp, it is *not* an error if an element of an association list is not a cons cell. The alist search functions simply ignore such elements. Many other versions of Lisp signal errors in such cases.

Note that property lists are similar to association lists in several respects. A property list behaves like an association list in which each key can occur only once. See Section 5.9 [Property Lists], page 99, for a comparison of property lists and association lists.

assoc *key* *alist* &**optional** *testfn*

[Function]

This function returns the first association for *key* in *alist*, comparing *key* against the alist elements using *testfn* if it is a function, and `equal` otherwise (see Section 2.8 [Equality Predicates], page 34). If *testfn* is a function, it is called with two arguments: the CAR of an element from *alist* and *key*. The function returns `nil` if no association in *alist* has a CAR equal to *key*, as tested by *testfn*. For example:

```
(setq trees '((pine . cones) (oak . acorns) (maple . seeds)))
      → ((pine . cones) (oak . acorns) (maple . seeds)))
```

³ This usage of “key” is not related to the term “key sequence”; it means a value used to look up an item in a table. In this case, the table is the alist, and the alist associations are the items.

```
(assoc 'oak trees)
  ⇒ (oak . acorns)
(cdr (assoc 'oak trees))
  ⇒ acorns
(assoc 'birch trees)
  ⇒ nil
```

Here is another example, in which the keys and values are not symbols:

```
(setq needles-per-cluster
  '((2 "Austrian Pine" "Red Pine")
    (3 "Pitch Pine")
    (5 "White Pine")))

(cdr (assoc 3 needles-per-cluster))
  ⇒ ("Pitch Pine")
(cdr (assoc 2 needles-per-cluster))
  ⇒ ("Austrian Pine" "Red Pine")
```

The function `assoc-string` is much like `assoc` except that it ignores certain differences between strings. See Section 4.5 [Text Comparison], page 60.

rassoc value alist [Function]

This function returns the first association with value `value` in `alist`. It returns `nil` if no association in `alist` has a CDR `equal` to `value`.

`rassoc` is like `assoc` except that it compares the CDR of each `alist` association instead of the CAR. You can think of this as reverse `assoc`, finding the key for a given value.

assq key alist [Function]

This function is like `assoc` in that it returns the first association for `key` in `alist`, but it makes the comparison using `eq`. `assq` returns `nil` if no association in `alist` has a CAR `eq` to `key`. This function is used more often than `assoc`, since `eq` is faster than `equal` and most alists use symbols as keys. See Section 2.8 [Equality Predicates], page 34.

```
(setq trees '((pine . cones) (oak . acorns) (maple . seeds)))
  ⇒ ((pine . cones) (oak . acorns) (maple . seeds))
(assq 'pine trees)
  ⇒ (pine . cones)
```

On the other hand, `assq` is not usually useful in alists where the keys may not be symbols:

```
(setq leaves
  '(("simple leaves" . oak)
    ("compound leaves" . horsechestnut)))

(assq "simple leaves" leaves)
  ⇒ Unspecified; might be nil or ("simple leaves" . oak).
(assoc "simple leaves" leaves)
  ⇒ ("simple leaves" . oak)
```

alist-get key alist &optional default remove testfn [Function]

This function is similar to `assq`. It finds the first association `(key . value)` by comparing `key` with `alist` elements, and, if found, returns the `value` of that association. If no association is found, the function returns `default`. Comparison of `key` against `alist` elements uses the function specified by `testfn`, defaulting to `eq`.

This is a generalized variable (see Section 12.17 [Generalized Variables], page 224) that can be used to change a value with `setf`. When using it to set a value, optional argument `remove non-nil` means to remove `key`'s association from `alist` if the new value is `eql` to `default`.

rassq *value alist*

[Function]

This function returns the first association with value `value` in `alist`. It returns `nil` if no association in `alist` has a CDR `eq` to `value`.

`rassq` is like `assq` except that it compares the CDR of each `alist` association instead of the CAR. You can think of this as reverse `assq`, finding the key for a given value.

For example:

```
(setq trees '((pine . cones) (oak . acorns) (maple . seeds)))

(rassq 'acorns trees)
  ⇒ (oak . acorns)
(rassq 'spores trees)
  ⇒ nil
```

`rassq` cannot search for a value stored in the CAR of the CDR of an element:

```
(setq colors '((rose red) (lily white) (buttercup yellow)))

(rassq 'white colors)
  ⇒ nil
```

In this case, the CDR of the association (`lily white`) is not the symbol `white`, but rather the list (`white`). This becomes clearer if the association is written in dotted pair notation:

```
(lily white) ≡ (lily . (white))
```

assoc-default *key alist &optional test default*

[Function]

This function searches `alist` for a match for `key`. For each element of `alist`, it compares the element (if it is an atom) or the element's CAR (if it is a cons) against `key`, by calling `test` with two arguments: the element or its CAR, and `key`. The arguments are passed in that order so that you can get useful results using `string-match` with an alist that contains regular expressions (see Section 35.4 [Regexp Search], page 1008). If `test` is omitted or `nil`, `equal` is used for comparison.

If an alist element matches `key` by this criterion, then `assoc-default` returns a value based on this element. If the element is a cons, then the value is the element's CDR. Otherwise, the return value is `default`.

If no alist element matches `key`, `assoc-default` returns `nil`.

copy-alist *alist*

[Function]

This function returns a two-level deep copy of `alist`: it creates a new copy of each association, so that you can alter the associations of the new alist without changing the old one.

```
(setq needles-per-cluster
  '((2 . ("Austrian Pine" "Red Pine"))
    (3 . ("Pitch Pine"))
    (5 . ("White Pine"))))
  ⇒
  ((2 "Austrian Pine" "Red Pine")
```

```
(3 "Pitch Pine")
(5 "White Pine"))

(setq copy (copy-alist needles-per-cluster))
⇒
((2 "Austrian Pine" "Red Pine")
 (3 "Pitch Pine")
 (5 "White Pine"))

(eq needles-per-cluster copy)
  ⇒ nil
(equal needles-per-cluster copy)
  ⇒ t
(eq (car needles-per-cluster) (car copy))
  ⇒ nil
(cdr (car (cdr needles-per-cluster)))
  ⇒ ("Pitch Pine")
(eq (cdr (car (cdr needles-per-cluster)))
  (cdr (car (cdr copy))))
  ⇒ t
```

This example shows how `copy-alist` makes it possible to change the associations of one copy without affecting the other:

```
(setcdr (assq 3 copy) '("Martian Vacuum Pine"))
(cdr (assq 3 needles-per-cluster))
⇒ ("Pitch Pine")
```

`assq-delete-all key alist`

[Function]

This function deletes from `alist` all the elements whose CAR is `eq` to `key`, much as if you used `delq` to delete each such element one by one. It returns the shortened alist, and often modifies the original list structure of `alist`. For correct results, use the return value of `assq-delete-all` rather than looking at the saved value of `alist`.

```
(setq alist (list '(foo 1) '(bar 2) '(foo 3) '(lose 4)))
  ⇒ ((foo 1) (bar 2) (foo 3) (lose 4))
(assq-delete-all 'foo alist)
  ⇒ ((bar 2) (lose 4))
alist
  ⇒ ((foo 1) (bar 2) (lose 4))
```

`assoc-delete-all key alist &optional test`

[Function]

This function is like `assq-delete-all` except that it accepts an optional argument `test`, a predicate function to compare the keys in `alist`. If omitted or `nil`, `test` defaults to `equal`. As `assq-delete-all`, this function often modifies the original list structure of `alist`.

`rassq-delete-all value alist`

[Function]

This function deletes from `alist` all the elements whose CDR is `eq` to `value`. It returns the shortened alist, and often modifies the original list structure of `alist`. `rassq-delete-all` is like `assq-delete-all` except that it compares the CDR of each `alist` association instead of the CAR.

let-alist alist body [Macro]

Creates a binding for each symbol used as keys the association list *alist*, prefixed with dot. This can be useful when accessing several items in the same association list, and it's best understood through a simple example:

```
(setq colors '((rose . red) (lily . white) (buttercup . yellow)))
(let-alist colors
  (if (eq .rose 'red)
      .lily))
⇒ white
```

The *body* is inspected at compilation time, and only the symbols that appear in *body* with a ‘.’ as the first character in the symbol name will be bound. Finding the keys is done with `assq`, and the `cdr` of the return value of this `assq` is assigned as the value for the binding.

Nested association lists is supported:

```
(setq colors '((rose . red) (lily (belladonna . yellow) (brindisi . pink))))
(let-alist colors
  (if (eq .rose 'red)
      .lily.belladonna))
⇒ yellow
```

Nesting `let-alist` inside each other is allowed, but the code in the inner `let-alist` can't access the variables bound by the outer `let-alist`.

5.9 Property Lists

A *property list* (*plist* for short) is a list of paired elements. Each of the pairs associates a property name (usually a symbol) with a property or value. Here is an example of a property list:

```
(pine cones numbers (1 2 3) color "blue")
```

This property list associates `pine` with `cones`, `numbers` with `(1 2 3)`, and `color` with `"blue"`. The property names and values can be any Lisp objects, but the names are usually symbols (as they are in this example).

Property lists are used in several contexts. For instance, the function `put-text-property` takes an argument which is a property list, specifying text properties and associated values which are to be applied to text in a string or buffer. See Section 33.19 [Text Properties], page 917.

Another prominent use of property lists is for storing symbol properties. Every symbol possesses a list of properties, used to record miscellaneous information about the symbol; these properties are stored in the form of a property list. See Section 9.4 [Symbol Properties], page 138.

plistp object [Function]

This predicate function returns non-`nil` if *object* is a valid property list.

5.9.1 Property Lists and Association Lists

Association lists (see Section 5.8 [Association Lists], page 95) are very similar to property lists. In contrast to association lists, the order of the pairs in the property list is not significant, since the property names must be distinct.

Property lists are better than association lists for attaching information to various Lisp function names or variables. If your program keeps all such information in one association list, it will typically need to search that entire list each time it checks for an association for a particular Lisp function name or variable, which could be slow. By contrast, if you keep the same information in the property lists of the function names or variables themselves, each search will scan only the length of one property list, which is usually short. This is why the documentation for a variable is recorded in a property named `variable-documentation`. The byte compiler likewise uses properties to record those functions needing special treatment.

However, association lists have their own advantages. Depending on your application, it may be faster to add an association to the front of an association list than to update a property. All properties for a symbol are stored in the same property list, so there is a possibility of a conflict between different uses of a property name. (For this reason, it is a good idea to choose property names that are probably unique, such as by beginning the property name with the program's usual name-prefix for variables and functions.) An association list may be used like a stack where associations are pushed on the front of the list and later discarded; this is not possible with a property list.

5.9.2 Property Lists Outside Symbols

The following functions can be used to manipulate property lists. They all default to comparing property names using `eq`.

`plist-get plist property &optional predicate`

[Function]

This returns the value of the `property` property stored in the property list `plist`. Comparisons are done with `predicate`, which defaults to `eq`. It accepts a malformed `plist` argument. If `property` is not found in the `plist`, it returns `nil`. For example,

```
(plist-get '(foo 4) 'foo)
⇒ 4
(plist-get '(foo 4 bad) 'foo)
⇒ 4
(plist-get '(foo 4 bad) 'bad)
⇒ nil
(plist-get '(foo 4 bad) 'bar)
⇒ nil
```

`plist-put plist property value &optional predicate`

[Function]

This stores `value` as the value of the `property` property in the property list `plist`. Comparisons are done with `predicate`, which defaults to `eq`. It may modify `plist` destructively, or it may construct a new list structure without altering the old. The function returns the modified property list, so you can store that back in the place where you got `plist`. For example,

```
(setq my-plist (list 'bar t 'foo 4))
⇒ (bar t foo 4)
```

```
(setq my-plist (plist-put my-plist 'foo 69))
  ⇒ (bar t foo 69)
(setq my-plist (plist-put my-plist 'quux '(a)))
  ⇒ (bar t foo 69 quux (a))
```

lax-plist-get *plist property* [Function]

This obsolete function is like `plist-get` except that it compares properties using `equal` instead of `eq`.

lax-plist-put *plist property value* [Function]

This obsolete function is like `plist-put` except that it compares properties using `equal` instead of `eq`.

plist-member *plist property &optional predicate* [Function]

This returns `non-nil` if *plist* contains the given *property*. Comparisons are done with *predicate*, which defaults to `eq`. Unlike `plist-get`, this allows you to distinguish between a missing property and a property with the value `nil`. The value is actually the tail of *plist* whose `car` is *property*.

6 Sequences, Arrays, and Vectors

The *sequence* type is the union of two other Lisp types: lists and arrays. In other words, any list is a sequence, and any array is a sequence. The common property that all sequences have is that each is an ordered collection of elements.

An *array* is a fixed-length object with a slot for each of its elements. All the elements are accessible in constant time. The four types of arrays are strings, vectors, char-tables and bool-vectors.

A list is a sequence of elements, but it is not a single primitive object; it is made of cons cells, one cell per element. Finding the n th element requires looking through n cons cells, so elements farther from the beginning of the list take longer to access. But it is possible to add elements to the list, or remove elements.

The following diagram shows the relationship between these types:

6.1 Sequences

This section describes functions that accept any kind of sequence.

sequencep *object* [Function]

This function returns `t` if *object* is a list, vector, string, bool-vector, or char-table, `nil` otherwise. See also `seqp` below.

length *sequence* [Function]

This function returns the number of elements in *sequence*. The function signals the `wrong-type-argument` error if the argument is not a sequence or is a dotted list; it signals the `circular-list` error if the argument is a circular list. For a char-table, the value returned is always one more than the maximum Emacs character code.

See [Definition of safe-length], page 81, for the related function `safe-length`.

```
(length '(1 2 3))
⇒ 3
```

```
(length ())
  ⇒ 0
(length "foobar")
  ⇒ 6
(length [1 2 3])
  ⇒ 3
(length (make-bool-vector 5 nil))
  ⇒ 5
```

See also **string-bytes**, in Section 34.1 [Text Representations], page 963.

If you need to compute the width of a string on display, you should use **string-width** (see Section 41.10 [Size of Displayed Text], page 1157), not **length**, since **length** only counts the number of characters, but does not account for the display width of each character.

length< sequence length [Function]

Return non-nil if *sequence* is shorter than *length*. This may be more efficient than computing the length of *sequence* if *sequence* is a long list.

length> sequence length [Function]

Return non-nil if *sequence* is longer than *length*.

length= sequence length [Function]

Return non-nil if the length of *sequence* is equal to *length*.

elt sequence index [Function]

This function returns the element of *sequence* indexed by *index*. Legitimate values of *index* are integers ranging from 0 up to one less than the length of *sequence*. If *sequence* is a list, out-of-range values behave as for **nth**. See [Definition of nth], page 80. Otherwise, out-of-range values trigger an **args-out-of-range** error.

```
(elt [1 2 3 4] 2)
  ⇒ 3
(elt '(1 2 3 4) 2)
  ⇒ 3
;; We use string to show clearly which character elt returns.
(string (elt "1234" 2))
  ⇒ "3"
(elt [1 2 3 4] 4)
  [error] Args out of range: [1 2 3 4], 4
(elt [1 2 3 4] -1)
  [error] Args out of range: [1 2 3 4], -1
```

This function generalizes **aref** (see Section 6.3 [Array Functions], page 116) and **nth** (see [Definition of nth], page 80).

copy-sequence seqr [Function]

This function returns a copy of *seqr*, which should be either a sequence or a record. The copy is the same type of object as the original, and it has the same elements in the same order. However, if *seqr* is empty, like a string or a vector of zero length, the value returned by this function might not be a copy, but an empty object of the same type and identical to *seqr*.

Storing a new element into the copy does not affect the original `seqr`, and vice versa. However, the elements of the copy are not copies; they are identical (`eq`) to the elements of the original. Therefore, changes made within these elements, as found via the copy, are also visible in the original.

If the argument is a string with text properties, the property list in the copy is itself a copy, not shared with the original's property list. However, the actual values of the properties are shared. See Section 33.19 [Text Properties], page 917.

This function does not work for dotted lists. Trying to copy a circular list may cause an infinite loop.

See also `append` in Section 5.4 [Building Lists], page 82, `concat` in Section 4.3 [Creating Strings], page 55, and `vconcat` in Section 6.5 [Vector Functions], page 118, for other ways to copy sequences.

```
(setq bar (list 1 2))
⇒ (1 2)
(setq x (vector 'foo bar))
⇒ [foo (1 2)]
(setq y (copy-sequence x))
⇒ [foo (1 2)]

(eq x y)
⇒ nil
(equal x y)
⇒ t
(eq (elt x 1) (elt y 1))
⇒ t

;; Replacing an element of one sequence.
(aset x 0 'quux)
x ⇒ [quux (1 2)]
y ⇒ [foo (1 2)]

;; Modifying the inside of a shared element.
(setcar (aref x 1) 69)
x ⇒ [quux (69 2)]
y ⇒ [foo (69 2)]
```

`reverse` sequence [Function]

This function creates a new sequence whose elements are the elements of `sequence`, but in reverse order. The original argument `sequence` is *not* altered. Note that char-tables cannot be reversed.

```
(setq x '(1 2 3 4))
⇒ (1 2 3 4)
(reverse x)
⇒ (4 3 2 1)
x
⇒ (1 2 3 4)
```

```
(setq x [1 2 3 4])
  ⇒ [1 2 3 4]
(reverse x)
  ⇒ [4 3 2 1]
x
  ⇒ [1 2 3 4]
(setq x "xyzzy")
  ⇒ "xyzzy"
(reverse x)
  ⇒ "yzzyx"
x
  ⇒ "xyzzy"
```

nreverse sequence

[Function]

This function reverses the order of the elements of *sequence*. Unlike **reverse** the original *sequence* may be modified.

For example:

```
(setq x (list 'a 'b 'c))
  ⇒ (a b c)
x
  ⇒ (a b c)
(nreverse x)
  ⇒ (c b a)
;; The cons cell that was first is now last.
x
  ⇒ (a)
```

To avoid confusion, we usually store the result of **nreverse** back in the same variable which held the original list:

```
(setq x (nreverse x))
```

Here is the **nreverse** of our favorite example, (**a b c**), presented graphically:

For the vector, it is even simpler because you don't need **setq**:

```
(setq x (copy-sequence [1 2 3 4]))
  ⇒ [1 2 3 4]
(nreverse x)
  ⇒ [4 3 2 1]
x
  ⇒ [4 3 2 1]
```

Note that unlike `reverse`, this function doesn't work with strings. Although you can alter string data by using `aset`, it is strongly encouraged to treat strings as immutable even when they are mutable. See Section 2.9 [Mutability], page 36.

sort sequence predicate

[Function]

This function sorts `sequence` stably. Note that this function doesn't work for all sequences; it may be used only for lists and vectors. If `sequence` is a list, it is modified destructively. This function returns the sorted `sequence` and compares elements using `predicate`. A stable sort is one in which elements with equal sort keys maintain their relative order before and after the sort. Stability is important when successive sorts are used to order elements according to different criteria.

The argument `predicate` must be a function that accepts two arguments. It is called with two elements of `sequence`. To get an increasing order sort, the `predicate` should return `non-nil` if the first element is “less” than the second, or `nil` if not.

The comparison function `predicate` must give reliable results for any given pair of arguments, at least within a single call to `sort`. It must be *antisymmetric*; that is, if `a` is less than `b`, `b` must not be less than `a`. It must be *transitive*—that is, if `a` is less than `b`, and `b` is less than `c`, then `a` must be less than `c`. If you use a comparison function which does not meet these requirements, the result of `sort` is unpredictable.

The destructive aspect of `sort` for lists is that it reuses the cons cells forming `sequence` by changing their contents, possibly rearranging them in a different order. This means that the value of the input list is undefined after sorting; only the list returned by `sort` has a well-defined value. Example:

```
(setq nums (list 2 1 4 3 0))
  (sort nums #'<)
    ⇒ (0 1 2 3 4)
      ; nums is unpredictable at this point
```

Most often we store the result back into the variable that held the original list:

```
(setq nums (sort nums #'<))
```

If you wish to make a sorted copy without destroying the original, copy it first and then sort:

```
(setq nums (list 2 1 4 3 0))
  (sort (copy-sequence nums) #'<)
    ⇒ (0 1 2 3 4)
  nums
    ⇒ (2 1 4 3 0)
```

For the better understanding of what stable sort is, consider the following vector example. After sorting, all items whose `car` is 8 are grouped at the beginning of `vector`, but their relative order is preserved. All items whose `car` is 9 are grouped at the end of `vector`, but their relative order is also preserved:

```
(setq
  vector
  (vector '(8 . "xxx") '(9 . "aaa") '(8 . "bbb") '(9 . "zzz")
          '(9 . "ppp") '(8 . "ttt") '(8 . "eee") '(9 . "fff")))
  ⇒ [(8 . "xxx") (9 . "aaa") (8 . "bbb") (9 . "zzz")
      (9 . "ppp") (8 . "ttt") (8 . "eee") (9 . "fff")]
```

```
(sort vector (lambda (x y) (< (car x) (car y))))
⇒ [(8 . "xxx") (8 . "bbb") (8 . "ttt") (8 . "eee")
     (9 . "aaa") (9 . "zzz") (9 . "ppp") (9 . "fff")]
```

See Section 33.15 [Sorting], page 906, for more functions that perform sorting. See **documentation** in Section 25.2 [Accessing Documentation], page 596, for a useful example of **sort**.

The **seq.el** library provides the following additional sequence manipulation macros and functions, prefixed with **seq-**.

All functions defined in this library are free of side-effects; i.e., they do not modify any sequence (list, vector, or string) that you pass as an argument. Unless otherwise stated, the result is a sequence of the same type as the input. For those functions that take a predicate, this should be a function of one argument.

The **seq.el** library can be extended to work with additional types of sequential data-structures. For that purpose, all functions are defined using **cl-defgeneric**. See Section 13.8 [Generic Functions], page 245, for more details about using **cl-defgeneric** for adding extensions.

seq-elt *sequence index*

[Function]

This function returns the element of *sequence* at the specified *index*, which is an integer whose valid value range is zero to one less than the length of *sequence*. For out-of-range values on built-in sequence types, **seq-elt** behaves like **elt**. For the details, see [Definition of elt], page 103.

```
(seq-elt [1 2 3 4] 2)
⇒ 3
```

seq-elt returns places settable using **setf** (see Section 12.17.1 [Setting Generalized Variables], page 224).

```
(setq vec [1 2 3 4])
(setf (seq-elt vec 2) 5)
vec
⇒ [1 2 5 4]
```

seq-length *sequence*

[Function]

This function returns the number of elements in *sequence*. For built-in sequence types, **seq-length** behaves like **length**. See [Definition of length], page 102.

seqp *object*

[Function]

This function returns **non-nil** if *object* is a sequence (a list or array), or any additional type of sequence defined via **seq.el** generic functions. This is an extensible variant of **sequencep**.

```
(seqp [1 2])
⇒ t
(seqp 2)
⇒ nil
```

seq-drop *sequence n*

[Function]

This function returns all but the first *n* (an integer) elements of *sequence*. If *n* is negative or zero, the result is *sequence*.

```
(seq-drop [1 2 3 4 5 6] 3)
⇒ [4 5 6]
(seq-drop "hello world" -4)
⇒ "hello world"
```

seq-take sequence n [Function]

This function returns the first *n* (an integer) elements of *sequence*. If *n* is negative or zero, the result is *nil*.

```
(seq-take '(1 2 3 4) 3)
⇒ (1 2 3)
(seq-take [1 2 3 4] 0)
⇒ []
```

seq-take-while predicate sequence [Function]

This function returns the members of *sequence* in order, stopping before the first one for which *predicate* returns *nil*.

```
(seq-take-while (lambda (elt) (> elt 0)) '(1 2 3 -1 -2))
⇒ (1 2 3)
(seq-take-while (lambda (elt) (> elt 0)) [-1 4 6])
⇒ []
```

seq-drop-while predicate sequence [Function]

This function returns the members of *sequence* in order, starting from the first one for which *predicate* returns *nil*.

```
(seq-drop-while (lambda (elt) (> elt 0)) '(1 2 3 -1 -2))
⇒ (-1 -2)
(seq-drop-while (lambda (elt) (< elt 0)) [1 4 6])
⇒ [1 4 6]
```

seq-split sequence length [Function]

This function returns a list consisting of sub-sequences of *sequence* of (at most) length *length*. (The final element may be shorter than *length* if the length of *sequence* isn't a multiple of *length*.)

```
(seq-split [0 1 2 3 4] 2)
⇒ ([0 1] [2 3] [4])
```

seq-do function sequence [Function]

This function applies *function* to each element of *sequence* in turn (presumably for side effects), and returns *sequence*.

seq-map function sequence [Function]

This function returns the result of applying *function* to each element of *sequence*. The returned value is a list.

```
(seq-map #'1+ '(2 4 6))
⇒ (3 5 7)
(seq-map #'symbol-name [foo bar])
⇒ ("foo" "bar")
```

seq-map-indexed *function sequence* [Function]

This function returns the result of applying *function* to each element of *sequence* and its index within *seq*. The returned value is a list.

```
(seq-map-indexed (lambda (elt idx)
                           (list idx elt))
                  '(a b c))
⇒ ((0 a) (1 b) (2 c))
```

seq-mapn *function &rest sequences* [Function]

This function returns the result of applying *function* to each element of *sequences*. The arity (see Section 13.1 [What Is a Function], page 230) of *function* must match the number of sequences. Mapping stops at the end of the shortest sequence, and the returned value is a list.

```
(seq-mapn #''+ '(2 4 6) '(20 40 60))
⇒ (22 44 66)
(seq-mapn #'concat '("mosquito" "bite") ["bee" "sting"])
⇒ ("moskitobee" "bitesting")
```

seq-filter *predicate sequence* [Function]

This function returns a list of all the elements in *sequence* for which *predicate* returns non-nil.

```
(seq-filter (lambda (elt) (> elt 0)) [1 -1 3 -3 5])
⇒ (1 3 5)
(seq-filter (lambda (elt) (> elt 0)) '(-1 -3 -5))
⇒ nil
```

seq-remove *predicate sequence* [Function]

This function returns a list of all the elements in *sequence* for which *predicate* returns nil.

```
(seq-remove (lambda (elt) (> elt 0)) [1 -1 3 -3 5])
⇒ (-1 -3)
(seq-remove (lambda (elt) (< elt 0)) '(-1 -3 -5))
⇒ nil
```

seq-remove-at-position *sequence n* [Function]

This function returns a copy of *sequence* where the element at (zero-based) index *n* got removed. The result is a sequence of the same type as *sequence*.

```
(seq-remove-at-position [1 -1 3 -3 5] 0)
⇒ [-1 3 -3 5]
(seq-remove-at-position [1 -1 3 -3 5] 3)
⇒ [1 -1 3 5]
```

seq-keep *function sequence* [Function]

This function returns a list of all non-nil results from calling *function* on the elements in *sequence*.

```
(seq-keep #'cl-digit-char-p '(?6 ?a ?7))
⇒ (6 7)
```

seq-reduce *function sequence initial-value* [Function]

This function returns the result of calling *function* with *initial-value* and the first element of *sequence*, then calling *function* with that result and the second element of *sequence*, then with that result and the third element of *sequence*, etc. *function* should be a function of two arguments.

function is called with two arguments. *initial-value* (and then the accumulated value) is used as the first argument, and the elements in *sequence* are used for the second argument.

If *sequence* is empty, this returns *initial-value* without calling *function*.

```
(seq-reduce #'+ [1 2 3 4] 0)
⇒ 10
(seq-reduce #'+ '(1 2 3 4) 5)
⇒ 15
(seq-reduce #'+ '() 3)
⇒ 3
```

seq-some *predicate sequence* [Function]

This function returns the first non-*nil* value returned by applying *predicate* to each element of *sequence* in turn.

```
(seq-some #'numberp ["abc" 1 nil])
⇒ t
(seq-some #'numberp ["abc" "def"])
⇒ nil
(seq-some #'null ["abc" 1 nil])
⇒ t
(seq-some #'1+ [2 4 6])
⇒ 3
```

seq-find *predicate sequence &optional default* [Function]

This function returns the first element in *sequence* for which *predicate* returns non-*nil*. If no element matches *predicate*, the function returns *default*.

Note that this function has an ambiguity if the found element is identical to *default*, as in that case it cannot be known whether an element was found or not.

```
(seq-find #'numberp ["abc" 1 nil])
⇒ 1
(seq-find #'numberp ["abc" "def"])
⇒ nil
```

seq-every-p *predicate sequence* [Function]

This function returns non-*nil* if applying *predicate* to every element of *sequence* returns non-*nil*.

```
(seq-every-p #'numberp [2 4 6])
⇒ t
(seq-every-p #'numberp [2 4 "6"])
⇒ nil
```

seq-empty-p *sequence* [Function]

This function returns non-nil if *sequence* is empty.

```
(seq-empty-p "not empty")
⇒ nil
(seq-empty-p "")
⇒ t
```

seq-count *predicate sequence* [Function]

This function returns the number of elements in *sequence* for which *predicate* returns non-nil.

```
(seq-count (lambda (elt) (> elt 0)) [-1 2 0 3 -2])
⇒ 2
```

seq-sort *function sequence* [Function]

This function returns a copy of *sequence* that is sorted according to *function*, a function of two arguments that returns non-nil if the first argument should sort before the second.

seq-sort-by *function predicate sequence* [Function]

This function is similar to **seq-sort**, but the elements of *sequence* are transformed by applying *function* on them before being sorted. *function* is a function of one argument.

```
(seq-sort-by #'seq-length #'> ["a" "ab" "abc"])
⇒ ["abc" "ab" "a"]
```

seq-contains-p *sequence elt &optional function* [Function]

This function returns non-nil if at least one element in *sequence* is equal to *elt*. If the optional argument *function* is non-nil, it is a function of two arguments to use instead of the default **equal**.

```
(seq-contains-p '(symbol1 symbol2) 'symbol1)
⇒ t
(seq-contains-p '(symbol1 symbol2) 'symbol3)
⇒ nil
```

seq-set-equal-p *sequence1 sequence2 &optional testfn* [Function]

This function checks whether *sequence1* and *sequence2* contain the same elements, regardless of the order. If the optional argument *testfn* is non-nil, it is a function of two arguments to use instead of the default **equal**.

```
(seq-set-equal-p '(a b c) '(c b a))
⇒ t
(seq-set-equal-p '(a b c) '(c b))
⇒ nil
(seq-set-equal-p '("a" "b" "c") '("c" "b" "a"))
⇒ t
(seq-set-equal-p '("a" "b" "c") '("c" "b" "a") #'eq)
⇒ nil
```

seq-position sequence elt &optional function [Function]

This function returns the (zero-based) index of the first element in *sequence* that is equal to *elt*. If the optional argument *function* is non-nil, it is a function of two arguments to use instead of the default `equal`.

```
(seq-position '(a b c) 'b)
⇒ 1
(seq-position '(a b c) 'd)
⇒ nil
```

seq-positions sequence elt &optional testfn [Function]

This function returns a list of the (zero-based) indices of the elements in *sequence* for which *testfn* returns non-nil when passed the element and *elt* as arguments. *testfn* defaults to `equal`.

```
(seq-positions '(a b c a d) 'a)
⇒ (0 3)
(seq-positions '(a b c a d) 'z)
⇒ nil
(seq-positions '(11 5 7 12 9 15) 10 #'>=)
⇒ (0 3 5)
```

seq-uniq sequence &optional function [Function]

This function returns a list of the elements of *sequence* with duplicates removed. If the optional argument *function* is non-nil, it is a function of two arguments to use instead of the default `equal`.

```
(seq-uniq '(1 2 2 1 3))
⇒ (1 2 3)
(seq-uniq '(1 2 2.0 1.0) #'=)
⇒ (1 2)
```

seq-subseq sequence start &optional end [Function]

This function returns a subset of *sequence* from *start* to *end*, both integers (*end* defaults to the last element). If *start* or *end* is negative, it counts from the end of *sequence*.

```
(seq-subseq '(1 2 3 4 5) 1)
⇒ (2 3 4 5)
(seq-subseq '[1 2 3 4 5] 1 3)
⇒ [2 3]
(seq-subseq '[1 2 3 4 5] -3 -1)
⇒ [3 4]
```

seq-concatenate type &rest sequences [Function]

This function returns a sequence of type *type* made of the concatenation of *sequences*. *type* may be: `vector`, `list` or `string`.

```
(seq-concatenate 'list '(1 2) '(3 4) [5 6])
⇒ (1 2 3 4 5 6)
(seq-concatenate 'string "Hello " "world")
⇒ "Hello world"
```

seq-mapcat *function sequence &optional type* [Function]

This function returns the result of applying `seq-concatenate` to the result of applying *function* to each element of *sequence*. The result is a sequence of type *type*, or a list if *type* is `nil`.

```
(seq-mapcat #'seq-reverse '((3 2 1) (6 5 4)))
⇒ (1 2 3 4 5 6)
```

seq-partition *sequence n* [Function]

This function returns a list of the elements of *sequence* grouped into sub-sequences of length *n*. The last sequence may contain less elements than *n*. *n* must be an integer. If *n* is a negative integer or 0, the return value is `nil`.

```
(seq-partition '(0 1 2 3 4 5 6 7) 3)
⇒ ((0 1 2) (3 4 5) (6 7))
```

seq-union *sequence1 sequence2 &optional function* [Function]

This function returns a list of the elements that appear either in *sequence1* or *sequence2*. The elements of the returned list are all unique, in the sense that no two elements there will compare equal. If the optional argument *function* is non-`nil`, it should be a function of two arguments to use to compare elements, instead of the default `equal`.

```
(seq-union [1 2 3] [3 5])
⇒ (1 2 3 5)
```

seq-intersection *sequence1 sequence2 &optional function* [Function]

This function returns a list of the elements that appear both in *sequence1* and *sequence2*. If the optional argument *function* is non-`nil`, it is a function of two arguments to use to compare elements instead of the default `equal`.

```
(seq-intersection [2 3 4 5] [1 3 5 6 7])
⇒ (3 5)
```

seq-difference *sequence1 sequence2 &optional function* [Function]

This function returns a list of the elements that appear in *sequence1* but not in *sequence2*. If the optional argument *function* is non-`nil`, it is a function of two arguments to use to compare elements instead of the default `equal`.

```
(seq-difference '(2 3 4 5) [1 3 5 6 7])
⇒ (2 4)
```

seq-group-by *function sequence* [Function]

This function separates the elements of *sequence* into an alist whose keys are the result of applying *function* to each element of *sequence*. Keys are compared using `equal`.

```
(seq-group-by #'integerp '(1 2.1 3 2 3.2))
⇒ ((t 1 3 2) (nil 2.1 3.2))
(seq-group-by #'car '((a 1) (b 2) (a 3) (c 4)))
⇒ ((b (b 2)) (a (a 1) (a 3)) (c (c 4)))
```

seq-into *sequence type* [Function]

This function converts the sequence *sequence* into a sequence of type *type*. *type* can be one of the following symbols: `vector`, `string` or `list`.

```
(seq-into [1 2 3] 'list)
⇒ (1 2 3)
```

```
(seq-into nil 'vector)
⇒ []
(seq-into "hello" 'vector)
⇒ [104 101 108 108 111]
```

seq-min sequence [Function]

This function returns the smallest element of *sequence*. The elements of *sequence* must be numbers or markers (see Chapter 32 [Markers], page 869).

```
(seq-min [3 1 2])
⇒ 1
(seq-min "Hello")
⇒ 72
```

seq-max sequence [Function]

This function returns the largest element of *sequence*. The elements of *sequence* must be numbers or markers.

```
(seq-max [1 3 2])
⇒ 3
(seq-max "Hello")
⇒ 111
```

seq-doseq (var sequence) body... [Macro]

This macro is like `dolist` (see Section 11.5 [Iteration], page 174), except that *sequence* can be a list, vector or string. This is primarily useful for side-effects.

seq-let var-sequence val-sequence body... [Macro]

This macro binds the variables defined in *var-sequence* to the values that are the corresponding elements of *val-sequence*. This is known as *destructuring binding*. The elements of *var-sequence* can themselves include sequences, allowing for nested destructuring.

The *var-sequence* sequence can also include the `&rest` marker followed by a variable name to be bound to the rest of *val-sequence*.

```
(seq-let [first second] [1 2 3 4]
        (list first second))
⇒ (1 2)
(seq-let (_ a _ b) '(1 2 3 4)
        (list a b))
⇒ (2 4)
(seq-let [a [b [c]]] [1 [2 [3]]]
        (list a b c))
⇒ (1 2 3)
(seq-let [a b &rest others] [1 2 3 4]
        others)
⇒ [3 4]
```

The `pcase` patterns provide an alternative facility for destructuring binding, see Section 11.4.4 [Destructuring with `pcase` Patterns], page 172.

seq-setq var-sequence val-sequence [Macro]

This macro works similarly to **seq-let**, except that values are assigned to variables as if by **setq** instead of as in a **let** binding.

```
(let ((a nil)
      (b nil))
  (seq-setq (_ a _ b) '(1 2 3 4))
  (list a b))
⇒ (2 4)
```

seq-random-elt sequence [Function]

This function returns an element of *sequence* taken at random.

```
(seq-random-elt [1 2 3 4])
⇒ 3
(seq-random-elt [1 2 3 4])
⇒ 2
(seq-random-elt [1 2 3 4])
⇒ 4
(seq-random-elt [1 2 3 4])
⇒ 2
(seq-random-elt [1 2 3 4])
⇒ 1
```

If *sequence* is empty, this function signals an error.

6.2 Arrays

An array object has slots that hold a number of other Lisp objects, called the elements of the array. Any element of an array may be accessed in constant time. In contrast, the time to access an element of a list is proportional to the position of that element in the list.

Emacs defines four types of array, all one-dimensional: *strings* (see Section 2.4.8 [String Type], page 20), *vectors* (see Section 2.4.9 [Vector Type], page 22), *bool-vectors* (see Section 2.4.11 [Bool-Vector Type], page 23), and *char-tables* (see Section 2.4.10 [Char-Table Type], page 22). Vectors and char-tables can hold elements of any type, but strings can only hold characters, and bool-vectors can only hold **t** and **nil**.

All four kinds of array share these characteristics:

- The first element of an array has index zero, the second element has index 1, and so on. This is called *zero-origin* indexing. For example, an array of four elements has indices 0, 1, 2, and 3.
- The length of the array is fixed once you create it; you cannot change the length of an existing array.
- For purposes of evaluation, the array is a constant—i.e., it evaluates to itself.
- The elements of an array may be referenced or changed with the functions **aref** and **aset**, respectively (see Section 6.3 [Array Functions], page 116).

When you create an array, other than a char-table, you must specify its length. You cannot specify the length of a char-table, because that is determined by the range of character codes.

In principle, if you want an array of text characters, you could use either a string or a vector. In practice, we always choose strings for such applications, for four reasons:

- They occupy one-fourth the space of a vector of the same elements.
- Strings are printed in a way that shows the contents more clearly as text.
- Strings can hold text properties. See Section 33.19 [Text Properties], page 917.
- Many of the specialized editing and I/O facilities of Emacs accept only strings. For example, you cannot insert a vector of characters into a buffer the way you can insert a string. See Chapter 4 [Strings and Characters], page 54.

By contrast, for an array of keyboard input characters (such as a key sequence), a vector may be necessary, because many keyboard input characters are outside the range that will fit in a string. See Section 22.8.1 [Key Sequence Input], page 461.

6.3 Functions that Operate on Arrays

In this section, we describe the functions that accept all types of arrays.

arrayp object [Function]

This function returns `t` if *object* is an array (i.e., a vector, a string, a bool-vector or a char-table).

```
(arrayp [a])
⇒ t
(arrayp "asdf")
⇒ t
(arrayp (syntax-table))    ;; A char-table.
⇒ t
```

aref arr index [Function]

This function returns the *index*th element of the array or record *arr*. The first element is at index zero.

```
(setq primes [2 3 5 7 11 13])
⇒ [2 3 5 7 11 13]
(aref primes 4)
⇒ 11
(aref "abcdefg" 1)
⇒ 98           ; 'b' is ASCII code 98.
```

See also the function `elt`, in Section 6.1 [Sequence Functions], page 102.

aset array index object [Function]

This function sets the *index*th element of *array* to be *object*. It returns *object*.

```
(setq w (vector 'foo 'bar 'baz))
⇒ [foo bar baz]
(aset w 0 'fu)
⇒ fu
w
⇒ [fu bar baz]
```

```
;; copy-sequence copies the string to be modified later.
(setq x (copy-sequence "asdfasfd"))
⇒ "asdfasfd"
(aset x 3 ?Z)
⇒ 90
x
⇒ "asdZasfd"
```

The array should be mutable. See Section 2.9 [Mutability], page 36.

If *array* is a string and *object* is not a character, a `wrong-type-argument` error results. The function converts a unibyte string to multibyte if necessary to insert a character.

`fillarray array object` [Function]

This function fills the array *array* with *object*, so that each element of *array* is *object*. It returns *array*.

```
(setq a (copy-sequence [a b c d e f g]))
⇒ [a b c d e f g]
(fillarray a 0)
⇒ [0 0 0 0 0 0 0]
a
⇒ [0 0 0 0 0 0 0]
(setq s (copy-sequence "When in the course"))
⇒ "When in the course"
(fillarray s ?-)
⇒ "-----"
```

If *array* is a string and *object* is not a character, a `wrong-type-argument` error results.

The general sequence functions `copy-sequence` and `length` are often useful for objects known to be arrays. See Section 6.1 [Sequence Functions], page 102.

6.4 Vectors

A vector is a general-purpose array whose elements can be any Lisp objects. (By contrast, the elements of a string can only be characters. See Chapter 4 [Strings and Characters], page 54.) Vectors are used in Emacs for many purposes: as key sequences (see Section 23.1 [Key Sequences], page 480), as symbol-lookup tables (see Section 9.3 [Creating Symbols], page 135), as part of the representation of a byte-compiled function (see Chapter 17 [Byte Compilation], page 316), and more.

Like other arrays, vectors use zero-origin indexing: the first element has index 0.

Vectors are printed with square brackets surrounding the elements. Thus, a vector whose elements are the symbols `a`, `b` and `a` is printed as `[a b a]`. You can write vectors in the same way in Lisp input.

A vector, like a string or a number, is considered a constant for evaluation: the result of evaluating it is the same vector. This does not evaluate or even examine the elements of the vector. See Section 10.1.1 [Self-Evaluating Forms], page 146. Vectors written with square brackets should not be modified via `aset` or other destructive operations. See Section 2.9 [Mutability], page 36.

Here are examples illustrating these principles:

```
(setq avector [1 two '(three) "four" [five]])
  ⇒ [1 two '(three) "four" [five]]
(eval avector)
  ⇒ [1 two '(three) "four" [five]]
(eq avector (eval avector))
  ⇒ t
```

6.5 Functions for Vectors

Here are some functions that relate to vectors:

vectorp *object* [Function]

This function returns *t* if *object* is a vector.

```
(vectorp [a])
  ⇒ t
(vectorp "asdf")
  ⇒ nil
```

vector &rest *objects* [Function]

This function creates and returns a vector whose elements are the arguments, *objects*.

```
(vector 'foo 23 [bar baz] "rats")
  ⇒ [foo 23 [bar baz] "rats"]
(vector)
  ⇒ []
```

make-vector *length object* [Function]

This function returns a new vector consisting of *length* elements, each initialized to *object*.

```
(setq sleepy (make-vector 9 'Z))
  ⇒ [Z Z Z Z Z Z Z Z Z]
```

vconcat &rest *sequences* [Function]

This function returns a new vector containing all the elements of *sequences*. The arguments *sequences* may be proper lists, vectors, strings or bool-vectors. If no *sequences* are given, the empty vector is returned.

The value is either the empty vector, or is a newly constructed nonempty vector that is not *eq* to any existing vector.

```
(setq a (vconcat '(A B C) '(D E F)))
  ⇒ [A B C D E F]
(eq a (vconcat a))
  ⇒ nil
(vconcat)
  ⇒ []
(vconcat [A B C] "aa" '(foo (6 7)))
  ⇒ [A B C 97 97 foo (6 7)]
```

The `vconcat` function also allows byte-code function objects as arguments. This is a special feature to make it easy to access the entire contents of a byte-code function object. See Section 17.7 [Byte-Code Objects], page 323.

For other concatenation functions, see `mapconcat` in Section 13.6 [Mapping Functions], page 241, `concat` in Section 4.3 [Creating Strings], page 55, and `append` in Section 5.4 [Building Lists], page 82.

The `append` function also provides a way to convert a vector into a list with the same elements:

```
(setq avector [1 two (quote (three)) "four" [five]])
  ⇒ [1 two '(three) "four" [five]]
(append avector nil)
  ⇒ (1 two '(three) "four" [five])
```

6.6 Char-Tables

A char-table is much like a vector, except that it is indexed by character codes. Any valid character code, without modifiers, can be used as an index in a char-table. You can access a char-table's elements with `aref` and `aset`, as with any array. In addition, a char-table can have *extra slots* to hold additional data not associated with particular character codes. Like vectors, char-tables are constants when evaluated, and can hold elements of any type.

Each char-table has a *subtype*, a symbol, which serves two purposes:

- The subtype provides an easy way to tell what the char-table is for. For instance, display tables are char-tables with `display-table` as the subtype, and syntax tables are char-tables with `syntax-table` as the subtype. The subtype can be queried using the function `char-table-subtype`, described below.
- The subtype controls the number of *extra slots* in the char-table. This number is specified by the subtype's `char-table-extra-slots` symbol property (see Section 9.4 [Symbol Properties], page 138), whose value should be an integer between 0 and 10. If the subtype has no such symbol property, the char-table has no extra slots.

A char-table can have a *parent*, which is another char-table. If it does, then whenever the char-table specifies `nil` for a particular character *c*, it inherits the value specified in the parent. In other words, `(aref char-table c)` returns the value from the parent of *char-table* if *char-table* itself specifies `nil`.

A char-table can also have a *default value*. If so, then `(aref char-table c)` returns the default value whenever the char-table does not specify any other non-`nil` value.

make-char-table subtype &optional init [Function]

Return a newly-created char-table, with subtype *subtype* (a symbol). Each element is initialized to *init*, which defaults to `nil`. You cannot alter the subtype of a char-table after the char-table is created.

There is no argument to specify the length of the char-table, because all char-tables have room for any valid character code as an index.

If *subtype* has the `char-table-extra-slots` symbol property, that specifies the number of extra slots in the char-table. This should be an integer between 0 and 10;

otherwise, `make-char-table` raises an error. If `subtype` has no `char-table-extra-slots` symbol property (see Section 5.9 [Property Lists], page 99), the char-table has no extra slots.

char-table-p *object* [Function]

This function returns `t` if *object* is a char-table, and `nil` otherwise.

char-table-subtype *char-table* [Function]

This function returns the subtype symbol of *char-table*.

There is no special function to access default values in a char-table. To do that, use `char-table-range` (see below).

char-table-parent *char-table* [Function]

This function returns the parent of *char-table*. The parent is always either `nil` or another char-table.

set-char-table-parent *char-table new-parent* [Function]

This function sets the parent of *char-table* to *new-parent*.

char-table-extra-slot *char-table n* [Function]

This function returns the contents of extra slot *n* (zero based) of *char-table*. The number of extra slots in a char-table is determined by its subtype.

set-char-table-extra-slot *char-table n value* [Function]

This function stores *value* in extra slot *n* (zero based) of *char-table*.

A char-table can specify an element value for a single character code; it can also specify a value for an entire character set.

char-table-range *char-table range* [Function]

This returns the value specified in *char-table* for a range of characters *range*. Here are the possibilities for *range*:

`nil` Refers to the default value.

`char` Refers to the element for character *char* (supposing *char* is a valid character code).

`(from . to)`

A cons cell refers to all the characters in the inclusive range ‘`[from..to]`’. In this case, the function returns the value for the character specified by *from*.

set-char-table-range *char-table range value* [Function]

This function sets the value in *char-table* for a range of characters *range*. Here are the possibilities for *range*:

`nil` Refers to the default value.

`t` Refers to the whole range of character codes.

`char` Refers to the element for character *char* (supposing *char* is a valid character code).

`(from . to)`

A cons cell refers to all the characters in the inclusive range ‘`[from..to]`’.

map-char-table *function char-table*

[Function]

This function calls its argument *function* for each element of *char-table* that has a non-*nil* value. The call to *function* is with two arguments, a key and a value. The key is a possible *range* argument for **char-table-range**—either a valid character or a cons cell `(from . to)`, specifying a range of characters that share the same value. The value is what `(char-table-range char-table key)` returns.

Overall, the key-value pairs passed to *function* describe all the values stored in *char-table*.

The return value is always *nil*; to make calls to **map-char-table** useful, *function* should have side effects. For example, here is how to examine the elements of the syntax table:

```
(let (accumulator)
  (map-char-table
   (lambda (key value)
     (setq accumulator
           (cons (list
                  (if (consp key)
                      (list (car key) (cdr key))
                      key)
                  value)
                  accumulator)))
   (syntax-table))
  accumulator)
⇒ (((2597602 4194303) (2)) ((2597523 2597601) (3))
... (65379 (5 . 65378)) (65378 (4 . 65379)) (65377 (1))
... (12 (0)) (11 (3)) (10 (12)) (9 (0)) ((0 8) (3)))
```

6.7 Bool-vectors

A bool-vector is much like a vector, except that it stores only the values `t` and `nil`. If you try to store any non-*nil* value into an element of the bool-vector, the effect is to store `t` there. As with all arrays, bool-vector indices start from 0, and the length cannot be changed once the bool-vector is created. Bool-vectors are constants when evaluated.

Several functions work specifically with bool-vectors; aside from that, you manipulate them with same functions used for other kinds of arrays.

make-bool-vector *length initial*

[Function]

Return a new bool-vector of *length* elements, each one initialized to *initial*.

bool-vector &rest objects

[Function]

This function creates and returns a bool-vector whose elements are the arguments, *objects*.

bool-vector-p object [Function]

This returns `t` if `object` is a bool-vector, and `nil` otherwise.

There are also some bool-vector set operation functions, described below:

bool-vector-exclusive-or a b &optional c [Function]

Return *bitwise exclusive or* of bool vectors `a` and `b`. If optional argument `c` is given, the result of this operation is stored into `c`. All arguments should be bool vectors of the same length.

bool-vector-union a b &optional c [Function]

Return *bitwise or* of bool vectors `a` and `b`. If optional argument `c` is given, the result of this operation is stored into `c`. All arguments should be bool vectors of the same length.

bool-vector-intersection a b &optional c [Function]

Return *bitwise and* of bool vectors `a` and `b`. If optional argument `c` is given, the result of this operation is stored into `c`. All arguments should be bool vectors of the same length.

bool-vector-set-difference a b &optional c [Function]

Return *set difference* of bool vectors `a` and `b`. If optional argument `c` is given, the result of this operation is stored into `c`. All arguments should be bool vectors of the same length.

bool-vector-not a &optional b [Function]

Return *set complement* of bool vector `a`. If optional argument `b` is given, the result of this operation is stored into `b`. All arguments should be bool vectors of the same length.

bool-vector-subsetp a b [Function]

Return `t` if every `t` value in `a` is also `t` in `b`, `nil` otherwise. All arguments should be bool vectors of the same length.

bool-vector-count-consecutive a b i [Function]

Return the number of consecutive elements in `a` equal `b` starting at `i`. `a` is a bool vector, `b` is `t` or `nil`, and `i` is an index into `a`.

bool-vector-count-population a [Function]

Return the number of elements that are `t` in bool vector `a`.

The printed form represents up to 8 boolean values as a single character:

```
(bool-vector t nil t nil)
  ⇒ #&4"E"
(bool-vector)
  ⇒ #&0""
```

You can use `vconcat` to print a bool-vector like other vectors:

```
(vconcat (bool-vector nil t nil t))
  ⇒ [nil t nil t]
```

Here is another example of creating, examining, and updating a bool-vector:

```
(setq bv (make-bool-vector 5 t))
  ⇒ #&5"^-"
(aref bv 1)
  ⇒ t
(aset bv 3 nil)
  ⇒ nil
bv
  ⇒ #&5"^-W"
```

These results make sense because the binary codes for control-_ and control-W are 11111 and 10111, respectively.

6.8 Managing a Fixed-Size Ring of Objects

A *ring* is a fixed-size data structure that supports insertion, deletion, rotation, and modulo-indexed reference and traversal. An efficient ring data structure is implemented by the `ring` package. It provides the functions listed in this section.

Note that several rings in Emacs, like the kill ring and the mark ring, are actually implemented as simple lists, *not* using the `ring` package; thus the following functions won't work on them.

make-ring size [Function]
 This returns a new ring capable of holding *size* objects. *size* should be an integer.

ring-p object [Function]
 This returns `t` if *object* is a ring, `nil` otherwise.

ring-size ring [Function]
 This returns the maximum capacity of the *ring*.

ring-length ring [Function]
 This returns the number of objects that *ring* currently contains. The value will never exceed that returned by `ring-size`.

ring-elements ring [Function]
 This returns a list of the objects in *ring*, in order, newest first.

ring-copy ring [Function]
 This returns a new ring which is a copy of *ring*. The new ring contains the same (`eq`) objects as *ring*.

ring-empty-p ring [Function]
 This returns `t` if *ring* is empty, `nil` otherwise.

The newest element in the ring always has index 0. Higher indices correspond to older elements. Indices are computed modulo the ring length. Index -1 corresponds to the oldest element, -2 to the next-oldest, and so forth.

ring-ref ring index [Function]
 This returns the object in *ring* found at index *index*. *index* may be negative or greater than the ring length. If *ring* is empty, `ring-ref` signals an error.

ring-insert *ring object* [Function]

This inserts *object* into *ring*, making it the newest element, and returns *object*.

If the ring is full, insertion removes the oldest element to make room for the new element.

ring-remove *ring &optional index* [Function]

Remove an object from *ring*, and return that object. The argument *index* specifies which item to remove; if it is *nil*, that means to remove the oldest item. If *ring* is empty, **ring-remove** signals an error.

ring-insert-at-beginning *ring object* [Function]

This inserts *object* into *ring*, treating it as the oldest element. The return value is not significant.

If the ring is full, this function removes the newest element to make room for the inserted element.

ring-resize *ring size* [Function]

Set the size of *ring* to *size*. If the new size is smaller, then the oldest items in the ring are discarded.

If you are careful not to exceed the ring size, you can use the ring as a first-in-first-out queue. For example:

```
(let ((fifo (make-ring 5)))
  (mapc (lambda (obj) (ring-insert fifo obj))
        '(0 one "two"))
  (list (ring-remove fifo) t
        (ring-remove fifo) t
        (ring-remove fifo)))
  ⇒ (0 t one t "two"))
```

7 Records

The purpose of records is to allow programmers to create objects with new types that are not built into Emacs. They are used as the underlying representation of `cl-defstruct` and `defclass` instances.

Internally, a record object is much like a vector; its slots can be accessed using `aref` and it can be copied using `copy-sequence`. However, the first slot is used to hold its type as returned by `type-of`. Also, in the current implementation records can have at most 4096 slots, whereas vectors can be much larger. Like arrays, records use zero-origin indexing: the first slot has index 0.

The type slot should be a symbol or a type descriptor. If it's a type descriptor, the symbol naming its type will be returned; Section 2.4.18 [Type Descriptors], page 25. Any other kind of object is returned as-is.

The printed representation of records is ‘#s’ followed by a list specifying the contents. The first list element must be the record type. The following elements are the record slots.

To avoid conflicts with other type names, Lisp programs that define new types of records should normally use the naming conventions of the package where these record types are introduced for the names of the types. Note that the names of the types which could possibly conflict might not be known at the time the package defining a record type is loaded; they could be loaded at some future point in time.

A record is considered a constant for evaluation: the result of evaluating it is the same record. This does not evaluate or even examine the slots. See Section 10.1.1 [Self-Evaluating Forms], page 146.

7.1 Record Functions

`recordp object`

[Function]

This function returns `t` if `object` is a record.

```
(recordp #s(a))
⇒ t
```

`record type &rest objects`

[Function]

This function creates and returns a record whose type is `type` and remaining slots are the rest of the arguments, `objects`.

```
(record 'foo 23 [bar baz] "rats")
⇒ #s(foo 23 [bar baz] "rats")
```

`make-record type length object`

[Function]

This function returns a new record with type `type` and `length` more slots, each initialized to `object`.

```
(setq sleepy (make-record 'foo 9 'Z))
⇒ #s(foo Z Z Z Z Z Z Z Z Z)
```

7.2 Backward Compatibility

Code compiled with older versions of `cl-defstruct` that doesn't use records may run into problems when used in a new Emacs. To alleviate this, Emacs detects when an old `cl-defstruct` is used, and enables a mode in which `type-of` handles old struct objects as if they were records.

`cl-old-struct-compat-mode arg` [Function]

If `arg` is positive, enable backward compatibility with old-style structs.

8 Hash Tables

A hash table is a very fast kind of lookup table, somewhat like an alist (see Section 5.8 [Association Lists], page 95) in that it maps keys to corresponding values. It differs from an alist in these ways:

- Lookup in a hash table is extremely fast for large tables—in fact, the time required is essentially *independent* of how many elements are stored in the table. For smaller tables (a few tens of elements) alists may still be faster because hash tables have a more-or-less constant overhead.
- The correspondences in a hash table are in no particular order.
- There is no way to share structure between two hash tables, the way two alists can share a common tail.

Emacs Lisp provides a general-purpose hash table data type, along with a series of functions for operating on them. Hash tables have a special printed representation, which consists of ‘#s’ followed by a list specifying the hash table properties and contents. See Section 8.1 [Creating Hash], page 127. (Hash notation, the initial ‘#’ character used in the printed representations of objects with no read representation, has nothing to do with hash tables. See Section 2.1 [Printed Representation], page 8.)

Obarrays are also a kind of hash table, but they are a different type of object and are used only for recording interned symbols (see Section 9.3 [Creating Symbols], page 135).

8.1 Creating Hash Tables

The principal function for creating a hash table is `make-hash-table`.

`make-hash-table` &rest keyword-args [Function]

This function creates a new hash table according to the specified arguments. The arguments should consist of alternating keywords (particular symbols recognized specially) and values corresponding to them.

Several keywords make sense in `make-hash-table`, but the only two that you really need to know about are `:test` and `:weakness`.

`:test test`

This specifies the method of key lookup for this hash table. The default is `eql`; `eq` and `equal` are other alternatives:

`eql` Keys which are numbers are the same if they are `equal`, that is, if they are equal in value and either both are integers or both are floating point; otherwise, two distinct objects are never the same.

`eq` Any two distinct Lisp objects are different as keys.

`equal` Two Lisp objects are the same, as keys, if they are equal according to `equal`.

You can use `define-hash-table-test` (see Section 8.3 [Defining Hash], page 130) to define additional possibilities for `test`.

:weakness weak

The weakness of a hash table specifies whether the presence of a key or value in the hash table preserves it from garbage collection.

The value, `weak`, must be one of `nil`, `key`, `value`, `key-or-value`, `key-and-value`, or `t` which is an alias for `key-and-value`. If `weak` is `key` then the hash table does not prevent its keys from being collected as garbage (if they are not referenced anywhere else); if a particular key does get collected, the corresponding association is removed from the hash table.

If `weak` is `value`, then the hash table does not prevent values from being collected as garbage (if they are not referenced anywhere else); if a particular value does get collected, the corresponding association is removed from the hash table.

If `weak` is `key-and-value` or `t`, both the key and the value must be live in order to preserve the association. Thus, the hash table does not protect either keys or values from garbage collection; if either one is collected as garbage, that removes the association.

If `weak` is `key-or-value`, either the key or the value can preserve the association. Thus, associations are removed from the hash table when both their key and value would be collected as garbage (if not for references from weak hash tables).

The default for `weak` is `nil`, so that all keys and values referenced in the hash table are preserved from garbage collection.

:size size

This specifies a hint for how many associations you plan to store in the hash table. If you know the approximate number, you can make things a little more efficient by specifying it this way. If you specify too small a size, the hash table will grow automatically when necessary, but doing that takes some extra time.

The default size is 65.

:rehash-size rehash-size

When you add an association to a hash table and the table is full, it grows automatically. This value specifies how to make the hash table larger, at that time.

If `rehash-size` is an integer, it should be positive, and the hash table grows by adding approximately that much to the nominal size. If `rehash-size` is floating point, it had better be greater than 1, and the hash table grows by multiplying the old size by approximately that number.

The default value is 1.5.

:rehash-threshold threshold

This specifies the criterion for when the hash table is full (so it should be made larger). The value, `threshold`, should be a positive floating-point number, no greater than 1. The hash table is full whenever the actual

number of entries exceeds the nominal size multiplied by an approximation to this value. The default for *threshold* is 0.8125.

You can also create a hash table using the printed representation for hash tables. The Lisp reader can read this printed representation, provided each element in the specified hash table has a valid read syntax (see Section 2.1 [Printed Representation], page 8). For instance, the following specifies a hash table containing the keys `key1` and `key2` (both symbols) associated with `val1` (a symbol) and 300 (a number) respectively.

```
#s(hash-table size 30 data (key1 val1 key2 300))
```

Note, however, that when using this in Emacs Lisp code, it's undefined whether this creates a new hash table or not. If you want to create a new hash table, you should always use `make-hash-table` (see Section 10.1.1 [Self-Evaluating Forms], page 146).

The printed representation for a hash table consists of ‘#s’ followed by a list beginning with ‘hash-table’. The rest of the list should consist of zero or more property-value pairs specifying the hash table’s properties and initial contents. The properties and values are read literally. Valid property names are `size`, `test`, `weakness`, `rehash-size`, `rehash-threshold`, and `data`. The `data` property should be a list of key-value pairs for the initial contents; the other properties have the same meanings as the matching `make-hash-table` keywords (`:size`, `:test`, etc.), described above.

Note that you cannot specify a hash table whose initial contents include objects that have no read syntax, such as buffers and frames. Such objects may be added to the hash table after it is created.

8.2 Hash Table Access

This section describes the functions for accessing and storing associations in a hash table. In general, any Lisp object can be used as a hash key, unless the comparison method imposes limits. Any Lisp object can also be used as the value.

`gethash key table &optional default`

[Function]

This function looks up `key` in `table`, and returns its associated `value`—or `default`, if `key` has no association in `table`.

`puthash key value table`

[Function]

This function enters an association for `key` in `table`, with value `value`. If `key` already has an association in `table`, `value` replaces the old associated value. This function always returns `value`.

`remhash key table`

[Function]

This function removes the association for `key` from `table`, if there is one. If `key` has no association, `remhash` does nothing.

Common Lisp note: In Common Lisp, `remhash` returns `non-nil` if it actually removed an association and `nil` otherwise. In Emacs Lisp, `remhash` always returns `nil`.

`clrhash table`

[Function]

This function removes all the associations from hash table `table`, so that it becomes empty. This is also called *clearing* the hash table. `clrhash` returns the empty `table`.

maphash *function table*

[Function]

This function calls *function* once for each of the associations in *table*. The function *function* should accept two arguments—a key listed in *table*, and its associated value. **maphash** returns **nil**.

8.3 Defining Hash Comparisons

You can define new methods of key lookup by means of **define-hash-table-test**. In order to use this feature, you need to understand how hash tables work, and what a *hash code* means.

You can think of a hash table conceptually as a large array of many slots, each capable of holding one association. To look up a key, **gethash** first computes an integer, the hash code, from the key. It can reduce this integer modulo the length of the array, to produce an index in the array. Then it looks in that slot, and if necessary in other nearby slots, to see if it has found the key being sought.

Thus, to define a new method of key lookup, you need to specify both a function to compute the hash code from a key, and a function to compare two keys directly. The two functions should be consistent with each other: that is, two keys' hash codes should be the same if the keys compare as equal. Also, since the two functions can be called at any time (such as by the garbage collector), the functions should be free of side effects and should return quickly, and their behavior should depend on only on properties of the keys that do not change.

define-hash-table-test *name test-fn hash-fn*

[Function]

This function defines a new hash table test, named *name*.

After defining *name* in this way, you can use it as the *test* argument in **make-hash-table**. When you do that, the hash table will use *test-fn* to compare key values, and *hash-fn* to compute a hash code from a key value.

The function *test-fn* should accept two arguments, two keys, and return **non-nil** if they are considered the same.

The function *hash-fn* should accept one argument, a key, and return an integer that is the hash code of that key. For good results, the function should use the whole range of fixnums for hash codes, including negative fixnums.

The specified functions are stored in the property list of *name* under the property **hash-table-test**; the property value's form is (*test-fn hash-fn*).

sxhash-equal *obj*

[Function]

This function returns a hash code for Lisp object *obj*. This is an integer that reflects the contents of *obj* and the other Lisp objects it points to.

If two objects *obj1* and *obj2* are **equal**, then (**sxhash-equal obj1**) and (**sxhash-equal obj2**) are the same integer.

If the two objects are not **equal**, the values returned by **sxhash-equal** are usually different, but not always. **sxhash-equal** is designed to be reasonably fast (since it's used for indexing hash tables) so it won't recurse deeply into nested structures. In addition; once in a rare while, by luck, you will encounter two distinct-looking simple

objects that give the same result from `sxhash-equal`. So you can't, in general, use `sxhash-equal` to check whether an object has changed.

Common Lisp note: In Common Lisp a similar function is called `sxhash`. Emacs provides this name as a compatibility alias for `sxhash-equal`.

`sxhash-eq obj` [Function]

This function returns a hash code for Lisp object `obj`. Its result reflects identity of `obj`, but not its contents.

If two objects `obj1` and `obj2` are `eq`, then `(sxhash-eq obj1)` and `(sxhash-eq obj2)` are the same integer.

`sxhash-eql obj` [Function]

This function returns a hash code for Lisp object `obj` suitable for `eql` comparison. I.e. it reflects identity of `obj` except for the case where the object is a bignum or a float number, in which case a hash code is generated for the value.

If two objects `obj1` and `obj2` are `eql`, then `(sxhash-eql obj1)` and `(sxhash-eql obj2)` are the same integer.

This example creates a hash table whose keys are strings that are compared case-insensitively.

```
(defun string-hash-ignore-case (a)
  (sxhash-equal (upcase a)))

(define-hash-table-test 'ignore-case
  'string-equal-ignore-case 'string-hash-ignore-case)

(make-hash-table :test 'ignore-case)
```

Here is how you could define a hash table test equivalent to the predefined test value `equal`. The keys can be any Lisp object, and equal-looking objects are considered the same key.

```
(define-hash-table-test 'contents-hash 'equal 'sxhash-equal)

(make-hash-table :test 'contents-hash)
```

Lisp programs should *not* rely on hash codes being preserved between Emacs sessions, as the implementation of the hash functions uses some details of the object storage that can change between sessions and between different architectures.

8.4 Other Hash Table Functions

Here are some other functions for working with hash tables.

`hash-table-p table` [Function]

This returns `non-nil` if `table` is a hash table object.

`copy-hash-table table` [Function]

This function creates and returns a copy of `table`. Only the table itself is copied—the keys and values are shared.

hash-table-count *table* [Function]

This function returns the actual number of entries in *table*.

hash-table-test *table* [Function]

This returns the *test* value that was given when *table* was created, to specify how to hash and compare keys. See **make-hash-table** (see Section 8.1 [Creating Hash], page 127).

hash-table-weakness *table* [Function]

This function returns the *weak* value that was specified for hash table *table*.

hash-table-rehash-size *table* [Function]

This returns the rehash size of *table*.

hash-table-rehash-threshold *table* [Function]

This returns the rehash threshold of *table*.

hash-table-size *table* [Function]

This returns the current nominal size of *table*.

9 Symbols

A *symbol* is an object with a unique name. This chapter describes symbols, their components, their property lists, and how they are created and interned. Separate chapters describe the use of symbols as variables and as function names; see Chapter 12 [Variables], page 189, and Chapter 13 [Functions], page 230. For the precise read syntax for symbols, see Section 2.4.4 [Symbol Type], page 14.

You can test whether an arbitrary Lisp object is a symbol with `symbolp`:

<code>symbolp object</code>	[Function]
This function returns <code>t</code> if <i>object</i> is a symbol, <code>nil</code> otherwise.	

9.1 Symbol Components

Each symbol has four components (or “cells”), each of which references another object:

Print name

The symbol’s name.

Value The symbol’s current value as a variable.

Function The symbol’s function definition. It can also hold a symbol, a keymap, or a keyboard macro.

Property list

The symbol’s property list.

The print name cell always holds a string, and cannot be changed. Each of the other three cells can be set to any Lisp object.

The print name cell holds the string that is the name of a symbol. Since symbols are represented textually by their names, it is important not to have two symbols with the same name. The Lisp reader ensures this: every time it reads a symbol, it looks for an existing symbol with the specified name before it creates a new one. To get a symbol’s name, use the function `symbol-name` (see Section 9.3 [Creating Symbols], page 135). However, although each symbol has only one unique *print name*, it is nevertheless possible to refer to that same symbol via different alias names called “shorthands” (see Section 9.5 [Shorthands], page 142).

The value cell holds a symbol’s value as a variable, which is what you get if the symbol itself is evaluated as a Lisp expression. See Chapter 12 [Variables], page 189, for details about how values are set and retrieved, including complications such as *local bindings* and *scoping rules*. Most symbols can have any Lisp object as a value, but certain special symbols have values that cannot be changed; these include `nil` and `t`, and any symbol whose name starts with ‘`:`’ (those are called *keywords*). See Section 12.2 [Constant Variables], page 189.

The function cell holds a symbol’s function definition. Often, we refer to “the function `foo`” when we really mean the function stored in the function cell of `foo`; we make the distinction explicit only when necessary. Typically, the function cell is used to hold a function (see Chapter 13 [Functions], page 230) or a macro (see Chapter 14 [Macros], page 268). However, it can also be used to hold a symbol (see Section 10.1.4 [Function Indirection], page 147), keyboard macro (see Section 22.16 [Keyboard Macros], page 478), keymap (see

Chapter 23 [Keymaps], page 480), or autoload object (see Section 10.1.8 [Autoloading], page 150). To get the contents of a symbol’s function cell, use the function `symbol-function` (see Section 13.9 [Function Cells], page 248).

The property list cell normally should hold a correctly formatted property list. To get a symbol’s property list, use the function `symbol-plist`. See Section 9.4 [Symbol Properties], page 138.

The function cell or the value cell may be `void`, which means that the cell does not reference any object. (This is not the same thing as holding the symbol `void`, nor the same as holding the symbol `nil`.) Examining a function or value cell that is `void` results in an error, such as ‘Symbol’s value as variable is `void`’.

Because each symbol has separate value and function cells, variables names and function names do not conflict. For example, the symbol `buffer-file-name` has a value (the name of the file being visited in the current buffer) as well as a function definition (a primitive function that returns the name of the file):

```
buffer-file-name
  ⇒ "/gnu/elisp/symbols.texi"
(symbol-function 'buffer-file-name)
  ⇒ #<subr buffer-file-name>
```

9.2 Defining Symbols

A *definition* is a special kind of Lisp expression that announces your intention to use a symbol in a particular way. It typically specifies a value or meaning for the symbol for one kind of use, plus documentation for its meaning when used in this way. Thus, when you define a symbol as a variable, you can supply an initial value for the variable, plus documentation for the variable.

`defvar` and `defconst` are special forms that define a symbol as a *global variable*—a variable that can be accessed at any point in a Lisp program. See Chapter 12 [Variables], page 189, for details about variables. To define a customizable variable, use the `defcustom` macro, which also calls `defvar` as a subroutine (see Chapter 15 [Customization], page 277).

In principle, you can assign a variable value to any symbol with `setq`, whether or not it has first been defined as a variable. However, you ought to write a variable definition for each global variable that you want to use; otherwise, your Lisp program may not act correctly if it is evaluated with lexical scoping enabled (see Section 12.10 [Variable Scoping], page 201).

`defun` defines a symbol as a function, creating a lambda expression and storing it in the function cell of the symbol. This lambda expression thus becomes the function definition of the symbol. (The term “function definition”, meaning the contents of the function cell, is derived from the idea that `defun` gives the symbol its definition as a function.) `defsubst` and `defalias` are two other ways of defining a function. See Chapter 13 [Functions], page 230.

`defmacro` defines a symbol as a macro. It creates a macro object and stores it in the function cell of the symbol. Note that a given symbol can be a macro or a function, but not both at once, because both macro and function definitions are kept in the function cell, and that cell can hold only one Lisp object at any given time. See Chapter 14 [Macros], page 268.

As previously noted, Emacs Lisp allows the same symbol to be defined both as a variable (e.g., with `defvar`) and as a function or macro (e.g., with `defun`). Such definitions do not conflict.

These definitions also act as guides for programming tools. For example, the `C-h f` and `C-h v` commands create help buffers containing links to the relevant variable, function, or macro definitions. See Section “Name Help” in *The GNU Emacs Manual*.

9.3 Creating and Interning Symbols

To understand how symbols are created in GNU Emacs Lisp, you must know how Lisp reads them. Lisp must ensure that it finds the same symbol every time it reads the same sequence of characters in the same context. Failure to do so would cause complete confusion.

When the Lisp reader encounters a name that references a symbol in the source code, it reads all the characters of that name. Then it looks up that name in a table called an obarray to find the symbol that the programmer meant. The technique used in this lookup is called “hashing”, an efficient method of looking something up by converting a sequence of characters to a number, known as a “hash code”. For example, instead of searching a telephone book cover to cover when looking up Jan Jones, you start with the J’s and go from there. That is a simple version of hashing. Each element of the obarray is a *bucket* which holds all the symbols with a given hash code; to look for a given name, it is sufficient to look through all the symbols in the bucket for that name’s hash code. (The same idea is used for general Emacs hash tables, but they are a different data type; see Chapter 8 [Hash Tables], page 127.)

When looking up names, the Lisp reader also considers “shorthands”. If the programmer supplied them, this allows the reader to find a symbol even if its name isn’t present in its full form in the source code. Of course, the reader needs to be aware of some pre-established context about such shorthands, much as one needs context to be able to refer uniquely to Jan Jones by just the name “Jan”: it’s probably fine when amongst the Joneses, or when Jan has been mentioned recently, but very ambiguous in any other situation. See Section 9.5 [Shorthands], page 142.

If a symbol with the desired name is found, the reader uses that symbol. If the obarray does not contain a symbol with that name, the reader makes a new symbol and adds it to the obarray. Finding or adding a symbol with a certain name is called *interning* it, and the symbol is then called an *interned symbol*.

Interning ensures that each obarray has just one symbol with any particular name. Other like-named symbols may exist, but not in the same obarray. Thus, the reader gets the same symbols for the same names, as long as you keep reading with the same obarray.

Interning usually happens automatically in the reader, but sometimes other programs may want to do it. For example, after the `M-x` command obtains the command name as a string using the minibuffer, it then interns the string, to get the interned symbol with that name. As another example, a hypothetical telephone book program could intern the name of each looked up person’s name as a symbol, even if the obarray did not contain it, so that it could attach information to that new symbol, such as the last time someone looked it up.

No obarray contains all symbols; in fact, some symbols are not in any obarray. They are called *uninterned symbols*. An uninterned symbol has the same four cells as other symbols; however, the only way to gain access to it is by finding it in some other object or as the

value of a variable. Uninterned symbols are sometimes useful in generating Lisp code, see below.

In Emacs Lisp, an obarray is actually a vector. Each element of the vector is a bucket; its value is either an interned symbol whose name hashes to that bucket, or 0 if the bucket is empty. Each interned symbol has an internal link (invisible to the user) to the next symbol in the bucket. Because these links are invisible, there is no way to find all the symbols in an obarray except using `mapatoms` (below). The order of symbols in a bucket is not significant.

In an empty obarray, every element is 0, so you can create an obarray with `(make-vector length 0)`. **This is the only valid way to create an obarray.** Prime numbers as lengths tend to result in good hashing; lengths one less than a power of two are also good.

Do not try to put symbols in an obarray yourself. This does not work—only `intern` can enter a symbol in an obarray properly.

Common Lisp note: Unlike Common Lisp, Emacs Lisp does not provide for interning the same name in several different “packages”, thus creating multiple symbols with the same name but different packages. Emacs Lisp provides a different namespacing system called “shorthands” (see Section 9.5 [Shorthands], page 142).

Most of the functions below take a name and sometimes an obarray as arguments. A `wrong-type-argument` error is signaled if the name is not a string, or if the obarray is not a vector.

symbol-name *symbol* [Function]

This function returns the string that is *symbol*’s name. For example:

```
(symbol-name 'foo)
⇒ "foo"
```

Warning: Never alter the string returned by that function. Doing that might make Emacs dysfunctional, and might even crash Emacs.

Creating an uninterned symbol is useful in generating Lisp code, because an uninterned symbol used as a variable in the code you generate cannot clash with any variables used in other Lisp programs.

make-symbol *name* [Function]

This function returns a newly-allocated, uninterned symbol whose name is *name* (which must be a string). Its value and function definition are void, and its property list is `nil`. In the example below, the value of *sym* is not `eq` to *foo* because it is a distinct uninterned symbol whose name is also ‘*foo*’.

```
(setq sym (make-symbol "foo"))
⇒ foo
(eq sym 'foo)
⇒ nil
```

gensym &*optional prefix* [Function]

This function returns a symbol using `make-symbol`, whose name is made by appending `gensym-counter` to *prefix* and incrementing that counter, guaranteeing that no two calls to this function will generate a symbol with the same name. The prefix defaults to “*g*”.

To avoid problems when accidentally interning printed representation of generated code (see Section 2.1 [Printed Representation], page 8), it is recommended to use `gensym` instead of `make-symbol`.

intern name &optional obarray [Function]

This function returns the interned symbol whose name is `name`. If there is no such symbol in the obarray `obarray`, `intern` creates a new one, adds it to the obarray, and returns it. If `obarray` is omitted, the value of the global variable `obarray` is used.

```
(setq sym (intern "foo"))
      ⇒ foo
(eq sym 'foo)
      ⇒ t

(setq sym1 (intern "foo" other-obarray))
      ⇒ foo
(eq sym1 'foo)
      ⇒ nil
```

Common Lisp note: In Common Lisp, you can intern an existing symbol in an obarray. In Emacs Lisp, you cannot do this, because the argument to `intern` must be a string, not a symbol.

intern-soft name &optional obarray [Function]

This function returns the symbol in `obarray` whose name is `name`, or `nil` if `obarray` has no symbol with that name. Therefore, you can use `intern-soft` to test whether a symbol with a given name is already interned. If `obarray` is omitted, the value of the global variable `obarray` is used.

The argument `name` may also be a symbol; in that case, the function returns `name` if `name` is interned in the specified obarray, and otherwise `nil`.

```
(intern-soft "frazzle")           ; No such symbol exists.
      ⇒ nil
(make-symbol "frazzle")          ; Create an uninterned one.
      ⇒ frazzle
(intern-soft "frazzle")          ; That one cannot be found.
      ⇒ nil
(setq sym (intern "frazzle"))    ; Create an interned one.
      ⇒ frazzle
(intern-soft "frazzle")          ; That one can be found!
      ⇒ frazzle
(eq sym 'frazzle)               ; And it is the same one.
      ⇒ t
```

obarray [Variable]

This variable is the standard obarray for use by `intern` and `read`.

mapatoms function &optional obarray [Function]

This function calls `function` once with each symbol in the obarray `obarray`. Then it returns `nil`. If `obarray` is omitted, it defaults to the value of `obarray`, the standard obarray for ordinary symbols.

```
(setq count 0)
⇒ 0
(defun count-syms (s)
  (setq count (1+ count)))
⇒ count-syms
(mapatoms 'count-syms)
⇒ nil
count
⇒ 1871
```

See `documentation` in Section 25.2 [Accessing Documentation], page 596, for another example using `mapatoms`.

unintern symbol obarray [Function]

This function deletes *symbol* from the obarray *obarray*. If *symbol* is not actually in the obarray, `unintern` does nothing. If *obarray* is `nil`, the current obarray is used.

If you provide a string instead of a symbol as *symbol*, it stands for a symbol name. Then `unintern` deletes the symbol (if any) in the obarray which has that name. If there is no such symbol, `unintern` does nothing.

If `unintern` does delete a symbol, it returns `t`. Otherwise it returns `nil`.

9.4 Symbol Properties

A symbol may possess any number of *symbol properties*, which can be used to record miscellaneous information about the symbol. For example, when a symbol has a `risky-local-variable` property with a non-`nil` value, that means the variable which the symbol names is a risky file-local variable (see Section 12.12 [File Local Variables], page 213).

Each symbol's properties and property values are stored in the symbol's property list cell (see Section 9.1 [Symbol Components], page 133), in the form of a property list (see Section 5.9 [Property Lists], page 99).

9.4.1 Accessing Symbol Properties

The following functions can be used to access symbol properties.

get symbol property [Function]

This function returns the value of the property named *property* in *symbol*'s property list. If there is no such property, it returns `nil`. Thus, there is no distinction between a value of `nil` and the absence of the property.

The name *property* is compared with the existing property names using `eq`, so any object is a legitimate property.

See `put` for an example.

put symbol property value [Function]

This function puts *value* onto *symbol*'s property list under the property name *property*, replacing any previous property value. The `put` function returns *value*.

```
(put 'fly 'verb 'transitive)
⇒ 'transitive
```

```
(put 'fly 'noun '(a buzzing little bug))
      ⇒ (a buzzing little bug)
(get 'fly 'verb)
      ⇒ transitive
(symbol-plist 'fly)
      ⇒ (verb transitive noun (a buzzing little bug))
```

symbol-plist symbol

[Function]

This function returns the property list of *symbol*.

setplist symbol plist

[Function]

This function sets *symbol*'s property list to *plist*. Normally, *plist* should be a well-formed property list, but this is not enforced. The return value is *plist*.

```
(setplist 'foo '(a 1 b (2 3) c nil))
      ⇒ (a 1 b (2 3) c nil)
(symbol-plist 'foo)
      ⇒ (a 1 b (2 3) c nil)
```

For symbols in special obarrays, which are not used for ordinary purposes, it may make sense to use the property list cell in a nonstandard fashion; in fact, the abbrev mechanism does so (see Chapter 38 [Abbrevs], page 1066).

You could define *put* in terms of *setplist* and *plist-put*, as follows:

```
(defun put (symbol prop value)
  (setplist symbol
    (plist-put (symbol-plist symbol) prop value)))
```

function-get symbol property &optional autoload

[Function]

This function is identical to *get*, except that if *symbol* is the name of a function alias, it looks in the property list of the symbol naming the actual function. See Section 13.4 [Defining Functions], page 237. If the optional argument *autoload* is non-*nil*, and *symbol* is auto-loaded, this function will try to autoload it, since autoloading might set *property* of *symbol*. If *autoload* is the symbol *macro*, only try autoloading if *symbol* is an auto-loaded macro.

function-put function property value

[Function]

This function sets *property* of *function* to *value*. *function* should be a symbol. This function is preferred to calling *put* for setting properties of a function, because it will allow us some day to implement remapping of old properties to new ones.

9.4.2 Standard Symbol Properties

Here, we list the symbol properties which are used for special purposes in Emacs. In the following table, whenever we say “the named function”, that means the function whose name is the relevant symbol; similarly for “the named variable” etc.

:advertised-binding

This property value specifies the preferred key binding, when showing documentation, for the named function. See Section 25.3 [Keys in Documentation], page 598.

char-table-extra-slots

The value, if non-`nil`, specifies the number of extra slots in the named char-table type. See Section 6.6 [Char-Tables], page 119.

customized-face**face-defface-spec****saved-face****theme-face**

These properties are used to record a face’s standard, saved, customized, and themed face specs. Do not set them directly; they are managed by `defface` and related functions. See Section 41.12.2 [Defining Faces], page 1168.

customized-value**saved-value****standard-value****theme-value**

These properties are used to record a customizable variable’s standard value, saved value, customized-but-unsaved value, and themed values. Do not set them directly; they are managed by `defcustom` and related functions. See Section 15.3 [Variable Definitions], page 280.

definition-name

This property is used to find the definition of a symbol in the source code, when it might be hard to find the definition by textual search of the source file. For example, a `define-derived-mode` (see Section 24.2.4 [Derived Modes], page 534) might define a mode-specific function or a variable implicitly; or your Lisp program might generate a run-time call to `defun` to define a function (see Section 13.4 [Defining Functions], page 237). In these and similar cases, the `definition-name` property of the symbol should be another symbol whose definition can be found by textual search and whose code defines the original symbol. In the example with `define-derived-mode`, the value of this property of the functions and variables it defines should be the mode symbol. The Emacs Help commands such as `C-h f` (see Section “Help” in *The GNU Emacs Manual*) use this property to show the definition of a symbol via a button in the `*Help*` buffer where the symbol’s documentation is shown.

disabled If the value is non-`nil`, the named function is disabled as a command. See Section 22.14 [Disabling Commands], page 476.

face-documentation

The value stores the documentation string of the named face. This is set automatically by `defface`. See Section 41.12.2 [Defining Faces], page 1168.

history-length

The value, if non-`nil`, specifies the maximum minibuffer history length for the named history list variable. See Section 21.4 [Minibuffer History], page 392.

interactive-form

The value is an interactive form for the named function. Normally, you should not set this directly; use the `interactive` special form instead. See Section 22.3 [Interactive Call], page 432.

menu-enable

The value is an expression for determining whether the named menu item should be enabled in menus. See Section 23.18.1.1 [Simple Menu Items], page 510.

mode-class

If the value is **special**, the named major mode is special. See Section 24.2.1 [Major Mode Conventions], page 528.

permanent-local

If the value is **non-nil**, the named variable is a buffer-local variable whose value should not be reset when changing major modes. See Section 12.11.2 [Creating Buffer-Local], page 208.

permanent-local-hook

If the value is **non-nil**, the named function should not be deleted from the local value of a hook variable when changing major modes. See Section 24.1.2 [Setting Hooks], page 525.

pure

If the value is **non-nil**, the named function is considered to be pure (see Section 13.1 [What Is a Function], page 230). Calls with constant arguments can be evaluated at compile time. This may shift run time errors to compile time. Not to be confused with pure storage (see Section E.2 [Pure Storage], page 1349).

risky-local-variable

If the value is **non-nil**, the named variable is considered risky as a file-local variable. See Section 12.12 [File Local Variables], page 213.

safe-function

If the value is **non-nil**, the named function is considered generally safe for evaluation. See Section 13.17 [Function Safety], page 266.

safe-local-eval-function

If the value is **non-nil**, the named function is safe to call in file-local evaluation forms. See Section 12.12 [File Local Variables], page 213.

safe-local-variable

The value specifies a function for determining safe file-local values for the named variable. See Section 12.12 [File Local Variables], page 213. Since this value is consulted when loading files, the function should be efficient and should ideally not lead to loading any libraries to determine the safeness (e.g., it should not be an autoloaded function).

side-effect-free

A **non-nil** value indicates that the named function is free of side effects (see Section 13.1 [What Is a Function], page 230), so the byte compiler may ignore a call whose value is unused. If the property's value is **error-free**, the byte compiler may even delete such unused calls. In addition to byte compiler optimizations, this property is also used for determining function safety (see Section 13.17 [Function Safety], page 266).

undo-inhibit-region

If non-`nil`, the named function prevents the `undo` operation from being restricted to the active region, if `undo` is invoked immediately after the function. See Section 33.9 [Undo], page 895.

variable-documentation

If non-`nil`, this specifies the named variable's documentation string. This is set automatically by `defvar` and related functions. See Section 41.12.2 [Defining Faces], page 1168.

9.5 Shorthands

The symbol *shorthands*, sometimes known as “renamed symbols”, are symbolic forms found in Lisp source. They're just like regular symbolic forms, except that when the Lisp reader encounters them, it produces symbols which have a different and usually longer *print name* (see Section 9.1 [Symbol Components], page 133).

It is useful to think of shorthands as *abbreviating* the full names of intended symbols. Despite this, do not confuse shorthands with the Abbrev system (see Chapter 38 [Abbrevs], page 1066).

Shorthands make Emacs Lisp's *namespacing etiquette* easier to work with. Since all symbols are stored in a single obarray (see Section 9.3 [Creating Symbols], page 135), programmers commonly prefix each symbol name with the name of the library where it originates. For example, the functions `text-property-search-forward` and `text-property-search-backward` both belong to the `text-property-search.el` library (see Chapter 16 [Loading], page 298). By properly prefixing symbol names, one effectively prevents clashes between similarly named symbols which belong to different libraries and thus do different things. However, this practice commonly originates very long symbols names, which are inconvenient to type and read after a while. Shorthands solve these issues in a clean way.

read-symbol-shorthands

[Variable]

This variable's value is an alist whose elements have the form (*shorthand-prefix* . *longhand-prefix*). Each element instructs the Lisp reader to read every symbol form which starts with *shorthand-prefix* as if it started with *longhand-prefix* instead.

This variable may only be set in file-local variables (see Section “Local Variables in Files” in *The GNU Emacs Manual*).

Here's an example of shorthands usage in a hypothetical string manipulating library `some-nice-string-utils.el`.

```
(defun some-nice-string-utils-split (separator s &optional omit-nulls)
  "A match-data saving variant of `split-string'."
  (save-match-data (split-string s separator omit-nulls)))

(defun some-nice-string-utils-lines (s)
  "Split string S at newline characters into a list of strings."
  (some-nice-string-utils-split "\\\(\r\n\\\|[\n\r]\\\)" s))
```

As can be seen, it's quite tedious to read or develop this code since the symbol names to type are so long. We can use shorthands to alleviate that.

```
(defun snu-split (separator s &optional omit-nulls)
```

```

"A match-data saving variation on `split-string'."  

(save-match-data (split-string s separator omit-nulls)))  
  

(defun snu-lines (s)  

  "Split string S into a list of strings on newline characters."  

  (snu-split "\\\(\r\n\\\|[\n\r]\\\\)" s))  
  

;; Local Variables:  

;; read-symbol-shorthands: ((\"snu-\" . \"some-nice-string-utils-\"))  

;; End:  

```

Even though the two excerpts look different, they are quite identical after the Lisp reader processes them. Both will lead to the very same symbols being interned (see Section 9.3 [Creating Symbols], page 135). Thus loading or byte-compiling any of the two files has equivalent results. The shorthands `snu-split` and `snu-lines` used in the second version are *not* interned in the obarray. This is easily seen by moving point to the location where the shorthands are used and waiting for ElDoc (see Section “Local Variables in Files” in *The GNU Emacs Manual*) to hint at the true full name of the symbol under point in the echo area.

Since `read-symbol-shorthands` is a file-local variable, it is possible that multiple libraries depending on `some-nice-string-utils-lines.el` refer to the same symbols under *different* shorthands, or not using shorthands at all. In the next example, the `my-tricks.el` library refers to the symbol `some-nice-string-utils-lines` using the `sns-` prefix instead of `snu-`.

```

(defun t-reverse-lines (s) (string-join (reverse (sns-lines s)) "\n")  
  

;; Local Variables:  

;; read-symbol-shorthands: ((\"t-\" . \"my-tricks-\")  

;;                           (\"sns-\" . \"some-nice-string-utils-\"))  

;; End:  

```

9.5.1 Exceptions

There are two exceptions to rules governing Shorthand transformations:

- Symbol forms comprised entirely of characters in the Emacs Lisp symbol constituent class (see Section 36.2.1 [Syntax Class Table], page 1023) are not transformed. For example, it’s possible to use `-` or `/=` as shorthand prefixes, but that won’t shadow the arithmetic *functions* of those names.
- Symbol forms whose names start with ‘`#_`’ are not transformed.

9.6 Symbols with Position

A *symbol with position* is a symbol, the *bare symbol*, together with an unsigned integer called the *position*. These objects are intended for use by the byte compiler, which records in them the position of each symbol occurrence and uses those positions in warning and error messages.

The printed representation of a symbol with position uses the hash notation outlined in Section 2.1 [Printed Representation], page 8. It looks like ‘`#<symbol foo at 12345>`’. It has no read syntax. You can cause just the bare symbol to be printed by binding the variable

print-symbols-bare to non-**nil** around the print operation. The byte compiler does this before writing its output to the compiled Lisp file.

For most purposes, when the flag variable **symbols-with-pos-enabled** is non-**nil**, symbols with positions behave just as bare symbols do. For example, ‘(eq #<symbol foo at 12345> foo)’ has a value **t** when that variable is set (but **nil** when it isn’t set). Most of the time in Emacs this variable is **nil**, but the byte compiler binds it to **t** when it runs.

Typically, symbols with position are created by the byte compiler calling the reader function **read-positioning-symbols** (see Section 20.3 [Input Functions], page 374). One can also be created with the function **position-symbol**.

symbols-with-pos-enabled

[Variable]

When this variable is non-**nil**, symbols with position behave like the contained bare symbol. Emacs runs a little more slowly in this case.

print-symbols-bare

[Variable]

When bound to non-**nil**, the Lisp printer prints only the bare symbol of a symbol with position, ignoring the position.

symbol-with-pos-p symbol

[Function]

This function returns **t** if *symbol* is a symbol with position, **nil** otherwise.

bare-symbol symbol

[Function]

This function returns the bare symbol contained in *symbol*, or *symbol* itself if it is already a bare symbol. For any other type of object, it signals an error.

symbol-with-pos-pos symbol

[Function]

This function returns the position, a number, from a symbol with position. For any other type of object, it signals an error.

position-symbol sym pos

[Function]

Make a new symbol with position. *sym* is either a bare symbol or a symbol with position, and supplies the symbol part of the new object. *pos* is either an integer which becomes the number part of the new object, or a symbol with position whose position is used. Emacs signals an error if either argument is invalid.

10 Evaluation

The *evaluation* of expressions in Emacs Lisp is performed by the *Lisp interpreter*—a program that receives a Lisp object as input and computes its *value as an expression*. How it does this depends on the data type of the object, according to rules described in this chapter. The interpreter runs automatically to evaluate portions of your program, but can also be called explicitly via the Lisp primitive function `eval`.

A Lisp object that is intended for evaluation is called a *form* or *expression*¹. The fact that forms are data objects and not merely text is one of the fundamental differences between Lisp-like languages and typical programming languages. Any object can be evaluated, but in practice only numbers, symbols, lists and strings are evaluated very often.

In subsequent sections, we will describe the details of what evaluation means for each kind of form.

It is very common to read a Lisp form and then evaluate the form, but reading and evaluation are separate activities, and either can be performed alone. Reading per se does not evaluate anything; it converts the printed representation of a Lisp object to the object itself. It is up to the caller of `read` to specify whether this object is a form to be evaluated, or serves some entirely different purpose. See Section 20.3 [Input Functions], page 374.

Evaluation is a recursive process, and evaluating a form often involves evaluating parts within that form. For instance, when you evaluate a *function call* form such as `(car x)`, Emacs first evaluates the argument (the subform `x`). After evaluating the argument, Emacs executes the function `(car)`, and if the function is written in Lisp, execution works by evaluating the *body* of the function (in this example, however, `car` is not a Lisp function; it is a primitive function implemented in C). See Chapter 13 [Functions], page 230, for more information about functions and function calls.

Evaluation takes place in a context called the *environment*, which consists of the current values and bindings of all Lisp variables (see Chapter 12 [Variables], page 189).² Whenever a form refers to a variable without creating a new binding for it, the variable evaluates to the value given by the current environment. Evaluating a form may also temporarily alter the environment by binding variables (see Section 12.3 [Local Variables], page 190).

Evaluating a form may also make changes that persist; these changes are called *side effects*. An example of a form that produces a side effect is `(setq foo 1)`.

Do not confuse evaluation with command key interpretation. The editor command loop translates keyboard input into a command (an interactively callable function) using the active keymaps, and then uses `call-interactively` to execute that command. Executing the command usually involves evaluation, if the command is written in Lisp; however, this step is not considered a part of command key interpretation. See Chapter 22 [Command Loop], page 423.

¹ It is sometimes also referred to as an *S-expression* or *sexp*, but we generally do not use this terminology in this manual.

² This definition of “environment” is specifically not intended to include all the data that can affect the result of a program.

10.1 Kinds of Forms

A Lisp object that is intended to be evaluated is called a *form* (or an *expression*). How Emacs evaluates a form depends on its data type. Emacs has three different kinds of form that are evaluated differently: symbols, lists, and all other types. This section describes all three kinds, one by one, starting with the other types, which are self-evaluating forms.

10.1.1 Self-Evaluating Forms

A *self-evaluating form* is any form that is not a list or symbol. Self-evaluating forms evaluate to themselves: the result of evaluation is the same object that was evaluated. Thus, the number 25 evaluates to 25, and the string "foo" evaluates to the string "foo". Likewise, evaluating a vector does not cause evaluation of the elements of the vector—it returns the same vector with its contents unchanged.

```
'123           ; A number, shown without evaluation.
⇒ 123

123           ; Evaluated as usual—result is the same.
⇒ 123

(eval '123)    ; Evaluated "by hand"—result is the same.
⇒ 123

(eval (eval '123)) ; Evaluating twice changes nothing.
⇒ 123
```

A self-evaluating form yields a value that becomes part of the program, and you should not try to modify it via `setcar`, `aset` or similar operations. The Lisp interpreter might unify the constants yielded by your program's self-evaluating forms, so that these constants might share structure. See Section 2.9 [Mutability], page 36.

It is common to write numbers, characters, strings, and even vectors in Lisp code, taking advantage of the fact that they self-evaluate. However, it is quite unusual to do this for types that lack a read syntax, because there's no way to write them textually. It is possible to construct Lisp expressions containing these types by means of a Lisp program. Here is an example:

```
; ; Build an expression containing a buffer object.
(setq print-exp (list 'print (current-buffer)))
⇒ (print #<buffer eval.texi>)
; ; Evaluate it.
(eval print-exp)
⇒ #<buffer eval.texi>
⇒ #<buffer eval.texi>
```

10.1.2 Symbol Forms

When a symbol is evaluated, it is treated as a variable. The result is the variable's value, if it has one. If the symbol has no value as a variable, the Lisp interpreter signals an error. For more information on the use of variables, see Chapter 12 [Variables], page 189.

In the following example, we set the value of a symbol with `setq`. Then we evaluate the symbol, and get back the value that `setq` stored.

```
(setq a 123)
⇒ 123
```

```
(eval 'a)
⇒ 123
a
⇒ 123
```

The symbols `nil` and `t` are treated specially, so that the value of `nil` is always `nil`, and the value of `t` is always `t`; you cannot set or bind them to any other values. Thus, these two symbols act like self-evaluating forms, even though `eval` treats them like any other symbol. A symbol whose name starts with ‘`:`’ also self-evaluates in the same way; likewise, its value ordinarily cannot be changed. See Section 12.2 [Constant Variables], page 189.

10.1.3 Classification of List Forms

A form that is a nonempty list is either a function call, a macro call, or a special form, according to its first element. These three kinds of forms are evaluated in different ways, described below. The remaining list elements constitute the *arguments* for the function, macro, or special form.

The first step in evaluating a nonempty list is to examine its first element. This element alone determines what kind of form the list is and how the rest of the list is to be processed. The first element is *not* evaluated, as it would be in some Lisp dialects such as Scheme.

10.1.4 Symbol Function Indirection

If the first element of the list is a symbol then evaluation examines the symbol’s function cell, and uses its contents instead of the original symbol. If the contents are another symbol, this process, called *symbol function indirection*, is repeated until it obtains a non-symbol. See Section 13.3 [Function Names], page 236, for more information about symbol function indirection.

One possible consequence of this process is an infinite loop, in the event that a symbol’s function cell refers to the same symbol. Otherwise, we eventually obtain a non-symbol, which ought to be a function or other suitable object.

More precisely, we should now have a Lisp function (a lambda expression), a byte-code function, a primitive function, a Lisp macro, a special form, or an autoload object. Each of these types is a case described in one of the following sections. If the object is not one of these types, Emacs signals an `invalid-function` error.

The following example illustrates the symbol indirection process. We use `fset` to set the function cell of a symbol and `symbol-function` to get the function cell contents (see Section 13.9 [Function Cells], page 248). Specifically, we store the symbol `car` into the function cell of `first`, and the symbol `first` into the function cell of `erste`.

```
;; Build this function cell linkage:
;; -----
;; | #<subr car> | <-- | car | <-- | first | <-- | erste |
;; -----
(symbol-function 'car)
⇒ #<subr car>
(fset 'first 'car)
⇒ car
(fset 'erste 'first)
⇒ first
```

```
(erste '(1 2 3)) ; Call the function referenced by erste.
⇒ 1
```

By contrast, the following example calls a function without any symbol function indirection, because the first element is an anonymous Lisp function, not a symbol.

```
((lambda (arg) (erste arg))
 '(1 2 3))
⇒ 1
```

Executing the function itself evaluates its body; this does involve symbol function indirection when calling `erste`.

This form is rarely used and is now deprecated. Instead, you should write it as:

```
(funcall (lambda (arg) (erste arg))
 '(1 2 3))
```

or just

```
(let ((arg '(1 2 3))) (erste arg))
```

The built-in function `indirect-function` provides an easy way to perform symbol function indirection explicitly.

`indirect-function` *function* &`optional` *noerror*

[Function]

This function returns the meaning of *function* as a function. If *function* is a symbol, then it finds *function*'s function definition and starts over with that value. If *function* is not a symbol, then it returns *function* itself.

This function returns `nil` if the final symbol is unbound. It signals a `cyclic-function-indirection` error if there is a loop in the chain of symbols.

The optional argument *noerror* is obsolete, kept for backward compatibility, and has no effect.

Here is how you could define `indirect-function` in Lisp:

```
(defun indirect-function (function)
  (if (and function
            (symbolp function))
      (indirect-function (symbol-function function))
      function))
```

10.1.5 Evaluation of Function Forms

If the first element of a list being evaluated is a Lisp function object, byte-code object or primitive function object, then that list is a *function call*. For example, here is a call to the function `+`:

```
(+ 1 x)
```

The first step in evaluating a function call is to evaluate the remaining elements of the list from left to right. The results are the actual argument values, one value for each list element. The next step is to call the function with this list of arguments, effectively using the function `apply` (see Section 13.5 [Calling Functions], page 239). If the function is written in Lisp, the arguments are used to bind the argument variables of the function (see Section 13.2 [Lambda Expressions], page 232); then the forms in the function body are evaluated in order, and the value of the last body form becomes the value of the function call.

10.1.6 Lisp Macro Evaluation

If the first element of a list being evaluated is a macro object, then the list is a *macro call*. When a macro call is evaluated, the elements of the rest of the list are *not* initially evaluated. Instead, these elements themselves are used as the arguments of the macro. The macro definition computes a replacement form, called the *expansion* of the macro, to be evaluated in place of the original form. The expansion may be any sort of form: a self-evaluating constant, a symbol, or a list. If the expansion is itself a macro call, this process of expansion repeats until some other sort of form results.

Ordinary evaluation of a macro call finishes by evaluating the expansion. However, the macro expansion is not necessarily evaluated right away, or at all, because other programs also expand macro calls, and they may or may not evaluate the expansions.

Normally, the argument expressions are not evaluated as part of computing the macro expansion, but instead appear as part of the expansion, so they are computed when the expansion is evaluated.

For example, given a macro defined as follows:

```
(defmacro cadr (x)
  (list 'car (list 'cdr x)))
```

an expression such as (cadr (assq 'handler list)) is a macro call, and its expansion is:

```
(car (cdr (assq 'handler list)))
```

Note that the argument (assq 'handler list) appears in the expansion.

See Chapter 14 [Macros], page 268, for a complete description of Emacs Lisp macros.

10.1.7 Special Forms

A *special form* is a primitive specially marked so that its arguments are not all evaluated. Most special forms define control structures or perform variable bindings—things which functions cannot do.

Each special form has its own rules for which arguments are evaluated and which are used without evaluation. Whether a particular argument is evaluated may depend on the results of evaluating other arguments.

If an expression’s first symbol is that of a special form, the expression should follow the rules of that special form; otherwise, Emacs’s behavior is not well-defined (though it will not crash). For example, ((lambda (x) x . 3) 4) contains a subexpression that begins with `lambda` but is not a well-formed `lambda` expression, so Emacs may signal an error, or may return 3 or 4 or `nil`, or may behave in other ways.

special-form-p *object* [Function]

This predicate tests whether its argument is a special form, and returns `t` if so, `nil` otherwise.

Here is a list, in alphabetical order, of all of the special forms in Emacs Lisp with a reference to where each is described.

`and` see Section 11.3 [Combining Conditions], page 162,

`catch` see Section 11.7.1 [Catch and Throw], page 177,

`cond` see Section 11.2 [Conditionals], page 159,

condition-case
 see Section 11.7.3.3 [Handling Errors], page 182,

defconst see Section 12.5 [Defining Variables], page 194,

defvar see Section 12.5 [Defining Variables], page 194,

function see Section 13.7 [Anonymous Functions], page 243,

if see Section 11.2 [Conditionals], page 159,

interactive
 see Section 22.3 [Interactive Call], page 432,

lambda see Section 13.2 [Lambda Expressions], page 232,

let

let* see Section 12.3 [Local Variables], page 190,

or see Section 11.3 [Combining Conditions], page 162,

prog1

prog2

progn see Section 11.1 [Sequencing], page 158,

quote see Section 10.2 [Quoting], page 151,

save-current-buffer
 see Section 28.2 [Current Buffer], page 671,

save-excursion
 see Section 31.3 [Excursions], page 864,

save-restriction
 see Section 31.4 [Narrowing], page 865,

setq see Section 12.8 [Setting Variables], page 198,

setq-default
 see Section 12.11.2 [Creating Buffer-Local], page 208,

unwind-protect
 see Section 11.7 [Nonlocal Exits], page 177,

while see Section 11.5 [Iteration], page 174,

Common Lisp note: Here are some comparisons of special forms in GNU Emacs Lisp and Common Lisp. `setq`, `if`, and `catch` are special forms in both Emacs Lisp and Common Lisp. `save-excursion` is a special form in Emacs Lisp, but doesn't exist in Common Lisp. `throw` is a special form in Common Lisp (because it must be able to throw multiple values), but it is a function in Emacs Lisp (which doesn't have multiple values).

10.1.8 Autoloading

The *autoload* feature allows you to call a function or macro whose function definition has not yet been loaded into Emacs. It specifies which file contains the definition. When an autoload object appears as a symbol's function definition, calling that symbol as a function

automatically loads the specified file; then it calls the real definition loaded from that file. The way to arrange for an autoload object to appear as a symbol's function definition is described in Section 16.5 [Autoload], page 304.

10.2 Quoting

The special form `quote` returns its single argument, as written, without evaluating it. This provides a way to include constant symbols and lists, which are not self-evaluating objects, in a program. (It is not necessary to quote self-evaluating objects such as numbers, strings, and vectors.)

`quote object` [Special Form]

This special form returns *object*, without evaluating it. The returned value might be shared and should not be modified. See Section 10.1.1 [Self-Evaluating Forms], page 146.

Because `quote` is used so often in programs, Lisp provides a convenient read syntax for it. An apostrophe character ('') followed by a Lisp object (in read syntax) expands to a list whose first element is `quote`, and whose second element is the object. Thus, the read syntax '`x`' is an abbreviation for `(quote x)`.

Here are some examples of expressions that use `quote`:

```
(quote (+ 1 2))
      ⇒ (+ 1 2)
(quote foo)
      ⇒ foo
'foo
      ⇒ foo
''foo
      ⇒ 'foo
'(quote foo)
      ⇒ 'foo
['foo]
      ⇒ ['foo]
```

Although the expressions `(list '+ 1 2)` and `'(+ 1 2)` both yield lists equal to `(+ 1 2)`, the former yields a freshly-minted mutable list whereas the latter yields a list built from conses that might be shared and should not be modified. See Section 10.1.1 [Self-Evaluating Forms], page 146.

Other quoting constructs include `function` (see Section 13.7 [Anonymous Functions], page 243), which causes an anonymous lambda expression written in Lisp to be compiled, and ``~` (see Section 10.3 [Backquote], page 151), which is used to quote only part of a list, while computing and substituting other parts.

10.3 Backquote

Backquote constructs allow you to quote a list, but selectively evaluate elements of that list. In the simplest case, it is identical to the special form `quote`. For example, these two forms yield identical results:

```

` (a list of (+ 2 3) elements)
  ⇒ (a list of (+ 2 3) elements)
'(a list of (+ 2 3) elements)
  ⇒ (a list of (+ 2 3) elements)

```

The special marker ‘,’ inside of the argument to backquote indicates a value that isn’t constant. The Emacs Lisp evaluator evaluates the argument of ‘,’, and puts the value in the list structure:

```

` (a list of ,(+ 2 3) elements)
  ⇒ (a list of 5 elements)

```

Substitution with ‘,’ is allowed at deeper levels of the list structure also. For example:

```

` (1 2 (3 ,(+ 4 5)))
  ⇒ (1 2 (3 9))

```

You can also *splice* an evaluated value into the resulting list, using the special marker ‘,@’. The elements of the spliced list become elements at the same level as the other elements of the resulting list. The equivalent code without using ‘~’ is often unreadable. Here are some examples:

```

(setq some-list '(2 3))
  ⇒ (2 3)
(cons 1 (append some-list '(4) some-list))
  ⇒ (1 2 3 4 2 3)
` (1 ,@some-list 4 ,@some-list)
  ⇒ (1 2 3 4 2 3)

(setq list '(hack foo bar))
  ⇒ (hack foo bar)
(cons 'use
  (cons 'the
    (cons 'words (append (cdr list) '(as elements)))))

  ⇒ (use the words foo bar as elements)
` (use the words ,@(cdr list) as elements)
  ⇒ (use the words foo bar as elements)

```

If a subexpression of a backquote construct has no substitutions or splices, it acts like quote in that it yields conses, vectors and strings that might be shared and should not be modified. See Section 10.1.1 [Self-Evaluating Forms], page 146.

10.4 Eval

Most often, forms are evaluated automatically, by virtue of their occurrence in a program being run. On rare occasions, you may need to write code that evaluates a form that is computed at run time, such as after reading a form from text being edited or getting one from a property list. On these occasions, use the `eval` function. Often `eval` is not needed and something else should be used instead. For example, to get the value of a variable, while `eval` works, `symbol-value` is preferable; or rather than store expressions in a property list that then need to go through `eval`, it is better to store functions instead that are then passed to `funcall`.

The functions and variables described in this section evaluate forms, specify limits to the evaluation process, or record recently returned values. Loading a file also does evaluation (see Chapter 16 [Loading], page 298).

It is generally cleaner and more flexible to store a function in a data structure, and call it with `funcall` or `apply`, than to store an expression in the data structure and evaluate it. Using functions provides the ability to pass information to them as arguments.

eval form &optional lexical [Function]

This is the basic function for evaluating an expression. It evaluates *form* in the current environment, and returns the result. The type of the *form* object determines how it is evaluated. See Section 10.1 [Forms], page 146.

The argument *lexical* specifies the scoping rule for local variables (see Section 12.10 [Variable Scoping], page 201). If it is omitted or `nil`, that means to evaluate *form* using the default dynamic scoping rule. If it is `t`, that means to use the lexical scoping rule. The value of *lexical* can also be a non-empty alist specifying a particular *lexical environment* for lexical bindings; however, this feature is only useful for specialized purposes, such as in Emacs Lisp debuggers. See Section 12.10.3 [Lexical Binding], page 203.

Since `eval` is a function, the argument expression that appears in a call to `eval` is evaluated twice: once as preparation before `eval` is called, and again by the `eval` function itself. Here is an example:

```
(setq foo 'bar)
      ⇒ bar
(setq bar 'baz)
      ⇒ baz
;; Here eval receives argument foo
(eval 'foo)
      ⇒ bar
;; Here eval receives argument bar, which is the value of foo
(eval foo)
      ⇒ baz
```

The number of currently active calls to `eval` is limited to `max-lisp-eval-depth` (see below).

eval-region start end &optional stream read-function [Command]

This function evaluates the forms in the current buffer in the region defined by the positions *start* and *end*. It reads forms from the region and calls `eval` on them until the end of the region is reached, or until an error is signaled and not handled.

By default, `eval-region` does not produce any output. However, if *stream* is non-`nil`, any output produced by output functions (see Section 20.5 [Output Functions], page 377), as well as the values that result from evaluating the expressions in the region are printed using *stream*. See Section 20.4 [Output Streams], page 375.

If *read-function* is non-`nil`, it should be a function, which is used instead of `read` to read expressions one by one. This function is called with one argument, the stream for reading input. You can also use the variable `load-read-function` (see [How

Programs Do Loading], page 300) to specify this function, but it is more robust to use the *read-function* argument.

`eval-region` does not move point. It always returns `nil`.

eval-buffer &optional *buffer-or-name* *stream* *filename* *unibyte* [Command]
print

This is similar to `eval-region`, but the arguments provide different optional features. `eval-buffer` operates on the entire accessible portion of buffer *buffer-or-name* (see Section “Narrowing” in *The GNU Emacs Manual*). *buffer-or-name* can be a buffer, a buffer name (a string), or `nil` (or omitted), which means to use the current buffer. *stream* is used as in `eval-region`, unless *stream* is `nil` and *print* non-`nil`. In that case, values that result from evaluating the expressions are still discarded, but the output of the output functions is printed in the echo area. *filename* is the file name to use for `load-history` (see Section 16.9 [Unloading], page 313), and defaults to `buffer-file-name` (see Section 28.4 [Buffer File Name], page 675). If *unibyte* is non-`nil`, `read` converts strings to unibyte whenever possible.

max-lisp-eval-depth [User Option]

This variable defines the maximum depth allowed in calls to `eval`, `apply`, and `funcall` before an error is signaled (with error message “Lisp nesting exceeds `max-lisp-eval-depth`”).

This limit, with the associated error when it is exceeded, is how Emacs Lisp avoids infinite recursion on an ill-defined function. If you increase the value of `max-lisp-eval-depth` too much, such code can cause stack overflow instead. On some systems, this overflow can be handled. In that case, normal Lisp evaluation is interrupted and control is transferred back to the top level command loop (`top-level`). Note that there is no way to enter Emacs Lisp debugger in this situation. See Section 19.1.1 [Error Debugging], page 333.

The depth limit counts internal uses of `eval`, `apply`, and `funcall`, such as for calling the functions mentioned in Lisp expressions, and recursive evaluation of function call arguments and function body forms, as well as explicit calls in Lisp code.

The default value of this variable is 1600. If you set it to a value less than 100, Lisp will reset it to 100 if the given value is reached. Entry to the Lisp debugger increases the value, if there is little room left, to make sure the debugger itself has room to execute.

values [Variable]

The value of this variable is a list of the values returned by all the expressions that were read, evaluated, and printed from buffers (including the minibuffer) by the standard Emacs commands which do this. (Note that this does *not* include evaluation in `*ielm*` buffers, nor evaluation using `C-j`, `C-x C-e`, and similar evaluation commands in `lisp-interaction-mode`.)

This variable is obsolete, and will be removed in a future version, since it constantly enlarges the memory footprint of the Emacs process. For that reason, we recommend against using it.

The elements of `values` are ordered most recent first.

```
(setq x 1)
  ⇒ 1
(list 'A (1+ 2) auto-save-default)
  ⇒ (A 3 t)
values
  ⇒ ((A 3 t) 1 ...)
```

This variable could be useful for referring back to values of forms recently evaluated. It is generally a bad idea to print the value of `values` itself, since this may be very long. Instead, examine particular elements, like this:

```
; ; Refer to the most recent evaluation result.
(nth 0 values)
  ⇒ (A 3 t)
; ; That put a new element on,
; ; so all elements move back one.
(nth 1 values)
  ⇒ (A 3 t)
; ; This gets the element that was next-to-most-recent
; ; before this example.
(nth 3 values)
  ⇒ 1
```

10.5 Deferred and Lazy Evaluation

Sometimes it is useful to delay the evaluation of an expression, for example if you want to avoid performing a time-consuming calculation if it turns out that the result is not needed in the future of the program. The `thunk` library provides the following functions and macros to support such *deferred evaluation*:

`thunk-delay forms...`

[Macro]

Return a *thunk* for evaluating the *forms*. A thunk is a closure (see Section 13.10 [Closures], page 249) that inherits the lexical environment of the `thunk-delay` call. Using this macro requires `lexical-binding`.

`thunk-force thunk`

[Function]

Force *thunk* to perform the evaluation of the forms specified in the `thunk-delay` that created the thunk. The result of the evaluation of the last form is returned. The *thunk* also “remembers” that it has been forced: Any further calls of `thunk-force` with the same *thunk* will just return the same result without evaluating the forms again.

`thunk-let (bindings...) forms...`

[Macro]

This macro is analogous to `let` but creates “lazy” variable bindings. Any binding has the form (`symbol value-form`). Unlike `let`, the evaluation of any *value-form* is deferred until the binding of the according *symbol* is used for the first time when evaluating the *forms*. Any *value-form* is evaluated at most once. Using this macro requires `lexical-binding`.

Example:

```
(defun f (number)
  (thunk-let ((derived-number
               (progn (message "Calculating 1 plus 2 times %d" number)
                      (1+ (* 2 number)))))

  (if (> number 10)
      derived-number
      number)))

(f 5)
⇒ 5

(f 12)
⇒ Calculating 1 plus 2 times 12
⇒ 25
```

Because of the special nature of lazily bound variables, it is an error to set them (e.g. with `setq`).

thunk-let* (*bindings...*) *forms...* [Macro]

This is like `thunk-let` but any expression in *bindings* is allowed to refer to preceding bindings in this `thunk-let*` form. Using this macro requires `lexical-binding`.

```
(thunk-let* ((x (prog2 (message "Calculating x...")
                         (+ 1 1)
                         (message "Finished calculating x")))
            (y (prog2 (message "Calculating y...")
                         (+ x 1)
                         (message "Finished calculating y")))
            (z (prog2 (message "Calculating z...")
                         (+ y 1)
                         (message "Finished calculating z")))
            (a (prog2 (message "Calculating a...")
                         (+ z 1)
                         (message "Finished calculating a")))))
  (* z x))

⇒ Calculating z...
⇒ Calculating y...
⇒ Calculating x...
⇒ Finished calculating x
⇒ Finished calculating y
⇒ Finished calculating z
⇒ 8
```

`thunk-let` and `thunk-let*` use thunks implicitly: their expansion creates helper symbols and binds them to thunks wrapping the binding expressions. All references to the original variables in the body *forms* are then replaced by an expression that calls `thunk-force` with

the according helper variable as the argument. So, any code using `thunk-let` or `thunk-let*` could be rewritten to use thunks, but in many cases using these macros results in nicer code than using thunks explicitly.

11 Control Structures

A Lisp program consists of a set of *expressions*, or *forms* (see Section 10.1 [Forms], page 146). We control the order of execution of these forms by enclosing them in *control structures*. Control structures are special forms which control when, whether, or how many times to execute the forms they contain.

The simplest order of execution is sequential execution: first form *a*, then form *b*, and so on. This is what happens when you write several forms in succession in the body of a function, or at top level in a file of Lisp code—the forms are executed in the order written. We call this *textual order*. For example, if a function body consists of two forms *a* and *b*, evaluation of the function evaluates first *a* and then *b*. The result of evaluating *b* becomes the value of the function.

Explicit control structures make possible an order of execution other than sequential.

Emacs Lisp provides several kinds of control structure, including other varieties of sequencing, conditionals, iteration, and (controlled) jumps—all discussed below. The built-in control structures are special forms since their subforms are not necessarily evaluated or not evaluated sequentially. You can use macros to define your own control structure constructs (see Chapter 14 [Macros], page 268).

11.1 Sequencing

Evaluating forms in the order they appear is the most common way control passes from one form to another. In some contexts, such as in a function body, this happens automatically. Elsewhere you must use a control structure construct to do this: `progn`, the simplest control construct of Lisp.

A `progn` special form looks like this:

```
(progn a b c ...)
```

and it says to execute the forms *a*, *b*, *c*, and so on, in that order. These forms are called the *body* of the `progn` form. The value of the last form in the body becomes the value of the entire `progn`. (`progn`) returns `nil`.

In the early days of Lisp, `progn` was the only way to execute two or more forms in succession and use the value of the last of them. But programmers found they often needed to use a `progn` in the body of a function, where (at that time) only one form was allowed. So the body of a function was made into an implicit `progn`: several forms are allowed just as in the body of an actual `progn`. Many other control structures likewise contain an implicit `progn`. As a result, `progn` is not used as much as it was many years ago. It is needed now most often inside an `unwind-protect`, `and`, `or`, or in the *then*-part of an `if`.

`progn forms...`

[Special Form]

This special form evaluates all of the *forms*, in textual order, returning the result of the final form.

```
(progn (print "The first form")
       (print "The second form")
       (print "The third form"))
      |- "The first form"
      |- "The second form"
      |- "The third form"
⇒ "The third form"
```

Two other constructs likewise evaluate a series of forms but return different values:

prog1 *form1 forms...* [Special Form]

This special form evaluates *form1* and all of the *forms*, in textual order, returning the result of *form1*.

```
(prog1 (print "The first form")
       (print "The second form")
       (print "The third form"))
      |- "The first form"
      |- "The second form"
      |- "The third form"
⇒ "The first form"
```

Here is a way to remove the first element from a list in the variable *x*, then return the value of that former element:

```
(prog1 (car x) (setq x (cdr x)))
```

prog2 *form1 form2 forms...* [Special Form]

This special form evaluates *form1*, *form2*, and all of the following *forms*, in textual order, returning the result of *form2*.

```
(prog2 (print "The first form")
       (print "The second form")
       (print "The third form"))
      |- "The first form"
      |- "The second form"
      |- "The third form"
⇒ "The second form"
```

11.2 Conditionals

Conditional control structures choose among alternatives. Emacs Lisp has five conditional forms: **if**, which is much the same as in other languages; **when** and **unless**, which are variants of **if**; **cond**, which is a generalized case statement; and **pcase**, which is a generalization of **cond** (see Section 11.4 [Pattern-Matching Conditional], page 163).

if *condition then-form else-forms...* [Special Form]

if chooses between the *then-form* and the *else-forms* based on the value of *condition*. If the evaluated *condition* is non-*nil*, *then-form* is evaluated and the result returned. Otherwise, the *else-forms* are evaluated in textual order, and the value of the last one is returned. (The *else* part of **if** is an example of an implicit **progn**. See Section 11.1 [Sequencing], page 158.)

If *condition* has the value `nil`, and no *else-forms* are given, `if` returns `nil`.

`if` is a special form because the branch that is not selected is never evaluated—it is ignored. Thus, in this example, `true` is not printed because `print` is never called:

```
(if nil
    (print 'true)
    'very-false)
⇒ very-false
```

`when condition then-forms...`

[Macro]

This is a variant of `if` where there are no *else-forms*, and possibly several *then-forms*. In particular,

```
(when condition a b c)
```

is entirely equivalent to

```
(if condition (progn a b c) nil)
```

`unless condition forms...`

[Macro]

This is a variant of `if` where there is no *then-form*:

```
(unless condition a b c)
```

is entirely equivalent to

```
(if condition nil
    a b c)
```

`cond clause...`

[Special Form]

`cond` chooses among an arbitrary number of alternatives. Each *clause* in the `cond` must be a list. The CAR of this list is the *condition*; the remaining elements, if any, the *body-forms*. Thus, a clause looks like this:

```
(condition body-forms...)
```

`cond` tries the clauses in textual order, by evaluating the *condition* of each clause. If the value of *condition* is non-`nil`, the clause succeeds; then `cond` evaluates its *body-forms*, and returns the value of the last of *body-forms*. Any remaining clauses are ignored.

If the value of *condition* is `nil`, the clause fails, so the `cond` moves on to the following clause, trying its *condition*.

A clause may also look like this:

```
(condition)
```

Then, if *condition* is non-`nil` when tested, the `cond` form returns the value of *condition*.

If every *condition* evaluates to `nil`, so that every clause fails, `cond` returns `nil`.

The following example has four clauses, which test for the cases where the value of *x* is a number, string, buffer and symbol, respectively:

```
(cond ((numberp x) x)
      ((stringp x) x)
      ((bufferp x)
       (setq temporary-hack x) ; multiple body-forms
       (buffer-name x)) ; in one clause
      ((symbolp x) (symbol-value x)))
```

Often we want to execute the last clause whenever none of the previous clauses was successful. To do this, we use `t` as the *condition* of the last clause, like this: `(t body-forms)`. The form `t` evaluates to `t`, which is never `nil`, so this clause never fails, provided the `cond` gets to it at all. For example:

```
(setq a 5)
(cond ((eq a 'hack) 'foo)
      (t "default"))
⇒ "default"
```

This `cond` expression returns `foo` if the value of `a` is `hack`, and returns the string `"default"` otherwise.

Any conditional construct can be expressed with `cond` or with `if`. Therefore, the choice between them is a matter of style. For example:

```
(if a b c)
≡
(cond (a b) (t c))
```

It can be convenient to bind variables in conjunction with using a conditional. It's often the case that you compute a value, and then want to do something with that value if it's non-`nil`. The straightforward way to do that is to just write, for instance:

```
(let ((result1 (do-computation)))
  (when result1
    (let ((result2 (do-more result1)))
      (when result2
        (do-something result2)))))
```

Since this is a very common pattern, Emacs provides a number of macros to make this easier and more readable. The above can be written the following way instead:

```
(when-let ((result1 (do-computation))
          (result2 (do-more result1)))
  (do-something result2))
```

There's a number of variations on this theme, and they're briefly described below.

`if-let spec then-form else-forms...`

[Macro]

Evaluate each binding in `spec` in turn, like in `let*` (see Section 12.3 [Local Variables], page 190), stopping if a binding value is `nil`. If all are non-`nil`, return the value of `then-form`, otherwise the last form in `else-forms`.

`when-let spec then-forms...`

[Macro]

Like `if-let`, but without `else-forms`.

`while-let spec then-forms...`

[Macro]

Like `when-let`, but repeat until a binding in `spec` is `nil`. The return value is always `nil`.

11.3 Constructs for Combining Conditions

This section describes constructs that are often used together with `if` and `cond` to express complicated conditions. The constructs `and` and `or` can also be used individually as kinds of multiple conditional constructs.

`not condition`

[Function]

This function tests for the falsehood of `condition`. It returns `t` if `condition` is `nil`, and `nil` otherwise. The function `not` is identical to `null`, and we recommend using the name `null` if you are testing for an empty list or `nil` value.

`and conditions...`

[Special Form]

The `and` special form tests whether all the `conditions` are true. It works by evaluating the `conditions` one by one in the order written.

If any of the `conditions` evaluates to `nil`, then the result of the `and` must be `nil` regardless of the remaining `conditions`; so `and` returns `nil` right away, ignoring the remaining `conditions`.

If all the `conditions` turn out non-`nil`, then the value of the last of them becomes the value of the `and` form. Just `(and)`, with no `conditions`, returns `t`, appropriate because all the `conditions` turned out non-`nil`. (Think about it; which one did not?)

Here is an example. The first condition returns the integer 1, which is not `nil`. Similarly, the second condition returns the integer 2, which is not `nil`. The third condition is `nil`, so the remaining condition is never evaluated.

```
(and (print 1) (print 2) nil (print 3))
  ⇒ 1
  ⇒ 2
⇒ nil
```

Here is a more realistic example of using `and`:

```
(if (and (consp foo) (eq (car foo) 'x))
    (message "foo is a list starting with x"))
```

Note that `(car foo)` is not executed if `(consp foo)` returns `nil`, thus avoiding an error.

`and` expressions can also be written using either `if` or `cond`. Here's how:

```
(and arg1 arg2 arg3)
≡
(if arg1 (if arg2 arg3))
≡
(cond (arg1 (cond (arg2 arg3))))
```

`or conditions...`

[Special Form]

The `or` special form tests whether at least one of the `conditions` is true. It works by evaluating all the `conditions` one by one in the order written.

If any of the `conditions` evaluates to a non-`nil` value, then the result of the `or` must be non-`nil`; so `or` returns right away, ignoring the remaining `conditions`. The value it returns is the non-`nil` value of the condition just evaluated.

If all the *conditions* turn out `nil`, then the `or` expression returns `nil`. Just (`or`), with no *conditions*, returns `nil`, appropriate because all the *conditions* turned out `nil`. (Think about it; which one did not?)

For example, this expression tests whether `x` is either `nil` or the integer zero:

```
(or (eq x nil) (eq x 0))
```

Like the `and` construct, `or` can be written in terms of `cond`. For example:

```
(or arg1 arg2 arg3)
≡
(cond (arg1)
      (arg2)
      (arg3))
```

You could almost write `or` in terms of `if`, but not quite:

```
(if arg1 arg1
    (if arg2 arg2
        arg3))
```

This is not completely equivalent because it can evaluate `arg1` or `arg2` twice. By contrast, `(or arg1 arg2 arg3)` never evaluates any argument more than once.

`xor condition1 condition2`

[Function]

This function returns the boolean exclusive-or of `condition1` and `condition2`. That is, `xor` returns `nil` if either both arguments are `nil`, or both are non-`nil`. Otherwise, it returns the value of that argument which is non-`nil`.

Note that in contrast to `or`, both arguments are always evaluated.

11.4 Pattern-Matching Conditional

Aside from the four basic conditional forms, Emacs Lisp also has a pattern-matching conditional form, the `pcase` macro, a hybrid of `cond` and `cl-case` (see Section “Conditionals” in *Common Lisp Extensions*) that overcomes their limitations and introduces the *pattern matching programming style*. The limitations that `pcase` overcomes are:

- The `cond` form chooses among alternatives by evaluating the predicate `condition` of each of its clauses (see Section 11.2 [Conditionals], page 159). The primary limitation is that variables let-bound in `condition` are not available to the clause’s *body-forms*.

Another annoyance (more an inconvenience than a limitation) is that when a series of `condition` predicates implement equality tests, there is a lot of repeated code. (`cl-case` solves this inconvenience.)

- The `cl-case` macro chooses among alternatives by evaluating the equality of its first argument against a set of specific values.

Its limitations are two-fold:

1. The equality tests use `eql`.
2. The values must be known and written in advance.

These render `cl-case` unsuitable for strings or compound data structures (e.g., lists or vectors). (`cond` doesn’t have these limitations, but it has others, see above.)

Conceptually, the `pcase` macro borrows the first-arg focus of `cl-case` and the clause-processing flow of `cond`, replacing *condition* with a generalization of the equality test which is a variant of *pattern matching*, and adding facilities so that you can concisely express a clause’s predicate, and arrange to share let-bindings between a clause’s predicate and *body-forms*.

The concise expression of a predicate is known as a *pattern*. When the predicate, called on the value of the first arg, returns `non-nil`, we say that “the pattern matches the value” (or sometimes “the value matches the pattern”).

11.4.1 The `pcase` macro

For background, See Section 11.4 [Pattern-Matching Conditional], page 163.

`pcase expression &rest clauses`

[Macro]

Each clause in *clauses* has the form: *(pattern body-forms...)*.

Evaluate *expression* to determine its value, *expval*. Find the first clause in *clauses* whose *pattern* matches *expval* and pass control to that clause’s *body-forms*.

If there is a match, the value of `pcase` is the value of the last of *body-forms* in the successful clause. Otherwise, `pcase` evaluates to `nil`.

Each *pattern* has to be a *pcase pattern*, which can use either one of the core patterns defined below, or one of the patterns defined via `pcase-defmacro` (see Section 11.4.2 [Extending `pcase`], page 170).

The rest of this subsection describes different forms of core patterns, presents some examples, and concludes with important caveats on using the let-binding facility provided by some pattern forms. A core pattern can have the following forms:

- _ (underscore)

Matches any *expval*. This is also known as *don’t care* or *wildcard*.

`'val` Matches if *expval* equals *val*. The comparison is done as if by `equal` (see Section 2.8 [Equality Predicates], page 34).

`keyword`

`integer`

`string` Matches if *expval* equals the literal object. This is a special case of `'val`, above, possible because literal objects of these types are self-quoting.

`symbol` Matches any *expval*, and additionally let-binds *symbol* to *expval*, such that this binding is available to *body-forms* (see Section 12.10.1 [Dynamic Binding], page 201).

If *symbol* is part of a sequencing pattern `seqpat` (e.g., by using `and`, below), the binding is also available to the portion of `seqpat` following the appearance of *symbol*. This usage has some caveats, see [caveats], page 168.

Two symbols to avoid are `t`, which behaves like `_` (above) and is deprecated, and `nil`, which signals an error. Likewise, it makes no sense to bind keyword symbols (see Section 12.2 [Constant Variables], page 189).

``qpat` A backquote-style pattern. See Section 11.4.3 [Backquote Patterns], page 171, for the details.

(cl-type type)

Matches if *expval* is of type *type*, which is a type descriptor as accepted by `cl-typep` (see Section “Type Predicates” in *Common Lisp Extensions*). Examples:

```
(cl-type integer)
(cl-type (integer 0 10))
```

(pred function)

Matches if the predicate *function* returns non-`nil` when called on *expval*. The test can be negated with the syntax `(pred (not function))`. The predicate *function* can have one of the following forms:

function name (a symbol)

Call the named function with one argument, *expval*.

Example: `integerp`

lambda expression

Call the anonymous function with one argument, *expval* (see Section 13.2 [Lambda Expressions], page 232).

Example: `(lambda (n) (= 42 n))`

function call with *n* args

Call the function (the first element of the function call) with *n* arguments (the other elements) and an additional *n+1*-th argument that is *expval*.

Example: `(= 42)`

In this example, the function is `=`, *n* is one, and the actual function call becomes: `(= 42 expval)`.

(app function pattern)

Matches if *function* called on *expval* returns a value that matches *pattern*. *function* can take one of the forms described for `pred`, above. Unlike `pred`, however, `app` tests the result against *pattern*, rather than against a boolean truth value.

(guard boolean-expression)

Matches if *boolean-expression* evaluates to non-`nil`.

(let pattern expr)

Evaluates *expr* to get *exprval* and matches if *exprval* matches *pattern*. (It is called `let` because *pattern* can bind symbols to values using `symbol`.)

A sequencing pattern (also known as `seqpat`) is a pattern that processes its sub-pattern arguments in sequence. There are two for `pcase`: `and` and `or`. They behave in a similar manner to the special forms that share their name (see Section 11.3 [Combining Conditions], page 162), but instead of processing values, they process sub-patterns.

(and pattern1...)

Attempts to match *pattern1...*, in order, until one of them fails to match. In that case, `and` likewise fails to match, and the rest of the sub-patterns are not tested. If all sub-patterns match, `and` matches.

`(or pattern1 pattern2...)`

Attempts to match *pattern1*, *pattern2*, ..., in order, until one of them succeeds. In that case, `or` likewise matches, and the rest of the sub-patterns are not tested.

To present a consistent environment to *body-forms* (thus avoiding an evaluation error on match), the set of variables bound by the pattern is the union of the variables bound by each sub-pattern. If a variable is not bound by the sub-pattern that matched, then it is bound to `nil`.

Example: Advantage Over cl-case

Here's an example that highlights some advantages `pcase` has over `cl-case` (see Section "Conditionals" in *Common Lisp Extensions*).

```
(pcase (get-return-code x)
  ;; string
  ((and (pred stringp) msg)
   (message "%s" msg))
  ;; symbol
  ('success      (message "Done!"))
  ('would-block (message "Sorry, can't do it now"))
  ('read-only    (message "The schmilblick is read-only"))
  ('access-denied (message "You do not have the needed rights"))
  ;; default
  (code          (message "Unknown return code %S" code)))
```

With `cl-case`, you would need to explicitly declare a local variable `code` to hold the return value of `get-return-code`. Also `cl-case` is difficult to use with strings because it uses `eql` for comparison.

Example: Using and

A common idiom is to write a pattern starting with `and`, with one or more *symbol* sub-patterns providing bindings to the sub-patterns that follow (as well as to the body forms). For example, the following pattern matches single-digit integers.

```
(and
  (pred integerp)
  n                      ; bind n to expval
  (guard (<= -9 n 9)))
```

First, `pred` matches if `(integerp expval)` evaluates to non-`nil`. Next, `n` is a *symbol* pattern that matches anything and binds `n` to `expval`. Lastly, `guard` matches if the boolean expression `(<= -9 n 9)` (note the reference to `n`) evaluates to non-`nil`. If all these sub-patterns match, `and` matches.

Example: Reformulation with pcase

Here is another example that shows how to reformulate a simple matching task from its traditional implementation (function `grok/traditional`) to one using `pcase` (function `grok/pcase`). The docstring for both these functions is: "If OBJ is a string of the form "key:NUMBER", return NUMBER (a string). Otherwise, return the list ("149" default)." First, the traditional implementation (see Section 35.3 [Regular Expressions], page 995):

```
(defun grok/traditional (obj)
  (if (and (stringp obj)
            (string-match "^key:\\\\([[:digit:]]+\\\\)$" obj))
      (match-string 1 obj)
      (list "149" 'default)))

(grok/traditional "key:0")    => "0"
(grok/traditional "key:149")  => "149"
(grok/traditional 'monolith) => ("149" default)
```

The reformulation demonstrates *symbol* binding as well as `or`, `and`, `pred`, `app` and `let`.

```
(defun grok/pcase (obj)
  (pcase obj
    ((or
      (and
        (pred stringp)
        (pred (string-match
                  "^key:\\\\([[:digit:]]+\\\\)$"))
        (app (match-string 1)
              val))
      (let val (list "149" 'default)))
    val))) ; line 1
; line 2
; line 3
; line 4
; line 5
; line 6
; line 7
; line 8
; line 9

(grok/pcase "key:0")    => "0"
(grok/pcase "key:149")  => "149"
(grok/pcase 'monolith) => ("149" default)
```

The bulk of `grok/pcase` is a single clause of a `pcase` form, the pattern on lines 1-8, the (single) body form on line 9. The pattern is `or`, which tries to match in turn its argument sub-patterns, first `and` (lines 2-7), then `let` (line 8), until one of them succeeds.

As in the previous example (see [Example 1], page 166), `and` begins with a `pred` sub-pattern to ensure the following sub-patterns work with an object of the correct type (string, in this case). If `(stringp expval)` returns `nil`, `pred` fails, and thus `and` fails, too.

The next `pred` (lines 4-5) evaluates `(string-match RX expval)` and matches if the result is non-`nil`, which means that `expval` has the desired form: `key:NUMBER`. Again, failing this, `pred` fails and `and`, too.

Lastly (in this series of `and` sub-patterns), `app` evaluates `(match-string 1 expval)` (line 6) to get a temporary value `tmp` (i.e., the “NUMBER” substring) and tries to match `tmp` against pattern `val` (line 7). Since that is a *symbol* pattern, it matches unconditionally and additionally binds `val` to `tmp`.

Now that `app` has matched, all `and` sub-patterns have matched, and so `and` matches. Likewise, once `and` has matched, `or` matches and does not proceed to try sub-pattern `let` (line 8).

Let’s consider the situation where `obj` is not a string, or it is a string but has the wrong form. In this case, one of the `pred` (lines 3-5) fails to match, thus `and` (line 2) fails to match, thus `or` (line 1) proceeds to try sub-pattern `let` (line 8).

First, `let` evaluates `(list "149" 'default)` to get `("149" default)`, the `exprval`, and then tries to match `exprval` against pattern `val`. Since that is a `symbol` pattern, it matches unconditionally and additionally binds `val` to `exprval`. Now that `let` has matched, `or` matches.

Note how both `and` and `let` sub-patterns finish in the same way: by trying (always successfully) to match against the `symbol` pattern `val`, in the process binding `val`. Thus, `or` always matches and control always passes to the body form (line 9). Because that is the last body form in a successfully matched `pcase` clause, it is the value of `pcase` and likewise the return value of `grok/pcase` (see Section 13.1 [What Is a Function], page 230).

Caveats for `symbol` in Sequencing Patterns

The preceding examples all use sequencing patterns which include the `symbol` sub-pattern in some way. Here are some important details about that usage.

- When `symbol` occurs more than once in `seqpat`, the second and subsequent occurrences do not expand to re-binding, but instead expand to an equality test using `eq`.

The following example features a `pcase` form with two clauses and two `seqpat`, A and B. Both A and B first check that `expval` is a pair (using `pred`), and then bind symbols to the `car` and `cdr` of `expval` (using one `app` each).

For A, because symbol `st` is mentioned twice, the second mention becomes an equality test using `eq`. On the other hand, B uses two separate symbols, `s1` and `s2`, both of which become independent bindings.

```
(defun grok (object)
  (pcase object
    ((and (pred consp)          ; seqpat A
          (app car st)        ; first mention: st
          (app cdr st))      ; second mention: st
     (list 'eq st))
    ((and (pred consp)          ; seqpat B
          (app car s1)        ; first mention: s1
          (app cdr s2))      ; first mention: s2
     (list 'not-eq s1 s2)))))

(let ((s "yow!"))
  (grok (cons s s)))      ⇒ (eq "yow!")
  (grok (cons "yo!" "yo!")) ⇒ (not-eq "yo!" "yo!")
  (grok '(4 2))           ⇒ (not-eq 4 (2)))
```

- Side-effecting code referencing `symbol` is undefined. Avoid. For example, here are two similar functions. Both use `and`, `symbol` and `guard`:

```
(defun square-double-digit-p/CLEAN (integer)
  (pcase (* integer integer)
    ((and n (guard (< 9 n 100))) (list 'yes n)
     (sorry (list 'no sorry)))))

(square-double-digit-p/CLEAN 9) ⇒ (yes 81)
(square-double-digit-p/CLEAN 3) ⇒ (no 9)
```

```
(defun square-double-digit-p/MAYBE (integer)
  (pcase (* integer integer)
    ((and n (guard (< 9 (incf n) 100))) (list 'yes n))
    (sorry (list 'no sorry)))

  (square-double-digit-p/MAYBE 9) => (yes 81)
  (square-double-digit-p/MAYBE 3) => (yes 9) ; WRONG!
```

The difference is in *boolean-expression* in *guard*: CLEAN references *n* simply and directly, while MAYBE references *n* with a side-effect, in the expression `(incf n)`. When *integer* is 3, here's what happens:

- The first *n* binds it to *expval*, i.e., the result of evaluating `(* 3 3)`, or 9.
- *boolean-expression* is evaluated:

```
start: (< 9 (incf n) 100)
becomes: (< 9 (setq n (1+ n)) 100)
becomes: (< 9 (setq n (1+ 9)) 100)
becomes: (< 9 (setq n 10) 100)
                                              ; side-effect here!
becomes: (< 9      n      100) ; n now bound to 10
becomes: (< 9      10     100)
becomes: t
```

- Because the result of the evaluation is non-nil, *guard* matches, *and* matches, and control passes to that clause's body forms.

Aside from the mathematical incorrectness of asserting that 9 is a double-digit integer, there is another problem with MAYBE. The body form references *n* once more, yet we do not see the updated value—10—at all. What happened to it?

To sum up, it's best to avoid side-affecting references to *symbol* patterns entirely, not only in *boolean-expression* (in *guard*), but also in *expr* (in *let*) and *function* (in *pred* and *app*).

3. On match, the clause's body forms can reference the set of symbols the pattern let-binds. When *seqpat* is *and*, this set is the union of all the symbols each of its sub-patterns let-binds. This makes sense because, for *and* to match, all the sub-patterns must match. When *seqpat* is *or*, things are different: *or* matches at the first sub-pattern that matches; the rest of the sub-patterns are ignored. It makes no sense for each sub-pattern to let-bind a different set of symbols because the body forms have no way to distinguish which sub-pattern matched and choose among the different sets. For example, the following is invalid:

```
(require 'cl-lib)
(case (read-number "Enter an integer: ")
  ((or (and (pred cl-evenp)
             e-num)          ; bind e-num to expval
       o-num)          ; bind o-num to expval
   (list e-num o-num)))
```

```

Enter an integer: 42
[error] Symbol's value as variable is void: o-num
Enter an integer: 149
[error] Symbol's value as variable is void: e-num

```

Evaluating body form (`(list e-num o-num)`) signals error. To distinguish between sub-patterns, you can use another symbol, identical in name in all sub-patterns but differing in value. Reworking the above example:

```

(require 'cl-lib)
(case (read-number "Enter an integer: ")
  ((and num
        (or (and (pred cl-evenp)
                  (let spin 'even))
            (let spin 'odd)))
        (list spin num))) ; line 1
    ; line 2
    ; line 3
    ; line 4
    ; line 5
)

```

```

Enter an integer: 42
⇒ (even 42)
Enter an integer: 149
⇒ (odd 149)

```

Line 1 “factors out” the `expval` binding with `and` and `symbol` (in this case, `num`). On line 2, `or` begins in the same way as before, but instead of binding different symbols, uses `let` twice (lines 3-4) to bind the same symbol `spin` in both sub-patterns. The value of `spin` distinguishes the sub-patterns. The body form references both symbols (line 5).

11.4.2 Extending `case`

The `case` macro supports several kinds of patterns (see Section 11.4 [Pattern-Matching Conditional], page 163). You can add support for other kinds of patterns using the `case-defmacro` macro.

`case-defmacro name args [doc] &rest body` [Macro]

Define a new kind of pattern for `case`, to be invoked as `(name actual-args)`. The `case` macro expands this into a function call that evaluates `body`, whose job it is to rewrite the invoked pattern into some other pattern, in an environment where `args` are bound to `actual-args`.

Additionally, arrange to display `doc` along with the docstring of `case`. By convention, `doc` should use `EXPVAL` to stand for the result of evaluating expression (first arg to `case`).

Typically, `body` rewrites the invoked pattern to use more basic patterns. Although all patterns eventually reduce to core patterns, `body` need not use core patterns straight away. The following example defines two patterns, named `less-than` and `integer-less-than`.

```

(case-defmacro less-than (n)
  "Matches if EXPVAL is a number less than N."
  `(pred (> ,n)))

```

```
(pcase-defmacro integer-less-than (n)
  "Matches if EXPVAL is an integer less than N."
  `(and (pred integerp)
        (less-than ,n)))
```

Note that the docstrings mention `args` (in this case, only one: `n`) in the usual way, and also mention `EXPVAL` by convention. The first rewrite (i.e., `body` for `less-than`) uses one core pattern: `pred`. The second uses two core patterns: `and` and `pred`, as well as the newly-defined pattern `less-than`. Both use a single backquote construct (see Section 10.3 [Backquote], page 151).

11.4.3 Backquote-Style Patterns

This subsection describes *backquote-style patterns*, a set of builtin patterns that eases structural matching. For background, see Section 11.4 [Pattern-Matching Conditional], page 163.

Backquote-style patterns are a powerful set of `pcase` pattern extensions (created using `pcase-defmacro`) that make it easy to match `expval` against specifications of its *structure*.

For example, to match `expval` that must be a list of two elements whose first element is a specific string and the second element is any value, you can write a core pattern:

```
(and (pred listp)
     ls
     (guard (= 2 (length ls)))
     (guard (string= "first" (car ls)))
     (let second-elem (cadr ls)))
```

or you can write the equivalent backquote-style pattern:

```
`("first" ,second-elem)
```

The backquote-style pattern is more concise, resembles the structure of `expval`, and avoids binding `ls`.

A backquote-style pattern has the form ``qpat` where `qpat` can have the following forms:

`(qpat1 . qpat2)`

Matches if `expval` is a cons cell whose `car` matches `qpat1` and whose `cdr` matches `qpat2`. This readily generalizes to lists as in `(qpat1 qpat2 ...)`.

`[qpat1 qpat2 ... qpatm]`

Matches if `expval` is a vector of length `m` whose `0..(m-1)`th elements match `qpat1`, `qpat2` ... `qpatm`, respectively.

`symbol`

`keyword`

`number`

`string` Matches if the corresponding element of `expval` is `equal` to the specified literal object.

`,pattern` Matches if the corresponding element of `expval` matches `pattern`. Note that `pattern` is any kind that `pcase` supports. (In the example above, `second-elem` is a `symbol` core pattern; it therefore matches anything, and let-binds `second-elem`.)

The *corresponding element* is the portion of `expval` that is in the same structural position as the structural position of `qpat` in the backquote-style pattern. (In the example above, the corresponding element of `second-elem` is the second element of `expval`.)

Here is an example of using `pcase` to implement a simple interpreter for a little expression language (note that this requires lexical binding for the lambda expression in the `fn` clause to properly capture `body` and `arg` (see Section 12.10.3 [Lexical Binding], page 203):

```
(defun evaluate (form env)
  (pcase form
    (`(add ,x ,y)      (+ (evaluate x env)
                           (evaluate y env)))
    (`(call ,fun ,arg) (funcall (evaluate fun env)
                                 (evaluate arg env)))
    (`(fn ,arg ,body)  (lambda (val)
                           (evaluate body (cons (cons arg val)
                                                env))))
    ((pred numberp)     form)
    ((pred symbolp)    (cdr (assq form env)))
    (_                  (error "Syntax error: %S" form))))
```

The first three clauses use backquote-style patterns. ``(add ,x ,y)` is a pattern that checks that `form` is a three-element list starting with the literal symbol `add`, then extracts the second and third elements and binds them to symbols `x` and `y`, respectively. This is known as *destructuring*, see Section 11.4.4 [Destructuring with `pcase` Patterns], page 172. The clause body evaluates `x` and `y` and adds the results. Similarly, the `call` clause implements a function call, and the `fn` clause implements an anonymous function definition.

The remaining clauses use core patterns. `(pred numberp)` matches if `form` is a number. On match, the body evaluates it. `(pred symbolp)` matches if `form` is a symbol. On match, the body looks up the symbol in `env` and returns its association. Finally, `_` is the catch-all pattern that matches anything, so it's suitable for reporting syntax errors.

Here are some sample programs in this small language, including their evaluation results:

```
(evaluate '(add 1 2) nil)           ⇒ 3
(evaluate '(add x y) `((x . 1) (y . 2))) ⇒ 3
(evaluate '(call (fn x (add 1 x)) 2) nil) ⇒ 3
(evaluate '(sub 1 2) nil)           ⇒ error
```

11.4.4 Destructuring with `pcase` Patterns

`Pcase` patterns not only express a condition on the form of the objects they can match, but they can also extract sub-fields of those objects. For example we can extract 2 elements from a list that is the value of the variable `my-list` with the following code:

```
(pcase my-list
  (`(add ,x ,y) (message "Contains %S and %S" x y)))
```

This will not only extract `x` and `y` but will additionally test that `my-list` is a list containing exactly 3 elements and whose first element is the symbol `add`. If any of those tests fail, `pcase` will immediately return `nil` without calling `message`.

Extraction of multiple values stored in an object is known as *destructuring*. Using `pcase` patterns allows to perform *destructuring binding*, which is similar to a local binding (see

Section 12.3 [Local Variables], page 190), but gives values to multiple elements of a variable by extracting those values from an object of compatible structure.

The macros described in this section use `pcase` patterns to perform destructuring binding. The condition of the object to be of compatible structure means that the object must match the pattern, because only then the object's subfields can be extracted. For example:

```
(pcase-let ((`(add ,x ,y) my-list))
  (message "Contains %S and %S" x y))
```

does the same as the previous example, except that it directly tries to extract `x` and `y` from `my-list` without first verifying if `my-list` is a list which has the right number of elements and has `add` as its first element. The precise behavior when the object does not actually match the pattern is undefined, although the body will not be silently skipped: either an error is signaled or the body is run with some of the variables potentially bound to arbitrary values like `nil`.

The `pcase` patterns that are useful for destructuring bindings are generally those described in Section 11.4.3 [Backquote Patterns], page 171, since they express a specification of the structure of objects that will match.

For an alternative facility for destructuring binding, see [seq-let], page 114.

`pcase-let` *bindings* *body*... [Macro]

Perform destructuring binding of variables according to *bindings*, and then evaluate *body*.

bindings is a list of bindings of the form `(pattern exp)`, where *exp* is an expression to evaluate and *pattern* is a `pcase` pattern.

All *exp*s are evaluated first, after which they are matched against their respective *pattern*, introducing new variable bindings that can then be used inside *body*. The variable bindings are produced by destructuring binding of elements of *pattern* to the values of the corresponding elements of the evaluated *exp*.

Here's a trivial example:

```
(pcase-let ((`,major ,minor)
  (split-string "image/png" "/"))
  minor)
  ⇒ "png"
```

`pcase-let*` *bindings* *body*... [Macro]

Perform destructuring binding of variables according to *bindings*, and then evaluate *body*.

bindings is a list of bindings of the form `(pattern exp)`, where *exp* is an expression to evaluate and *pattern* is a `pcase` pattern. The variable bindings are produced by destructuring binding of elements of *pattern* to the values of the corresponding elements of the evaluated *exp*.

Unlike `pcase-let`, but similarly to `let*`, each *exp* is matched against its corresponding *pattern* before processing the next element of *bindings*, so the variable bindings introduced in each one of the *bindings* are available in the *exp*s of the *bindings* that follow it, additionally to being available in *body*.

pcase-dolist (*pattern list*) *body...* [Macro]

Execute *body* once for each element of *list*, on each iteration performing a destructuring binding of variables in *pattern* to the values of the corresponding subfields of the element of *list*. The bindings are performed as if by **pcase-let**. When *pattern* is a simple variable, this ends up being equivalent to **dolist** (see Section 11.5 [Iteration], page 174).

pcase-setq *pattern value...* [Macro]

Assign values to variables in a **setq** form, destructuring each *value* according to its respective *pattern*.

pcase-lambda *lambda-list &rest body* [Macro]

This is like **lambda**, but allows each argument to be a pattern. For instance, here's a simple function that takes a cons cell as the argument:

```
(setq fun
      (pcase-lambda ((key . val))
                    (vector key (* val 10)))
      (funcall fun '(foo . 2)))
⇒ [foo 20]
```

11.5 Iteration

Iteration means executing part of a program repetitively. For example, you might want to repeat some computation once for each element of a list, or once for each integer from 0 to *n*. You can do this in Emacs Lisp with the special form **while**:

while *condition forms...* [Special Form]

while first evaluates *condition*. If the result is non-**nil**, it evaluates *forms* in textual order. Then it reevaluates *condition*, and if the result is non-**nil**, it evaluates *forms* again. This process repeats until *condition* evaluates to **nil**.

There is no limit on the number of iterations that may occur. The loop will continue until either *condition* evaluates to **nil** or until an error or **throw** jumps out of it (see Section 11.7 [Nonlocal Exits], page 177).

The value of a **while** form is always **nil**.

```
(setq num 0)
⇒ 0
}while (< num 4)
(princ (format "Iteration %d." num))
(setq num (1+ num))
  ↓ Iteration 0.
  ↓ Iteration 1.
  ↓ Iteration 2.
  ↓ Iteration 3.
⇒ nil
```

To write a repeat-until loop, which will execute something on each iteration and then do the end-test, put the body followed by the end-test in a **progn** as the first argument of **while**, as shown here:

```
(while (progn
            (forward-line 1)
            (not (looking-at "^\$"))))
```

This moves forward one line and continues moving by lines until it reaches an empty line. It is peculiar in that the `while` has no body, just the end test (which also does the real work of moving point).

The `dolist` and `dotimes` macros provide convenient ways to write two common kinds of loops.

`dolist (var list [result]) body...`

[Macro]

This construct executes `body` once for each element of `list`, binding the variable `var` locally to hold the current element. Then it returns the value of evaluating `result`, or `nil` if `result` is omitted. For example, here is how you could use `dolist` to define the `reverse` function:

```
(defun reverse (list)
  (let (value)
    (dolist (elt list value)
      (setq value (cons elt value)))))
```

`dotimes (var count [result]) body...`

[Macro]

This construct executes `body` once for each integer from 0 (inclusive) to `count` (exclusive), binding the variable `var` to the integer for the current iteration. Then it returns the value of evaluating `result`, or `nil` if `result` is omitted. Use of `result` is deprecated. Here is an example of using `dotimes` to do something 100 times:

```
(dotimes (i 100)
  (insert "I will not obey absurd orders\n"))
```

11.6 Generators

A generator is a function that produces a potentially-infinite stream of values. Each time the function produces a value, it suspends itself and waits for a caller to request the next value.

`iter-defun name args [doc] [declare] [interactive] body...`

[Macro]

`iter-defun` defines a generator function. A generator function has the same signature as a normal function, but works differently. Instead of executing `body` when called, a generator function returns an iterator object. That iterator runs `body` to generate values, emitting a value and pausing where `iter-yield` or `iter-yield-from` appears. When `body` returns normally, `iter-next` signals `iter-end-of-sequence` with `body`'s result as its condition data.

Any kind of Lisp code is valid inside `body`, but `iter-yield` and `iter-yield-from` cannot appear inside `unwind-protect` forms.

`iter-lambda args [doc] [interactive] body...`

[Macro]

`iter-lambda` produces an unnamed generator function that works just like a generator function produced with `iter-defun`.

iter-yield value

[Macro]

When it appears inside a generator function, `iter-yield` indicates that the current iterator should pause and return `value` from `iter-next`. `iter-yield` evaluates to the `value` parameter of next call to `iter-next`.

iter-yield-from iterator

[Macro]

`iter-yield-from` yields all the values that `iterator` produces and evaluates to the value that `iterator`'s generator function returns normally. While it has control, `iterator` receives values sent to the iterator using `iter-next`.

To use a generator function, first call it normally, producing a `iterator` object. An iterator is a specific instance of a generator. Then use `iter-next` to retrieve values from this iterator. When there are no more values to pull from an iterator, `iter-next` raises an `iter-end-of-sequence` condition with the iterator's final value.

It's important to note that generator function bodies only execute inside calls to `iter-next`. A call to a function defined with `iter-defun` produces an iterator; you must drive this iterator with `iter-next` for anything interesting to happen. Each call to a generator function produces a *different* iterator, each with its own state.

iter-next iterator &`optional` value

[Function]

Retrieve the next value from `iterator`. If there are no more values to be generated (because `iterator`'s generator function returned), `iter-next` signals the `iter-end-of-sequence` condition; the data value associated with this condition is the value with which `iterator`'s generator function returned.

`value` is sent into the iterator and becomes the value to which `iter-yield` evaluates. `value` is ignored for the first `iter-next` call to a given iterator, since at the start of `iterator`'s generator function, the generator function is not evaluating any `iter-yield` form.

iter-close iterator

[Function]

If `iterator` is suspended inside an `unwind-protect`'s `bodyform` and becomes unreachable, Emacs will eventually run unwind handlers after a garbage collection pass. (Note that `iter-yield` is illegal inside an `unwind-protect`'s `unwindforms`.) To ensure that these handlers are run before then, use `iter-close`.

Some convenience functions are provided to make working with iterators easier:

iter-do (var iterator) body ...

[Macro]

Run `body` with `var` bound to each value that `iterator` produces.

The Common Lisp loop facility also contains features for working with iterators. See Section “Loop Facility” in *Common Lisp Extensions*.

The following piece of code demonstrates some important principles of working with iterators.

```
(require 'generator)
(iter-defun my-iter (x)
  (iter-yield (1+ (iter-yield (1+ x))))
  ;; Return normally
```

```

-1)

(let* ((iter (my-iter 5))
       (iter2 (my-iter 0)))
  ;; Prints 6
  (print (iter-next iter))
  ;; Prints 9
  (print (iter-next iter 8))
  ;; Prints 1; iter and iter2 have distinct states
  (print (iter-next iter2 nil))

  ;; We expect the iter sequence to end now
  (condition-case x
    (iter-next iter)
    (iter-end-of-sequence
     ;; Prints -1, which my-iter returned normally
     (print (cdr x)))))

```

11.7 Nonlocal Exits

A *nonlocal exit* is a transfer of control from one point in a program to another remote point. Nonlocal exits can occur in Emacs Lisp as a result of errors; you can also use them under explicit control. Nonlocal exits unbind all variable bindings made by the constructs being exited.

11.7.1 Explicit Nonlocal Exits: `catch` and `throw`

Most control constructs affect only the flow of control within the construct itself. The function `throw` is the exception to this rule of normal program execution: it performs a nonlocal exit on request. (There are other exceptions, but they are for error handling only.) `throw` is used inside a `catch`, and jumps back to that `catch`. For example:

```

(defun foo-outer ()
  (catch 'foo
    (foo-inner)))

(defun foo-inner ()
  ...
  (if x
    (throw 'foo t))
  ...)

```

The `throw` form, if executed, transfers control straight back to the corresponding `catch`, which returns immediately. The code following the `throw` is not executed. The second argument of `throw` is used as the return value of the `catch`.

The function `throw` finds the matching `catch` based on the first argument: it searches for a `catch` whose first argument is `eq` to the one specified in the `throw`. If there is more than one applicable `catch`, the innermost one takes precedence. Thus, in the above example, the `throw` specifies `foo`, and the `catch` in `foo-outer` specifies the same symbol, so that `catch` is the applicable one (assuming there is no other matching `catch` in between).

Executing `throw` exits all Lisp constructs up to the matching `catch`, including function calls. When binding constructs such as `let` or function calls are exited in this way, the bindings are unbound, just as they are when these constructs exit normally (see Section 12.3 [Local Variables], page 190). Likewise, `throw` restores the buffer and position saved by `save-excursion` (see Section 31.3 [Excursions], page 864), and the narrowing status saved by `save-restriction`. It also runs any cleanups established with the `unwind-protect` special form when it exits that form (see Section 11.7.4 [Cleanups], page 187).

The `throw` need not appear lexically within the `catch` that it jumps to. It can equally well be called from another function called within the `catch`. As long as the `throw` takes place chronologically after entry to the `catch`, and chronologically before exit from it, it has access to that `catch`. This is why `throw` can be used in commands such as `exit-recursive-edit` that throw back to the editor command loop (see Section 22.13 [Recursive Editing], page 475).

Common Lisp note: Most other versions of Lisp, including Common Lisp, have several ways of transferring control nonsequentially: `return`, `return-from`, and `go`, for example. Emacs Lisp has only `throw`. The `cl-lib` library provides versions of some of these. See Section “Blocks and Exits” in *Common Lisp Extensions*.

`catch tag body...`

[Special Form]

`catch` establishes a return point for the `throw` function. The return point is distinguished from other such return points by `tag`, which may be any Lisp object except `nil`. The argument `tag` is evaluated normally before the return point is established.

With the return point in effect, `catch` evaluates the forms of the `body` in textual order. If the forms execute normally (without error or nonlocal exit) the value of the last body form is returned from the `catch`.

If a `throw` is executed during the execution of `body`, specifying the same value `tag`, the `catch` form exits immediately; the value it returns is whatever was specified as the second argument of `throw`.

`throw tag value`

[Function]

The purpose of `throw` is to return from a return point previously established with `catch`. The argument `tag` is used to choose among the various existing return points; it must be `eq` to the value specified in the `catch`. If multiple return points match `tag`, the innermost one is used.

The argument `value` is used as the value to return from that `catch`.

If no return point is in effect with tag `tag`, then a `no-catch` error is signaled with data (`tag value`).

11.7.2 Examples of `catch` and `throw`

One way to use `catch` and `throw` is to exit from a doubly nested loop. (In most languages, this would be done with a `goto`.) Here we compute `(foo i j)` for `i` and `j` varying from 0 to 9:

```
(defun search-foo ()
  (catch 'loop
    (let ((i 0))
      (while (< i 10)
        (let ((j 0))
          (while (< j 10)
            (if (foo i j)
                (throw 'loop (list i j)))
              (setq j (1+ j))))
            (setq i (1+ i))))))
```

If `foo` ever returns non-`nil`, we stop immediately and return a list of `i` and `j`. If `foo` always returns `nil`, the `catch` returns normally, and the value is `nil`, since that is the result of the `while`.

Here are two tricky examples, slightly different, showing two return points at once. First, two return points with the same tag, `hack`:

```
(defun catch2 (tag)
  (catch tag
    (throw 'hack 'yes)))
⇒ catch2

(catch 'hack
  (print (catch2 'hack))
  'no)
⇒ yes
⇒ no
```

Since both return points have tags that match the `throw`, it goes to the inner one, the one established in `catch2`. Therefore, `catch2` returns normally with value `yes`, and this value is printed. Finally the second body form in the outer `catch`, which is '`no`', is evaluated and returned from the outer `catch`.

Now let's change the argument given to `catch2`:

```
(catch 'hack
  (print (catch2 'quux))
  'no)
⇒ yes
```

We still have two return points, but this time only the outer one has the tag `hack`; the inner one has the tag `quux` instead. Therefore, `throw` makes the outer `catch` return the value `yes`. The function `print` is never called, and the body-form '`no`' is never evaluated.

11.7.3 Errors

When Emacs Lisp attempts to evaluate a form that, for some reason, cannot be evaluated, it *signals* an *error*.

When an error is signaled, Emacs's default reaction is to print an error message and terminate execution of the current command. This is the right thing to do in most cases, such as if you type `C-f` at the end of the buffer.

In complicated programs, simple termination may not be what you want. For example, the program may have made temporary changes in data structures, or created temporary buffers that should be deleted before the program is finished. In such cases, you would use `unwind-protect` to establish *cleanup expressions* to be evaluated in case of error. (See Section 11.7.4 [Cleanups], page 187.) Occasionally, you may wish the program to continue execution despite an error in a subroutine. In these cases, you would use `condition-case` to establish *error handlers* to recover control in case of error.

For reporting problems without terminating the execution of the current command, consider issuing a warning instead. See Section 41.5 [Warnings], page 1138.

Resist the temptation to use error handling to transfer control from one part of the program to another; use `catch` and `throw` instead. See Section 11.7.1 [Catch and Throw], page 177.

11.7.3.1 How to Signal an Error

Signaling an error means beginning error processing. Error processing normally aborts all or part of the running program and returns to a point that is set up to handle the error (see Section 11.7.3.2 [Processing of Errors], page 181). Here we describe how to signal an error.

Most errors are signaled automatically within Lisp primitives which you call for other purposes, such as if you try to take the CAR of an integer or move forward a character at the end of the buffer. You can also signal errors explicitly with the functions `error` and `signal`.

Quitting, which happens when the user types *C-g*, is not considered an error, but it is handled almost like an error. See Section 22.11 [Quitting], page 471.

Every error specifies an error message, one way or another. The message should state what is wrong (“File does not exist”), not how things ought to be (“File must exist”). The convention in Emacs Lisp is that error messages should start with a capital letter, but should not end with any sort of punctuation.

error *format-string* &*rest args* [Function]

This function signals an error with an error message constructed by applying `format-message` (see Section 4.7 [Formatting Strings], page 66) to *format-string* and *args*.

These examples show typical uses of `error`:

```
(error "That is an error -- try something else")
  error That is an error -- try something else
```

```
(error "Invalid name `%" "A%%B")
  error Invalid name ‘A%%B’
```

`error` works by calling `signal` with two arguments: the error symbol `error`, and a list containing the string returned by `format-message`.

Typically grave accent and apostrophe in the format translate to matching curved quotes, e.g., “Missing ‘%s’” might result in “Missing ‘foo’”. See Section 25.4 [Text Quoting Style], page 600, for how to influence or inhibit this translation.

Warning: If you want to use your own string as an error message verbatim, don’t just write `(error string)`. If *string* contains ‘%’, ‘`’, or ‘’ it may be reformatted, with undesirable results. Instead, use `(error "%s" string)`.

When `noninteractive` is non-`nil` (see Section 42.17 [Batch Mode], page 1289), this function kills Emacs if the signaled error has no handler.

`signal` *error-symbol* *data*

[Function]

This function signals an error named by `error-symbol`. The argument `data` is a list of additional Lisp objects relevant to the circumstances of the error.

The argument `error-symbol` must be an *error symbol*—a symbol defined with `define-error`. This is how Emacs Lisp classifies different sorts of errors. See Section 11.7.3.4 [Error Symbols], page 186, for a description of error symbols, error conditions and condition names.

If the error is not handled, the two arguments are used in printing the error message. Normally, this error message is provided by the `error-message` property of `error-symbol`. If `data` is non-`nil`, this is followed by a colon and a comma separated list of the unevaluated elements of `data`. For `error`, the error message is the `CAR` of `data` (that must be a string). Subcategories of `file-error` are handled specially.

The number and significance of the objects in `data` depends on `error-symbol`. For example, with a `wrong-type-argument` error, there should be two objects in the list: a predicate that describes the type that was expected, and the object that failed to fit that type.

Both `error-symbol` and `data` are available to any error handlers that handle the error: `condition-case` binds a local variable to a list of the form `(error-symbol . data)` (see Section 11.7.3.3 [Handling Errors], page 182).

The function `signal` never returns. If the error `error-symbol` has no handler, and `noninteractive` is non-`nil` (see Section 42.17 [Batch Mode], page 1289), this function eventually kills Emacs.

```
(signal 'wrong-number-of-arguments '(x y))
[error] Wrong number of arguments: x, y

(signal 'no-such-error '("My unknown error condition"))
[error] peculiar error: "My unknown error condition"
```

`user-error` *format-string* &*rest args*

[Function]

This function behaves exactly like `error`, except that it uses the error symbol `user-error` rather than `error`. As the name suggests, this is intended to report errors on the part of the user, rather than errors in the code itself. For example, if you try to use the command `Info-history-back (1)` to move back beyond the start of your Info browsing history, Emacs signals a `user-error`. Such errors do not cause entry to the debugger, even when `debug-on-error` is non-`nil`. See Section 19.1.1 [Error Debugging], page 333.

Common Lisp note: Emacs Lisp has nothing like the Common Lisp concept of continuable errors.

11.7.3.2 How Emacs Processes Errors

When an error is signaled, `signal` searches for an active *handler* for the error. A handler is a sequence of Lisp expressions designated to be executed if an error happens in part

of the Lisp program. If the error has an applicable handler, the handler is executed, and control resumes following the handler. The handler executes in the environment of the `condition-case` that established it; all functions called within that `condition-case` have already been exited, and the handler cannot return to them.

If there is no applicable handler for the error, it terminates the current command and returns control to the editor command loop. (The command loop has an implicit handler for all kinds of errors.) The command loop's handler uses the error symbol and associated data to print an error message. You can use the variable `command-error-function` to control how this is done:

`command-error-function`

[Variable]

This variable, if non-`nil`, specifies a function to use to handle errors that return control to the Emacs command loop. The function should take three arguments: `data`, a list of the same form that `condition-case` would bind to its variable; `context`, a string describing the situation in which the error occurred, or (more often) `nil`; and `caller`, the Lisp function which called the primitive that signaled the error.

An error that has no explicit handler may call the Lisp debugger (see Section 19.1.10 [Invoking the Debugger], page 340). The debugger is enabled if the variable `debug-on-error` (see Section 19.1.1 [Error Debugging], page 333) is non-`nil`. Unlike error handlers, the debugger runs in the environment of the error, so that you can examine values of variables precisely as they were at the time of the error. In batch mode (see Section 42.17 [Batch Mode], page 1289), the Emacs process then normally exits with a non-zero exit status.

11.7.3.3 Writing Code to Handle Errors

The usual effect of signaling an error is to terminate the command that is running and return immediately to the Emacs editor command loop. You can arrange to trap errors occurring in a part of your program by establishing an error handler, with the special form `condition-case`. A simple example looks like this:

```
(condition-case nil
  (delete-file filename)
  (error nil))
```

This deletes the file named `filename`, catching any error and returning `nil` if an error occurs. (You can use the macro `ignore-errors` for a simple case like this; see below.)

The `condition-case` construct is often used to trap errors that are predictable, such as failure to open a file in a call to `insert-file-contents`. It is also used to trap errors that are totally unpredictable, such as when the program evaluates an expression read from the user.

The second argument of `condition-case` is called the *protected form*. (In the example above, the protected form is a call to `delete-file`.) The error handlers go into effect when this form begins execution and are deactivated when this form returns. They remain in effect for all the intervening time. In particular, they are in effect during the execution of functions called by this form, in their subroutines, and so on. This is a good thing, since, strictly speaking, errors can be signaled only by Lisp primitives (including `signal` and `error`) called by the protected form, not by the protected form itself.

The arguments after the protected form are handlers. Each handler lists one or more *condition names* (which are symbols) to specify which errors it will handle. The error symbol

specified when an error is signaled also defines a list of condition names. A handler applies to an error if they have any condition names in common. In the example above, there is one handler, and it specifies one condition name, `error`, which covers all errors.

The search for an applicable handler checks all the established handlers starting with the most recently established one. Thus, if two nested `condition-case` forms offer to handle the same error, the inner of the two gets to handle it.

If an error is handled by some `condition-case` form, this ordinarily prevents the debugger from being run, even if `debug-on-error` says this error should invoke the debugger.

If you want to be able to debug errors that are caught by a `condition-case`, set the variable `debug-on-signal` to a non-`nil` value. You can also specify that a particular handler should let the debugger run first, by writing `debug` among the conditions, like this:

```
(condition-case nil
  (delete-file filename)
  ((debug error) nil))
```

The effect of `debug` here is only to prevent `condition-case` from suppressing the call to the debugger. Any given error will invoke the debugger only if `debug-on-error` and the other usual filtering mechanisms say it should. See Section 19.1.1 [Error Debugging], page 333.

condition-case-unless-debug var *protected-form* *handlers...* [Macro]

The macro `condition-case-unless-debug` provides another way to handle debugging of such forms. It behaves exactly like `condition-case`, unless the variable `debug-on-error` is non-`nil`, in which case it does not handle any errors at all.

Once Emacs decides that a certain handler handles the error, it returns control to that handler. To do so, Emacs unbinds all variable bindings made by binding constructs that are being exited, and executes the cleanups of all `unwind-protect` forms that are being exited. Once control arrives at the handler, the body of the handler executes normally.

After execution of the handler body, execution returns from the `condition-case` form. Because the protected form is exited completely before execution of the handler, the handler cannot resume execution at the point of the error, nor can it examine variable bindings that were made within the protected form. All it can do is clean up and proceed.

Error signaling and handling have some resemblance to `throw` and `catch` (see Section 11.7.1 [Catch and Throw], page 177), but they are entirely separate facilities. An error cannot be caught by a `catch`, and a `throw` cannot be handled by an error handler (though using `throw` when there is no suitable `catch` signals an error that can be handled).

condition-case var *protected-form* *handlers...* [Special Form]

This special form establishes the error handlers *handlers* around the execution of *protected-form*. If *protected-form* executes without error, the value it returns becomes the value of the `condition-case` form (in the absence of a success handler; see below). In this case, the `condition-case` has no effect. The `condition-case` form makes a difference when an error occurs during *protected-form*.

Each of the *handlers* is a list of the form (*conditions* *body...*). Here *conditions* is an error condition name to be handled, or a list of condition names (which can include `debug` to allow the debugger to run before the handler). A condition name of

`t` matches any condition. `body` is one or more Lisp expressions to be executed when this handler handles an error. Here are examples of handlers:

```
(error nil)

(arith-error (message "Division by zero"))

((arith-error file-error)
 (message
  "Either division by zero or failure to open a file"))
```

Each error that occurs has an *error symbol* that describes what kind of error it is, and which describes also a list of condition names (see Section 11.7.3.4 [Error Symbols], page 186). Emacs searches all the active `condition-case` forms for a handler that specifies one or more of these condition names; the innermost matching `condition-case` handles the error. Within this `condition-case`, the first applicable handler handles the error.

After executing the body of the handler, the `condition-case` returns normally, using the value of the last form in the handler body as the overall value.

The argument `var` is a variable. `condition-case` does not bind this variable when executing the `protected-form`, only when it handles an error. At that time, it binds `var` locally to an *error description*, which is a list giving the particulars of the error. The error description has the form `(error-symbol . data)`. The handler can refer to this list to decide what to do. For example, if the error is for failure opening a file, the file name is the second element of `data`—the third element of the error description.

If `var` is `nil`, that means no variable is bound. Then the error symbol and associated data are not available to the handler.

As a special case, one of the *handlers* can be a list of the form `(:success body...)`, where `body` is executed with `var` (if non-`nil`) bound to the return value of `protected-form` when that expression terminates without error.

Sometimes it is necessary to re-throw a signal caught by `condition-case`, for some outer-level handler to catch. Here's how to do that:

```
(signal (car err) (cdr err))
```

where `err` is the error description variable, the first argument to `condition-case` whose error condition you want to re-throw. See [Definition of `signal`], page 181.

`error-message-string` `error-descriptor` [Function]

This function returns the error message string for a given error descriptor. It is useful if you want to handle an error by printing the usual error message for that error. See [Definition of `signal`], page 181.

Here is an example of using `condition-case` to handle the error that results from dividing by zero. The handler displays the error message (but without a beep), then returns a very large number.

```
(defun safe-divide (dividend divisor)
  (condition-case err
    ;; Protected form.
    (/ dividend divisor))
```

```

;; The handler.
(arith-error ; Condition.
  ;; Display the usual message for this error.
  (message "%s" (error-message-string err)
    1000000))
⇒ safe-divide

(safe-divide 5 0)
  ↓ Arithmetic error: (arith-error)
⇒ 1000000

```

The handler specifies condition name `arith-error` so that it will handle only division-by-zero errors. Other kinds of errors will not be handled (by this `condition-case`). Thus:

```
(safe-divide nil 3)
  [error] Wrong type argument: number-or-marker-p, nil
```

Here is a `condition-case` that catches all kinds of errors, including those from `error`:

```
(setq baz 34)
⇒ 34

(condition-case err
  (if (eq baz 35)
    t
    ;; This is a call to the function error.
    (error "Rats! The variable %s was %s, not 35" 'baz baz))
  ;; This is the handler; it is not a form.
  (error (princ (format "The error was: %s" err))
    2))
  ↓ The error was: (error "Rats! The variable baz was 34, not 35")
⇒ 2
```

`ignore-errors body...` [Macro]

This construct executes `body`, ignoring any errors that occur during its execution. If the execution is without error, `ignore-errors` returns the value of the last form in `body`; otherwise, it returns `nil`.

Here's the example at the beginning of this subsection rewritten using `ignore-errors`:

```
(ignore-errors
  (delete-file filename))
```

`ignore-error condition body...` [Macro]

This macro is like `ignore-errors`, but will only ignore the specific error condition specified.

```
(ignore-error end-of-file
  (read ""))
```

`condition` can also be a list of error conditions.

`with-demoted-errors format body...` [Macro]

This macro is like a milder version of `ignore-errors`. Rather than suppressing errors altogether, it converts them into messages. It uses the string `format` to format

the message. `format` should contain a single '%' -sequence; e.g., "Error: %S". Use `with-demoted-errors` around code that is not expected to signal errors, but should be robust if one does occur. Note that this macro uses `condition-case-unless-debug` rather than `condition-case`.

11.7.3.4 Error Symbols and Condition Names

When you signal an error, you specify an *error symbol* to specify the kind of error you have in mind. Each error has one and only one error symbol to categorize it. This is the finest classification of errors defined by the Emacs Lisp language.

These narrow classifications are grouped into a hierarchy of wider classes called *error conditions*, identified by *condition names*. The narrowest such classes belong to the error symbols themselves: each error symbol is also a condition name. There are also condition names for more extensive classes, up to the condition name `error` which takes in all kinds of errors (but not `quit`). Thus, each error has one or more condition names: `error`, the error symbol if that is distinct from `error`, and perhaps some intermediate classifications.

`define-error name message &optional parent` [Function]

In order for a symbol to be an error symbol, it must be defined with `define-error` which takes a parent condition (defaults to `error`). This parent defines the conditions that this kind of error belongs to. The transitive set of parents always includes the error symbol itself, and the symbol `error`. Because quitting is not considered an error, the set of parents of `quit` is just (`quit`).

In addition to its parents, the error symbol has a *message* which is a string to be printed when that error is signaled but not handled. If that message is not valid, the error message '`peculiar error`' is used. See [Definition of signal], page 181.

Internally, the set of parents is stored in the `error-conditions` property of the error symbol and the message is stored in the `error-message` property of the error symbol.

Here is how we define a new error symbol, `new-error`:

```
(define-error 'new-error "A new error" 'my-own-errors)
```

This error has several condition names: `new-error`, the narrowest classification; `my-own-errors`, which we imagine is a wider classification; and all the conditions of `my-own-errors` which should include `error`, which is the widest of all.

The error string should start with a capital letter but it should not end with a period. This is for consistency with the rest of Emacs.

Naturally, Emacs will never signal `new-error` on its own; only an explicit call to `signal` (see [Definition of signal], page 181) in your code can do this:

```
(signal 'new-error '(x y))
[error] A new error: x, y
```

This error can be handled through any of its condition names. This example handles `new-error` and any other errors in the class `my-own-errors`:

```
(condition-case foo
  (bar nil t)
  (my-own-errors nil))
```

The significant way that errors are classified is by their condition names—the names used to match errors with handlers. An error symbol serves only as a convenient way to specify the intended error message and list of condition names. It would be cumbersome to give `signal` a list of condition names rather than one error symbol.

By contrast, using only error symbols without condition names would seriously decrease the power of `condition-case`. Condition names make it possible to categorize errors at various levels of generality when you write an error handler. Using error symbols alone would eliminate all but the narrowest level of classification.

See Appendix F [Standard Errors], page 1390, for a list of the main error symbols and their conditions.

11.7.4 Cleaning Up from Nonlocal Exits

The `unwind-protect` construct is essential whenever you temporarily put a data structure in an inconsistent state; it permits you to make the data consistent again in the event of an error or throw. (Another more specific cleanup construct that is used only for changes in buffer contents is the atomic change group; Section 33.33 [Atomic Changes], page 959.)

`unwind-protect body-form cleanup-forms...` [Special Form]

`unwind-protect` executes `body-form` with a guarantee that the `cleanup-forms` will be evaluated if control leaves `body-form`, no matter how that happens. `body-form` may complete normally, or execute a `throw` out of the `unwind-protect`, or cause an error; in all cases, the `cleanup-forms` will be evaluated.

If `body-form` finishes normally, `unwind-protect` returns the value of `body-form`, after it evaluates the `cleanup-forms`. If `body-form` does not finish, `unwind-protect` does not return any value in the normal sense.

Only `body-form` is protected by the `unwind-protect`. If any of the `cleanup-forms` themselves exits nonlocally (via a `throw` or an error), `unwind-protect` is *not* guaranteed to evaluate the rest of them. If the failure of one of the `cleanup-forms` has the potential to cause trouble, then protect it with another `unwind-protect` around that form.

For example, here we make an invisible buffer for temporary use, and make sure to kill it before finishing:

```
(let ((buffer (get-buffer-create " *temp*")))
  (with-current-buffer buffer
    (unwind-protect
      body-form
      (kill-buffer buffer))))
```

You might think that we could just as well write `(kill-buffer (current-buffer))` and dispense with the variable `buffer`. However, the way shown above is safer, if `body-form` happens to get an error after switching to a different buffer! (Alternatively, you could write a `save-current-buffer` around `body-form`, to ensure that the temporary buffer becomes current again in time to kill it.)

Emacs includes a standard macro called `with-temp-buffer` which expands into more or less the code shown above (see [Current Buffer], page 673). Several of the macros defined in this manual use `unwind-protect` in this way.

Here is an actual example derived from an FTP package. It creates a process (see Chapter 40 [Processes], page 1078) to try to establish a connection to a remote machine. As the function `ftp-login` is highly susceptible to numerous problems that the writer of the function cannot anticipate, it is protected with a form that guarantees deletion of the process in the event of failure. Otherwise, Emacs might fill up with useless subprocesses.

```
(let ((win nil))
  (unwind-protect
    (progn
      (setq process (ftp-setup-buffer host file))
      (if (setq win (ftp-login process host user password))
          (message "Logged in")
          (error "Ftp login failed")))
    (or win (and process (delete-process process)))))
```

This example has a small bug: if the user types `C-g` to quit, and the quit happens immediately after the function `ftp-setup-buffer` returns but before the variable `process` is set, the process will not be killed. There is no easy way to fix this bug, but at least it is very unlikely.

12 Variables

A *variable* is a name used in a program to stand for a value. In Lisp, each variable is represented by a Lisp symbol (see Chapter 9 [Symbols], page 133). The variable name is simply the symbol’s name, and the variable’s value is stored in the symbol’s value cell¹. See Section 9.1 [Symbol Components], page 133. In Emacs Lisp, the use of a symbol as a variable is independent of its use as a function name.

As previously noted in this manual, a Lisp program is represented primarily by Lisp objects, and only secondarily as text. The textual form of a Lisp program is given by the read syntax of the Lisp objects that constitute the program. Hence, the textual form of a variable in a Lisp program is written using the read syntax for the symbol representing the variable.

12.1 Global Variables

The simplest way to use a variable is *globally*. This means that the variable has just one value at a time, and this value is in effect (at least for the moment) throughout the Lisp system. The value remains in effect until you specify a new one. When a new value replaces the old one, no trace of the old value remains in the variable.

You specify a value for a symbol with `setq`. For example,

```
(setq x '(a b))
```

gives the variable `x` the value `(a b)`. Note that `setq` is a special form (see Section 10.1.7 [Special Forms], page 149); it does not evaluate its first argument, the name of the variable, but it does evaluate the second argument, the new value.

Once the variable has a value, you can refer to it by using the symbol itself as an expression. Thus,

```
x ⇒ (a b)
```

assuming the `setq` form shown above has already been executed.

If you do set the same variable again, the new value replaces the old one:

```
x
  ⇒ (a b)
(setq x 4)
  ⇒ 4
x
  ⇒ 4
```

12.2 Variables that Never Change

In Emacs Lisp, certain symbols normally evaluate to themselves. These include `nil` and `t`, as well as any symbol whose name starts with ‘`:`’ (these are called *keywords*). These symbols cannot be rebound, nor can their values be changed. Any attempt to set or bind `nil` or `t` signals a `setting-constant` error. The same is true for a keyword (a symbol whose name

¹ To be precise, under the default *dynamic scoping* rule, the value cell always holds the variable’s current value, but this is not the case under the *lexical scoping* rule. See Section 12.10 [Variable Scoping], page 201, for details.

starts with ‘:’), if it is interned in the standard obarray, except that setting such a symbol to itself is not an error.

```
nil ≡ 'nil
      ⇒ nil
(setq nil 500)
[error] Attempt to set constant symbol: nil
```

keywordp object

[Function]

function returns **t** if *object* is a symbol whose name starts with ‘:’, interned in the standard obarray, and returns **nil** otherwise.

These constants are fundamentally different from the constants defined using the **defconst** special form (see Section 12.5 [Defining Variables], page 194). A **defconst** form serves to inform human readers that you do not intend to change the value of a variable, but Emacs does not raise an error if you actually change it.

A small number of additional symbols are made read-only for various practical reasons. These include **enable-multibyte-characters**, **most-positive-fixnum**, **most-negative-fixnum**, and a few others. Any attempt to set or bind these also signals a **setting-constant** error.

12.3 Local Variables

Global variables have values that last until explicitly superseded with new values. Sometimes it is useful to give a variable a *local value*—a value that takes effect only within a certain part of a Lisp program. When a variable has a local value, we say that it is *locally bound* to that value, and that it is a *local variable*.

For example, when a function is called, its argument variables receive local values, which are the actual arguments supplied to the function call; these local bindings take effect within the body of the function. To take another example, the **let** special form explicitly establishes local bindings for specific variables, which take effect only within the body of the **let** form.

We also speak of the *global binding*, which is where (conceptually) the global value is kept.

Establishing a local binding saves away the variable’s previous value (or lack of one). We say that the previous value is *shadowed*. Both global and local values may be shadowed. If a local binding is in effect, using **setq** on the local variable stores the specified value in the local binding. When that local binding is no longer in effect, the previously shadowed value (or lack of one) comes back.

A variable can have more than one local binding at a time (e.g., if there are nested **let** forms that bind the variable). The *current binding* is the local binding that is actually in effect. It determines the value returned by evaluating the variable symbol, and it is the binding acted on by **setq**.

For most purposes, you can think of the current binding as the innermost local binding, or the global binding if there is no local binding. To be more precise, a rule called the *scoping rule* determines where in a program a local binding takes effect. The default scoping rule in Emacs Lisp is called *dynamic scoping*, which simply states that the current binding at any given point in the execution of a program is the most recently-created binding for that

variable that still exists. For details about dynamic scoping, and an alternative scoping rule called *lexical scoping*, see Section 12.10 [Variable Scoping], page 201. Lately Emacs is moving towards using lexical binding in more and more places, with the goal of eventually making lexical binding the default. In particular, all Emacs Lisp source files and the ***scratch*** buffer use lexical scoping.

The special forms `let` and `let*` exist to create local bindings:

let (*bindings...*) *forms...* [Special Form]

This special form sets up local bindings for a certain set of variables, as specified by *bindings*, and then evaluates all of the *forms* in textual order. Its return value is the value of the last form in *forms*. The local bindings set up by `let` will be in effect only within the body of *forms*.

Each of the *bindings* is either (i) a symbol, in which case that symbol is locally bound to `nil`; or (ii) a list of the form `(symbol value-form)`, in which case *symbol* is locally bound to the result of evaluating *value-form*. If *value-form* is omitted, `nil` is used.

All of the *value-forms* in *bindings* are evaluated in the order they appear and *before* binding any of the symbols to them. Here is an example of this: *z* is bound to the old value of *y*, which is 2, not the new value of *y*, which is 1.

```
(setq y 2)
⇒ 2
```

```
(let ((y 1)
      (z y))
  (list y z))
⇒ (1 2)
```

On the other hand, the order of *bindings* is unspecified: in the following example, either 1 or 2 might be printed.

```
(let ((x 1)
      (x 2))
  (print x))
```

Therefore, avoid binding a variable more than once in a single `let` form.

let* (*bindings...*) *forms...* [Special Form]

This special form is like `let`, but it binds each variable right after computing its local value, before computing the local value for the next variable. Therefore, an expression in *bindings* can refer to the preceding symbols bound in this `let*` form. Compare the following example with the example above for `let`.

```
(setq y 2)
⇒ 2
```

```
(let* ((y 1)
       (z y)) ; Use the just-established value of y.
  (list y z))
⇒ (1 1)
```

Basically, the `let*` binding of *x* and *y* in the previous example is equivalent to using nested `let` bindings:

```
(let ((y 1))
  (let ((z y))
    (list y z)))
```

letrec (*bindings...*) *forms...* [Special Form]

This special form is like **let***, but all the variables are bound before any of the local values are computed. The values are then assigned to the locally bound variables. This is only useful when lexical binding is in effect, and you want to create closures that refer to bindings that would otherwise not yet be in effect when using **let***.

For instance, here's a closure that removes itself from a hook after being run once:

```
(letrec ((hookfun (lambda ()
                     (message "Run once")
                     (remove-hook 'post-command-hook hookfun)))
        (add-hook 'post-command-hook hookfun)))
```

dlet (*bindings...*) *forms...* [Special Form]

This special form is like **let**, but it binds all variables dynamically. This is rarely useful—you usually want to bind normal variables lexically, and special variables (i.e., variables that are defined with **defvar**) dynamically, and this is what **let** does.

dlet can be useful when interfacing with old code that assumes that certain variables are dynamically bound (see Section 12.10.1 [Dynamic Binding], page 201), but it's impractical to **defvar** these variables. **dlet** will temporarily make the bound variables special, execute the forms, and then make the variables non-special again.

named-let *name* *bindings &rest body* [Special Form]

This special form is a looping construct inspired from the Scheme language. It is similar to **let**: It binds the variables in *bindings*, and then evaluates *body*. However, **named-let** also binds *name* to a local function whose formal arguments are the variables in *bindings* and whose body is *body*. This allows *body* to call itself recursively by calling *name*, where the arguments passed to *name* are used as the new values of the bound variables in the recursive invocation.

Example of a loop summing a list of numbers:

```
(named-let sum ((numbers '(1 2 3 4))
               (running-sum 0))
  (if numbers
      (sum (cdr numbers) (+ running-sum (car numbers)))
      running-sum))
⇒ 10
```

Recursive calls to *name* that occur in *tail positions* in *body* are guaranteed to be optimized as *tail calls*, which means that they will not consume any additional stack space no matter how deeply the recursion runs. Such recursive calls will effectively jump to the top of the loop with new values for the variables.

A function call is in the tail position if it's the very last thing done so that the value returned by the call is the value of *body* itself, as is the case in the recursive call to **sum** above.

Warning: **named-let** works as expected only when lexical-binding is enabled. See Section 12.10.3 [Lexical Binding], page 203.

Here is a complete list of the other facilities that create local bindings:

- Function calls (see Chapter 13 [Functions], page 230).
- Macro calls (see Chapter 14 [Macros], page 268).
- `condition-case` (see Section 11.7.3 [Errors], page 179).

Variables can also have buffer-local bindings (see Section 12.11 [Buffer-Local Variables], page 207); a few variables have terminal-local bindings (see Section 30.2 [Multiple Terminals], page 787). These kinds of bindings work somewhat like ordinary local bindings, but they are localized depending on where you are in Emacs.

12.4 When a Variable is Void

We say that a variable is void if its symbol has an unassigned value cell (see Section 9.1 [Symbol Components], page 133).

Under Emacs Lisp's default dynamic scoping rule (see Section 12.10 [Variable Scoping], page 201), the value cell stores the variable's current (local or global) value. Note that an unassigned value cell is *not* the same as having `nil` in the value cell. The symbol `nil` is a Lisp object and can be the value of a variable, just as any other object can be; but it is still a value. If a variable is void, trying to evaluate the variable signals a `void-variable` error, instead of returning a value.

Under the optional lexical scoping rule, the value cell only holds the variable's global value—the value outside of any lexical binding construct. When a variable is lexically bound, the local value is determined by the lexical environment; hence, variables can have local values even if their symbols' value cells are unassigned.

`makunbound symbol`

[Function]

This function empties out the value cell of *symbol*, making the variable void. It returns *symbol*.

If *symbol* has a dynamic local binding, `makunbound` voids the current binding, and this voidness lasts only as long as the local binding is in effect. Afterwards, the previously shadowed local or global binding is reexposed; then the variable will no longer be void, unless the reexposed binding is void too.

Here are some examples (assuming dynamic binding is in effect):

```
(setq x 1) ; Put a value in the global binding.
             ⇒ 1
(let ((x 2)) ; Locally bind it.
  (makunbound 'x) ; Void the local binding.
  x)
error  Symbol's value as variable is void: x
x ; The global binding is unchanged.
             ⇒ 1

(let ((x 2)) ; Locally bind it.
  (let ((x 3)) ; And again.
    (makunbound 'x) ; Void the innermost-local binding.
    x))
error  Symbol's value as variable is void: x
```

```
(let ((x 2))
  (let ((x 3))
    (makunbound 'x)) ; Void inner binding, then remove it.
  x) ; Now outer let binding is visible.
⇒ 2
```

boundp variable

[Function]

This function returns `t` if `variable` (a symbol) is not void, and `nil` if it is void.

Here are some examples (assuming dynamic binding is in effect):

```
(boundp 'abracadabra) ; Starts out void.
⇒ nil
(let ((abracadabra 5)) ; Locally bind it.
  (boundp 'abracadabra))
⇒ t
(boundp 'abracadabra) ; Still globally void.
⇒ nil
(setq abracadabra 5) ; Make it globally nonvoid.
⇒ 5
(boundp 'abracadabra)
⇒ t
```

12.5 Defining Global Variables

A *variable definition* is a construct that announces your intention to use a symbol as a global variable. It uses the special forms `defvar` or `defconst`, which are documented below.

A variable definition serves three purposes. First, it informs people who read the code that the symbol is *intended* to be used a certain way (as a variable). Second, it informs the Lisp system of this, optionally supplying an initial value and a documentation string. Third, it provides information to programming tools such as `etags`, allowing them to find where the variable was defined.

The difference between `defconst` and `defvar` is mainly a matter of intent, serving to inform human readers of whether the value should ever change. Emacs Lisp does not actually prevent you from changing the value of a variable defined with `defconst`. One notable difference between the two forms is that `defconst` unconditionally initializes the variable, whereas `defvar` initializes it only if it is originally void.

To define a customizable variable, you should use `defcustom` (which calls `defvar` as a subroutine). See Section 15.3 [Variable Definitions], page 280.

defvar symbol [value [doc-string]]

[Special Form]

This special form defines `symbol` as a variable. Note that `symbol` is not evaluated; the symbol to be defined should appear explicitly in the `defvar` form. The variable is marked as *special*, meaning that it should always be dynamically bound (see Section 12.10 [Variable Scoping], page 201).

If `value` is specified, and `symbol` is void (i.e., it has no dynamically bound value; see Section 12.4 [Void Variables], page 193), then `value` is evaluated and `symbol` is set to the result. But if `symbol` is not void, `value` is not evaluated, and `symbol`'s value is left unchanged. If `value` is omitted, the value of `symbol` is not changed in any case.

Note that specifying a value, even `nil`, marks the variable as special permanently. Whereas if `value` is omitted then the variable is only marked special locally (i.e. within

the current lexical scope, or file if at the top-level). This can be useful for suppressing byte compilation warnings, see Section 17.6 [Compiler Errors], page 321.

If *symbol* has a buffer-local binding in the current buffer, `defvar` acts on the default value, which is buffer-independent, rather than the buffer-local binding. It sets the default value if the default value is void. See Section 12.11 [Buffer-Local Variables], page 207.

If *symbol* is already let bound (e.g., if the `defvar` form occurs in a `let` form), then `defvar` sets the toplevel default value, like `set-default-toplevel-value`. The let binding remains in effect until its binding construct exits. See Section 12.10 [Variable Scoping], page 201.

When you evaluate a top-level `defvar` form with *C-M-x (eval-defun)* or with *C-x C-e (eval-last-sexp)* in Emacs Lisp mode, a special feature of these two commands arranges to set the variable unconditionally, without testing whether its value is void.

If the *doc-string* argument is supplied, it specifies the documentation string for the variable (stored in the symbol's `variable-documentation` property). See Chapter 25 [Documentation], page 595.

Here are some examples. This form defines `foo` but does not initialize it:

```
(defvar foo)
⇒ foo
```

This example initializes the value of `bar` to 23, and gives it a documentation string:

```
(defvar bar 23
  "The normal weight of a bar.")
⇒ bar
```

The `defvar` form returns *symbol*, but it is normally used at top level in a file where its value does not matter.

For a more elaborate example of using `defvar` without a value, see [Local defvar example], page 205.

`defconst symbol value [doc-string]` [Special Form]

This special form defines *symbol* as a value and initializes it. It informs a person reading your code that *symbol* has a standard global value, established here, that should not be changed by the user or by other programs. Note that *symbol* is not evaluated; the symbol to be defined must appear explicitly in the `defconst`.

The `defconst` form, like `defvar`, marks the variable as *special*, meaning that it should always be dynamically bound (see Section 12.10 [Variable Scoping], page 201). In addition, it marks the variable as *risky* (see Section 12.12 [File Local Variables], page 213).

`defconst` always evaluates *value*, and sets the value of *symbol* to the result. If *symbol* does have a buffer-local binding in the current buffer, `defconst` sets the default value, not the buffer-local value. (But you should not be making buffer-local bindings for a symbol that is defined with `defconst`.)

An example of the use of `defconst` is Emacs's definition of `float-pi`—the mathematical constant *pi*, which ought not to be changed by anyone (attempts by the Indiana

State Legislature notwithstanding). As the second form illustrates, however, `defconst` is only advisory.

```
(defconst float-pi 3.141592653589793 "The value of Pi.")
      ⇒ float-pi
(setq float-pi 3)
      ⇒ float-pi
float-pi
      ⇒ 3
```

Warning: If you use a `defconst` or `defvar` special form while the variable has a local binding (made with `let`, or a function argument), it sets the local binding rather than the global binding. This is not what you usually want. To prevent this, use these special forms at top level in a file, where normally no local binding is in effect, and make sure to load the file before making a local binding for the variable.

12.6 Tips for Defining Variables Robustly

When you define a variable whose value is a function, or a list of functions, use a name that ends in ‘`-function`’ or ‘`-functions`’, respectively.

There are several other variable name conventions; here is a complete list:

‘`...-hook`’

The variable is a normal hook (see Section 24.1 [Hooks], page 524).

‘`...-function`’

The value is a function.

‘`...-functions`’

The value is a list of functions.

‘`...-form`’

The value is a form (an expression).

‘`...-forms`’

The value is a list of forms (expressions).

‘`...-predicate`’

The value is a predicate—a function of one argument that returns `non-nil` for success and `nil` for failure.

‘`...-flag`’

The value is significant only as to whether it is `nil` or not. Since such variables often end up acquiring more values over time, this convention is not strongly recommended.

‘`...-program`’

The value is a program name.

‘`...-command`’

The value is a whole shell command.

‘`...-switches`’

The value specifies options for a command.

`'prefix--...'`

The variable is intended for internal use and is defined in the file `prefix.el`. (Emacs code contributed before 2018 may follow other conventions, which are being phased out.)

`'...-internal'`

The variable is intended for internal use and is defined in C code. (Emacs code contributed before 2018 may follow other conventions, which are being phased out.)

When you define a variable, always consider whether you should mark it as safe or risky; see Section 12.12 [File Local Variables], page 213.

When defining and initializing a variable that holds a complicated value (such as a syntax table for a major mode), it's best to put the entire computation of the value into the `defvar`, like this:

```
(defvar my-major-mode-syntax-table
  (let ((table (make-syntax-table)))
    (modify-syntax-entry ?# "<" table)
    ...
    table)
  docstring)
```

This method has several benefits. First, if the user quits while loading the file, the variable is either still uninitialized or initialized properly, never in-between. If it is still uninitialized, reloading the file will initialize it properly. Second, reloading the file once the variable is initialized will not alter it; that is important if the user has changed its value. Third, evaluating the `defvar` form with `C-M-x` will reinitialize the variable completely.

12.7 Accessing Variable Values

The usual way to reference a variable is to write the symbol which names it. See Section 10.1.2 [Symbol Forms], page 146.

Occasionally, you may want to reference a variable which is only determined at run time. In that case, you cannot specify the variable name in the text of the program. You can use the `symbol-value` function to extract the value.

`symbol-value symbol`

[Function]

This function returns the value stored in `symbol`'s value cell. This is where the variable's current (dynamic) value is stored. If the variable has no local binding, this is simply its global value. If the variable is void, a `void-variable` error is signaled.

If the variable is lexically bound, the value reported by `symbol-value` is not necessarily the same as the variable's lexical value, which is determined by the lexical environment rather than the symbol's value cell. See Section 12.10 [Variable Scoping], page 201.

```
(setq abracadabra 5)
⇒ 5
(setq foo 9)
⇒ 9
```

```

;; Here the symbol abracadabra
;;   is the symbol whose value is examined.
(let ((abracadabra 'foo))
  (symbol-value 'abracadabra))
⇒ foo

;; Here, the value of abracadabra,
;;   which is foo,
;;   is the symbol whose value is examined.
(let ((abracadabra 'foo))
  (symbol-value abracadabra))
⇒ 9

(symbol-value 'abracadabra)
⇒ 5

```

12.8 Setting Variable Values

The usual way to change the value of a variable is with the special form **setq**. When you need to compute the choice of variable at run time, use the function **set**.

setq [*symbol form*]... [Special Form]

This special form is the most common method of changing a variable's value. Each *symbol* is given a new value, which is the result of evaluating the corresponding *form*. The current binding of the symbol is changed.

setq does not evaluate *symbol*; it sets the symbol that you write. We say that this argument is *automatically quoted*. The 'q' in **setq** stands for "quoted".

The value of the **setq** form is the value of the last *form*.

```

(setq x (1+ 2))
⇒ 3
x ; x now has a global value.
⇒ 3
(let ((x 5))
  (setq x 6) ; The local binding of x is set.
  x)
⇒ 6
x ; The global value is unchanged.
⇒ 3

```

Note that the first *form* is evaluated, then the first *symbol* is set, then the second *form* is evaluated, then the second *symbol* is set, and so on:

```

(setq x 10 ; Notice that x is set before
      y (1+ x)) ; the value of y is computed.
⇒ 11

```

set *symbol value* [Function]

This function puts *value* in the value cell of *symbol*. Since it is a function rather than a special form, the expression written for *symbol* is evaluated to obtain the symbol to set. The return value is *value*.

When dynamic variable binding is in effect (the default), **set** has the same effect as **setq**, apart from the fact that **set** evaluates its *symbol* argument whereas **setq** does not. But when a variable is lexically bound, **set** affects its *dynamic* value, whereas **setq** affects its current (lexical) value. See Section 12.10 [Variable Scoping], page 201.

```
(set one 1)
[error] Symbol's value as variable is void: one
(set 'one 1)
⇒ 1
(set 'two 'one)
⇒ one
(set two 2)           ; two evaluates to symbol one.
⇒ 2
one                  ; So it is one that was set.
⇒ 2
(let ((one 1))        ; This binding of one is set,
  (set 'one 3)        ;     not the global value.
  one)
⇒ 3
one
⇒ 2
```

If *symbol* is not actually a symbol, a **wrong-type-argument** error is signaled.

```
(set '(x y) 'z)
[error] Wrong type argument: symbolp, (x y)
```

setopt [*symbol form*]... [Macro]

This is like **setq** (see above), but meant for user options. This macro uses the Customize machinery to set the variable(s) (see Section 15.3 [Variable Definitions], page 280). In particular, **setopt** will run the setter function associated with the variable. For instance, if you have:

```
(defcustom my-var 1
  "My var."
  :type 'number
  :set (lambda (var val)
    (set-default var val)
    (message "We set %s to %s" var val)))
```

then the following, in addition to setting *my-var* to ‘2’, will also issue a message:

```
(setopt my-var 2)
```

setopt also checks whether the value is valid for the user option. For instance, using **setopt** to set a user option defined with a **number** type to a string will signal an error. Unlike **defcustom** and related customization commands, such as **customize-variable**, **setopt** is meant for non-interactive use, in particular in the user init file. For that

reason, it doesn't record the standard, saved, and user-set values, and doesn't mark the variable as candidate for saving in the custom file.

The `setopt` macro can be used on regular, non-user option variables, but is much less efficient than `setq`. The main use case for this macro is setting user options in the user's init file.

12.9 Running a function when a variable is changed.

It is sometimes useful to take some action when a variable changes its value. The `variable-watcher` facility provides the means to do so. Some possible uses for this feature include keeping display in sync with variable settings, and invoking the debugger to track down unexpected changes to variables (see Section 19.1.5 [Variable Debugging], page 337).

The following functions may be used to manipulate and query the watch functions for a variable.

`add-variable-watcher symbol watch-function` [Function]

This function arranges for `watch-function` to be called whenever `symbol` is modified. Modifications through aliases (see Section 12.15 [Variable Aliases], page 222) will have the same effect.

`watch-function` will be called, just before changing the value of `symbol`, with 4 arguments: `symbol`, `newval`, `operation`, and `where`. `symbol` is the variable being changed. `newval` is the value it will be changed to. (The old value is available to `watch-function` as the value of `symbol`, since it was not yet changed to `newval`.) `operation` is a symbol representing the kind of change, one of: `set`, `let`, `unlet`, `makunbound`, or `defvaralias`. `where` is a buffer if the buffer-local value of the variable is being changed, `nil` otherwise.

`remove-variable-watcher symbol watch-function` [Function]

This function removes `watch-function` from `symbol`'s list of watchers.

`get-variable-watchers symbol` [Function]

This function returns the list of `symbol`'s active watcher functions.

12.9.1 Limitations

There are a couple of ways in which a variable could be modified (or at least appear to be modified) without triggering a watchpoint.

Since watchpoints are attached to symbols, modification to the objects contained within variables (e.g., by a list modification function see Section 5.6 [Modifying Lists], page 87) is not caught by this mechanism.

Additionally, C code can modify the value of variables directly, bypassing the watchpoint mechanism.

A minor limitation of this feature, again because it targets symbols, is that only variables of dynamic scope may be watched. This poses little difficulty, since modifications to lexical variables can be discovered easily by inspecting the code within the scope of the variable (unlike dynamic variables, which can be modified by any code at all, see Section 12.10 [Variable Scoping], page 201).

12.10 Scoping Rules for Variable Bindings

When you create a local binding for a variable, that binding takes effect only within a limited portion of the program (see Section 12.3 [Local Variables], page 190). This section describes exactly what this means.

Each local binding has a certain *scope* and *extent*. *Scope* refers to *where* in the textual source code the binding can be accessed. *Extent* refers to *when*, as the program is executing, the binding exists.

By default, the local bindings that Emacs creates are *dynamic bindings*. Such a binding has *dynamic scope*, meaning that any part of the program can potentially access the variable binding. It also has *dynamic extent*, meaning that the binding lasts only while the binding construct (such as the body of a `let` form) is being executed.

Emacs can optionally create *lexical bindings*. A lexical binding has *lexical scope*, meaning that any reference to the variable must be located textually within the binding construct². It also has *indefinite extent*, meaning that under some circumstances the binding can live on even after the binding construct has finished executing, by means of special objects called *closures*.

The dynamic binding was (and still is) the default in Emacs for many years, but lately Emacs is moving towards using lexical binding in more and more places, with the goal of eventually making that the default.

The following subsections describe dynamic binding and lexical binding in greater detail, and how to enable lexical binding in Emacs Lisp programs.

12.10.1 Dynamic Binding

By default, the local variable bindings made by Emacs are dynamic bindings. When a variable is dynamically bound, its current binding at any point in the execution of the Lisp program is simply the most recently-created dynamic local binding for that symbol, or the global binding if there is no such local binding.

Dynamic bindings have dynamic scope and extent, as shown by the following example:

```
(defvar x -99) ; x receives an initial value of -99.

(defun getx ()
  x) ; x is used free in this function.

(let ((x 1)) ; x is dynamically bound.
  (getx))
  ⇒ 1

; After the let form finishes, x reverts to its
; previous value, which is -99.

(getx)
  ⇒ -99
```

² With some exceptions; for instance, a lexical binding can also be accessed from the Lisp debugger.

The function `getx` refers to `x`. This is a free reference, in the sense that there is no binding for `x` within that `defun` construct itself. When we call `getx` from within a `let` form in which `x` is (dynamically) bound, it retrieves the local value (i.e., 1). But when we call `getx` outside the `let` form, it retrieves the global value (i.e., -99).

Here is another example, which illustrates setting a dynamically bound variable using `setq`:

```
(defvar x -99)           ; x receives an initial value of -99.

(defun addx ()
  (setq x (1+ x)))    ; Add 1 to x and return its new value.

(let ((x 1))
  (addx)
  (addx))
⇒ 3                   ; The two addx calls add to x twice.

;; After the let form finishes, x reverts to its
;; previous value, which is -99.

(addx)
⇒ -98
```

Dynamic binding is implemented in Emacs Lisp in a simple way. Each symbol has a value cell, which specifies its current dynamic value (or absence of value). See Section 9.1 [Symbol Components], page 133. When a symbol is given a dynamic local binding, Emacs records the contents of the value cell (or absence thereof) in a stack, and stores the new local value in the value cell. When the binding construct finishes executing, Emacs pops the old value off the stack, and puts it in the value cell.

Note that when code using Dynamic Binding is native compiled the native compiler will not perform any Lisp specific optimization.

12.10.2 Proper Use of Dynamic Binding

Dynamic binding is a powerful feature, as it allows programs to refer to variables that are not defined within their local textual scope. However, if used without restraint, this can also make programs hard to understand. There are two clean ways to use this technique:

- If a variable has no global definition, use it as a local variable only within a binding construct, such as the body of the `let` form where the variable was bound. If this convention is followed consistently throughout a program, the value of the variable will not affect, nor be affected by, any uses of the same variable symbol elsewhere in the program.
- Otherwise, define the variable with `defvar`, `defconst` (see Section 12.5 [Defining Variables], page 194), or `defcustom` (see Section 15.3 [Variable Definitions], page 280). Usually, the definition should be at top-level in an Emacs Lisp file. As far as possible, it should include a documentation string which explains the meaning and purpose of the variable. You should also choose the variable's name to avoid name conflicts (see Section D.1 [Coding Conventions], page 1331).

Then you can bind the variable anywhere in a program, knowing reliably what the effect will be. Wherever you encounter the variable, it will be easy to refer back to the definition, e.g., via the *C-h v* command (provided the variable definition has been loaded into Emacs). See Section “Name Help” in *The GNU Emacs Manual*.

For example, it is common to use local bindings for customizable variables like `case-fold-search`:

```
(defun search-for-abc ()
  "Search for the string \"abc\", ignoring case differences."
  (let ((case-fold-search t))
    (re-search-forward "abc")))
```

12.10.3 Lexical Binding

Lexical binding was introduced to Emacs, as an optional feature, in version 24.1. We expect its importance to increase with time. Lexical binding opens up many more opportunities for optimization, so programs using it are likely to run faster in future Emacs versions. Lexical binding is also more compatible with concurrency, which was added to Emacs in version 26.1.

A lexically-bound variable has *lexical scope*, meaning that any reference to the variable must be located textually within the binding construct. Here is an example (see the next subsection, for how to actually enable lexical binding):

```
(let ((x 1))      ; x is lexically bound.
  (+ x 3))
  ⇒ 4

(defun getx ()
  x)                  ; x is used free in this function.

(let ((x 1))      ; x is lexically bound.
  (getx))
  [error] Symbol's value as variable is void: x
```

Here, the variable `x` has no global value. When it is lexically bound within a `let` form, it can be used in the textual confines of that `let` form. But it can *not* be used from within a `getx` function called from the `let` form, since the function definition of `getx` occurs outside the `let` form itself.

Here is how lexical binding works. Each binding construct defines a *lexical environment*, specifying the variables that are bound within the construct and their local values. When the Lisp evaluator wants the current value of a variable, it looks first in the lexical environment; if the variable is not specified in there, it looks in the symbol’s value cell, where the dynamic value is stored.

(Internally, the lexical environment is a list whose members are usually cons cells that are symbol-value pairs, but some of its members can be symbols rather than cons cells. A symbol in the list means the lexical environment declared that symbol’s variable as locally considered to be dynamically bound. This list can be passed as the second argument to the `eval` function, in order to specify a lexical environment in which to evaluate a form.)

See Section 10.4 [Eval], page 152. Most Emacs Lisp programs, however, should not interact directly with lexical environments in this way; only specialized programs like debuggers.)

Lexical bindings have indefinite extent. Even after a binding construct has finished executing, its lexical environment can be “kept around” in Lisp objects called *closures*. A closure is created when you define a named or anonymous function with lexical binding enabled. See Section 13.10 [Closures], page 249, for details.

When a closure is called as a function, any lexical variable references within its definition use the retained lexical environment. Here is an example:

```
(defvar my-ticker nil)      ; We will use this dynamically bound
                           ; variable to store a closure.

(let ((x 0))                ; x is lexically bound.
  (setq my-ticker (lambda ()
    (setq x (1+ x)))))
  ⇒ (closure ((x . 0)) ())
  (setq x (1+ x)))

(funcall my-ticker)
⇒ 1

(funcall my-ticker)
⇒ 2

(funcall my-ticker)
⇒ 3

x                         ; Note that x has no global value.
[error] Symbol's value as variable is void: x
```

The `let` binding defines a lexical environment in which the variable `x` is locally bound to 0. Within this binding construct, we define a lambda expression which increments `x` by one and returns the incremented value. This lambda expression is automatically turned into a closure, in which the lexical environment lives on even after the `let` binding construct has exited. Each time we evaluate the closure, it increments `x`, using the binding of `x` in that lexical environment.

Note that unlike dynamic variables which are tied to the symbol object itself, the relationship between lexical variables and symbols is only present in the interpreter (or compiler). Therefore, functions which take a symbol argument (like `symbol-value`, `boundp`, and `set`) can only retrieve or modify a variable’s dynamic binding (i.e., the contents of its symbol’s value cell).

12.10.4 Using Lexical Binding

When loading an Emacs Lisp file or evaluating a Lisp buffer, lexical binding is enabled if the buffer-local variable `lexical-binding` is non-nil:

lexical-binding [Variable]

If this buffer-local variable is non-`nil`, Emacs Lisp files and buffers are evaluated using lexical binding instead of dynamic binding. (However, special variables are still dynamically bound; see below.) If `nil`, dynamic binding is used for all local variables. This variable is typically set for a whole Emacs Lisp file, as a file local variable (see Section 12.12 [File Local Variables], page 213). Note that unlike other such variables, this one must be set in the first line of a file.

When evaluating Emacs Lisp code directly using an `eval` call, lexical binding is enabled if the `lexical` argument to `eval` is non-`nil`. See Section 10.4 [Eval], page 152.

Lexical binding is also enabled in Lisp Interaction and IELM mode, used in the `*scratch*` and `*ielm*` buffers, and also when evaluating expressions via `M-:` (`eval-expression`) and when processing the `--eval` command-line options of Emacs (see Section “Action Arguments” in *The GNU Emacs Manual*) and `emacsclient` (see Section “emacsclient Options” in *The GNU Emacs Manual*).

Even when lexical binding is enabled, certain variables will continue to be dynamically bound. These are called *special variables*. Every variable that has been defined with `defvar`, `defcustom` or `defconst` is a special variable (see Section 12.5 [Defining Variables], page 194). All other variables are subject to lexical binding.

Using `defvar` without a value, it is possible to bind a variable dynamically just in one file, or in just one part of a file while still binding it lexically elsewhere. For example:

```
(let (_)
  (defvar x)      ; Let-bindings of x will be dynamic within this let.
  (let ((x -99)) ; This is a dynamic binding of x.
    (defun get-dynamic-x ()
      x))

(let ((x 'lexical)) ; This is a lexical binding of x.
  (defun get-lexical-x ()
    x))

(let (_)
  (defvar x)
  (let ((x 'dynamic))
    (list (get-lexical-x)
          (get-dynamic-x)))
  ⇒ (lexical dynamic))
```

special-variable-p symbol [Function]

This function returns non-`nil` if `symbol` is a special variable (i.e., it has a `defvar`, `defcustom`, or `defconst` variable definition). Otherwise, the return value is `nil`.

Note that since this is a function, it can only return non-`nil` for variables which are permanently special, but not for those that are only special in the current lexical scope.

The use of a special variable as a formal argument in a function is not supported.

12.10.5 Converting to Lexical Binding

Converting an Emacs Lisp program to lexical binding is easy. First, add a file-local variable setting of `lexical-binding` to `t` in the header line of the Emacs Lisp source file (see Section 12.12 [File Local Variables], page 213). Second, check that every variable in the program which needs to be dynamically bound has a variable definition, so that it is not inadvertently bound lexically.

A simple way to find out which variables need a variable definition is to byte-compile the source file. See Chapter 17 [Byte Compilation], page 316. If a non-special variable is used outside of a `let` form, the byte-compiler will warn about reference or assignment to a free variable. If a non-special variable is bound but not used within a `let` form, the byte-compiler will warn about an unused lexical variable. The byte-compiler will also issue a warning if you use a special variable as a function argument.

A warning about a reference or an assignment to a free variable is usually a clear sign that that variable should be marked as dynamically scoped, so you need to add an appropriate `defvar` before the first use of that variable.

A warning about an unused variable may be a good hint that the variable was intended to be dynamically scoped (because it is actually used, but in another function), but it may also be an indication that the variable is simply really not used and could simply be removed. So you need to find out which case it is, and based on that, either add a `defvar` or remove the variable altogether. If removal is not possible or not desirable (typically because it is a formal argument and that we cannot or don't want to change all the callers), you can also add a leading underscore to the variable's name to indicate to the compiler that this is a variable known not to be used.)

Cross-file variable checking

Caution: This is an experimental feature that may change or disappear without prior notice.

The byte-compiler can also warn about lexical variables that are special in other Emacs Lisp files, often indicating a missing `defvar` declaration. This useful but somewhat specialized check requires three steps:

1. Byte-compile all files whose special variable declarations may be of interest, with the environment variable `EMACS_GENERATE_DYNVARS` set to a nonempty string. These are typically all the files in the same package or related packages or Emacs subsystems. The process will generate a file whose name ends in `.dynvars` for each compiled Emacs Lisp file.
2. Concatenate the `.dynvars` files into a single file.
3. Byte-compile the files that need to be checked, this time with the environment variable `EMACS_DYNVARS_FILE` set to the name of the aggregated file created in step 2.

Here is an example illustrating how this could be done, assuming that a Unix shell and `make` are used for byte-compilation:

```
$ rm *.elc                                # force recompilation
$ EMACS_GENERATE_DYNVARS=1 make             # generate .dynvars
$ cat *.dynvars > ~/my-dynvars              # combine .dynvars
$ rm *.elc                                # force recompilation
$ EMACS_DYNVARS_FILE=~/my-dynvars make      # perform checks
```

12.11 Buffer-Local Variables

Global and local variable bindings are found in most programming languages in one form or another. Emacs, however, also supports additional, unusual kinds of variable binding, such as *buffer-local* bindings, which apply only in one buffer. Having different values for a variable in different buffers is an important customization method. (Variables can also have bindings that are local to each terminal. See Section 30.2 [Multiple Terminals], page 787.)

12.11.1 Introduction to Buffer-Local Variables

A buffer-local variable has a buffer-local binding associated with a particular buffer. The binding is in effect when that buffer is current; otherwise, it is not in effect. If you set the variable while a buffer-local binding is in effect, the new value goes in that binding, so its other bindings are unchanged. This means that the change is visible only in the buffer where you made it.

The variable's ordinary binding, which is not associated with any specific buffer, is called the *default binding*. In most cases, this is the global binding.

A variable can have buffer-local bindings in some buffers but not in other buffers. The default binding is shared by all the buffers that don't have their own bindings for the variable. (This includes all newly-created buffers.) If you set the variable in a buffer that does not have a buffer-local binding for it, this sets the default binding, so the new value is visible in all the buffers that see the default binding.

The most common use of buffer-local bindings is for major modes to change variables that control the behavior of commands. For example, C mode and Lisp mode both set the variable `paragraph-start` to specify that only blank lines separate paragraphs. They do this by making the variable buffer-local in the buffer that is being put into C mode or Lisp mode, and then setting it to the new value for that mode. See Section 24.2 [Major Modes], page 526.

The usual way to make a buffer-local binding is with `make-local-variable`, which is what major mode commands typically use. This affects just the current buffer; all other buffers (including those yet to be created) will continue to share the default value unless they are explicitly given their own buffer-local bindings.

A more powerful operation is to mark the variable as *automatically buffer-local* by calling `make-variable-buffer-local`. You can think of this as making the variable local in all buffers, even those yet to be created. More precisely, the effect is that setting the variable automatically makes the variable local to the current buffer if it is not already so. All buffers start out by sharing the default value of the variable as usual, but setting the variable creates a buffer-local binding for the current buffer. The new value is stored in the buffer-local binding, leaving the default binding untouched. This means that the default value cannot be changed with `setq` in any buffer; the only way to change it is with `setq-default`.

Warning: When a variable has buffer-local bindings in one or more buffers, `let` rebinds the binding that's currently in effect. For instance, if the current buffer has a buffer-local value, `let` temporarily rebinds that. If no buffer-local bindings are in effect, `let` rebinds the default value. If inside the `let` you then change to a different current buffer in which a different binding is in effect, you won't see the `let` binding any more. And if you exit the `let` while still in the other buffer, you won't see the unbinding occur (though it will occur properly). Here is an example to illustrate:

```
(setq foo 'g)
(set-buffer "a")
(make-local-variable 'foo)
(setq foo 'a)
(let ((foo 'temp))
  ;; foo ⇒ 'temp ; let binding in buffer 'a'
  (set-buffer "b")
  ;; foo ⇒ 'g      ; the global value since foo is not local in 'b'
  body...)
foo ⇒ 'g          ; exiting restored the local value in buffer 'a',
                     ; but we don't see that in buffer 'b'
(set-buffer "a") ; verify the local value was restored
foo ⇒ 'a
```

Note that references to `foo` in `body` access the buffer-local binding of buffer ‘`b`’.

When a file specifies local variable values, these become buffer-local values when you visit the file. See Section “File Variables” in *The GNU Emacs Manual*.

A buffer-local variable cannot be made terminal-local (see Section 30.2 [Multiple Terminals], page 787).

12.11.2 Creating and Deleting Buffer-Local Bindings

`make-local-variable variable` [Command]
 This function creates a buffer-local binding in the current buffer for `variable` (a symbol). Other buffers are not affected. The value returned is `variable`.

The buffer-local value of `variable` starts out as the same value `variable` previously had. If `variable` was void, it remains void.

```
; ; In buffer 'b1':
(setq foo 5)                      ; Affects all buffers.
⇒ 5
(make-local-variable 'foo)    ; Now it is local in 'b1'.
⇒ foo
foo                         ; That did not change
⇒ 5                         ; the value.
(setq foo 6)                      ; Change the value
⇒ 6                         ; in 'b1'.
foo
⇒ 6

; ; In buffer 'b2', the value hasn't changed.
(with-current-buffer "b2"
  foo)
⇒ 5
```

Making a variable buffer-local within a `let`-binding for that variable does not work reliably, unless the buffer in which you do this is not current either on entry to or exit from the `let`. This is because `let` does not distinguish between different kinds of bindings; it knows only which variable the binding was made for.

It is an error to make a constant or a read-only variable buffer-local. See Section 12.2 [Constant Variables], page 189.

If the variable is terminal-local (see Section 30.2 [Multiple Terminals], page 787), this function signals an error. Such variables cannot have buffer-local bindings as well.

Warning: do not use `make-local-variable` for a hook variable. The hook variables are automatically made buffer-local as needed if you use the `local` argument to `add-hook` or `remove-hook`.

`setq-local &rest pairs`

[Macro]

`pairs` is a list of variable and value pairs. This macro creates a buffer-local binding in the current buffer for each of the variables, and gives them a buffer-local value. It is equivalent to calling `make-local-variable` followed by `setq` for each of the variables. The variables should be unquoted symbols.

```
(setq-local var1 "value1"
           var2 "value2")
```

`make-variable-buffer-local variable`

[Command]

This function marks `variable` (a symbol) automatically buffer-local, so that any subsequent attempt to set it will make it local to the current buffer at the time. Unlike `make-local-variable`, with which it is often confused, this cannot be undone, and affects the behavior of the variable in all buffers.

A peculiar wrinkle of this feature is that binding the variable (with `let` or other binding constructs) does not create a buffer-local binding for it. Only setting the variable (with `set` or `setq`), while the variable does not have a `let`-style binding that was made in the current buffer, does so.

If `variable` does not have a default value, then calling this command will give it a default value of `nil`. If `variable` already has a default value, that value remains unchanged. Subsequently calling `makunbound` on `variable` will result in a void buffer-local value and leave the default value unaffected.

The value returned is `variable`.

It is an error to make a constant or a read-only variable buffer-local. See Section 12.2 [Constant Variables], page 189.

Warning: Don't assume that you should use `make-variable-buffer-local` for user-option variables, simply because users *might* want to customize them differently in different buffers. Users can make any variable local, when they wish to. It is better to leave the choice to them.

The time to use `make-variable-buffer-local` is when it is crucial that no two buffers ever share the same binding. For example, when a variable is used for internal purposes in a Lisp program which depends on having separate values in separate buffers, then using `make-variable-buffer-local` can be the best solution.

`defvar-local variable value &optional docstring`

[Macro]

This macro defines `variable` as a variable with initial value `value` and `docstring`, and marks it as automatically buffer-local. It is equivalent to calling `defvar` followed by `make-variable-buffer-local`. `variable` should be an unquoted symbol.

local-variable-p variable &optional buffer [Function]

This returns t if variable is buffer-local in buffer buffer (which defaults to the current buffer); otherwise, nil.

local-variable-if-set-p variable &optional buffer [Function]

This returns t if variable either has a buffer-local value in buffer buffer, or is automatically buffer-local. Otherwise, it returns nil. If omitted or nil, buffer defaults to the current buffer.

buffer-local-value variable buffer [Function]

This function returns the buffer-local binding of variable (a symbol) in buffer buffer. If variable does not have a buffer-local binding in buffer buffer, it returns the default value (see Section 12.11.3 [Default Value], page 211) of variable instead.

buffer-local-boundp variable buffer [Function]

This returns non-nil if there's either a buffer-local binding of variable (a symbol) in buffer buffer, or variable has a global binding.

buffer-local-variables &optional buffer [Function]

This function returns a list describing the buffer-local variables in buffer buffer. (If buffer is omitted, the current buffer is used.) Normally, each list element has the form (sym . val), where sym is a buffer-local variable (a symbol) and val is its buffer-local value. But when a variable's buffer-local binding in buffer is void, its list element is just sym.

```
(make-local-variable 'foobar)
(makunbound 'foobar)
(make-local-variable 'bind-me)
(setq bind-me 69)
(setq lcl (buffer-local-variables))
  ; First, built-in variables local in all buffers:
⇒ ((mark-active . nil)
  (buffer-undo-list . nil)
  (mode-name . "Fundamental"))

...
  ; Next, non-built-in buffer-local variables.
  ; This one is buffer-local and void:
foobar
  ; This one is buffer-local and nonvoid:
(bind-me . 69))
```

Note that storing new values into the CDRs of cons cells in this list does *not* change the buffer-local values of the variables.

kill-local-variable variable [Command]

This function deletes the buffer-local binding (if any) for variable (a symbol) in the current buffer. As a result, the default binding of variable becomes visible in this buffer. This typically results in a change in the value of variable, since the default value is usually different from the buffer-local value just eliminated.

If you kill the buffer-local binding of a variable that automatically becomes buffer-local when set, this makes the default value visible in the current buffer. However, if you set the variable again, that will once again create a buffer-local binding for it.

`kill-local-variable` returns *variable*.

This function is a command because it is sometimes useful to kill one buffer-local variable interactively, just as it is useful to create buffer-local variables interactively.

kill-all-local-variables &optional *kill-permanent* [Function]

This function eliminates all the buffer-local variable bindings of the current buffer. As a result, the buffer will see the default values of most variables. By default, for variables marked as permanent and local hook functions that have a non-*nil* `permanent-local-hook` property (see Section 24.1.2 [Setting Hooks], page 525) won't be killed, but if the optional `kill-permanent` argument is non-*nil*, even these variables will be killed.

This function also resets certain other information pertaining to the buffer: it sets the local keymap to `nil`, the syntax table to the value of `(standard-syntax-table)`, the case table to `(standard-case-table)`, and the abbrev table to the value of `fundamental-mode-abbrev-table`.

The very first thing this function does is run the normal hook `change-major-mode-hook` (see below).

Every major mode command begins by calling this function, which has the effect of switching to Fundamental mode and erasing most of the effects of the previous major mode. To ensure that this does its job, the variables that major modes set should not be marked permanent.

`kill-all-local-variables` returns `nil`.

change-major-mode-hook [Variable]

The function `kill-all-local-variables` runs this normal hook before it does anything else. This gives major modes a way to arrange for something special to be done if the user switches to a different major mode. It is also useful for buffer-specific minor modes that should be forgotten if the user changes the major mode.

For best results, make this variable buffer-local, so that it will disappear after doing its job and will not interfere with the subsequent major mode. See Section 24.1 [Hooks], page 524.

A buffer-local variable is *permanent* if the variable name (a symbol) has a `permanent-local` property that is non-*nil*. Such variables are unaffected by `kill-all-local-variables`, and their local bindings are therefore not cleared by changing major modes. Permanent locals are appropriate for data pertaining to where the file came from or how to save it, rather than with how to edit the contents.

12.11.3 The Default Value of a Buffer-Local Variable

The global value of a variable with buffer-local bindings is also called the *default* value, because it is the value that is in effect whenever neither the current buffer nor the selected frame has its own binding for the variable.

The functions `default-value` and `setq-default` access and change a variable's default value regardless of whether the current buffer has a buffer-local binding. For example, you could use `setq-default` to change the default setting of `paragraph-start` for most buffers; and this would work even when you are in a C or Lisp mode buffer that has a buffer-local value for this variable.

The special forms `defvar` and `defconst` also set the default value (if they set the variable at all), rather than any buffer-local value.

`default-value symbol`

[Function]

This function returns *symbol*'s default value. This is the value that is seen in buffers and frames that do not have their own values for this variable. If *symbol* is not buffer-local, this is equivalent to `symbol-value` (see Section 12.7 [Accessing Variables], page 197).

`default-boundp symbol`

[Function]

The function `default-boundp` tells you whether *symbol*'s default value is nonvoid. If `(default-boundp 'foo)` returns `nil`, then `(default-value 'foo)` would get an error.

`default-boundp` is to `default-value` as `boundp` is to `symbol-value`.

`setq-default [symbol form]...`

[Special Form]

This special form gives each *symbol* a new default value, which is the result of evaluating the corresponding *form*. It does not evaluate *symbol*, but does evaluate *form*. The value of the `setq-default` form is the value of the last *form*.

If a *symbol* is not buffer-local for the current buffer, and is not marked automatically buffer-local, `setq-default` has the same effect as `setq`. If *symbol* is buffer-local for the current buffer, then this changes the value that other buffers will see (as long as they don't have a buffer-local value), but not the value that the current buffer sees.

```
;; In buffer 'foo':
(make-local-variable 'buffer-local)
⇒ buffer-local
(setq buffer-local 'value-in-foo)
⇒ value-in-foo
(setq-default buffer-local 'new-default)
⇒ new-default
buffer-local
⇒ value-in-foo
(default-value 'buffer-local)
⇒ new-default

;; In (the new) buffer 'bar':
buffer-local
⇒ new-default
(default-value 'buffer-local)
⇒ new-default
(setq buffer-local 'another-default)
⇒ another-default
```

```
(default-value 'buffer-local)
  ⇒ another-default

;; Back in buffer ‘foo’:
buffer-local
  ⇒ value-in-foo
(default-value 'buffer-local)
  ⇒ another-default
```

set-default symbol value [Function]

This function is like `setq-default`, except that *symbol* is an ordinary evaluated argument.

```
(set-default (car '(a b c)) 23)
  ⇒ 23
(default-value 'a)
  ⇒ 23
```

A variable can be let-bound (see Section 12.3 [Local Variables], page 190) to a value. This makes its global value shadowed by the binding; `default-value` will then return the value from that binding, not the global value, and `set-default` will be prevented from setting the global value (it will change the let-bound value instead). The following two functions allow to reference the global value even if it’s shadowed by a let-binding.

default-toplevel-value symbol [Function]

This function returns the *top-level* default value of *symbol*, which is its value outside of any let-binding.

```
(defvar variable 'global-value)
  ⇒ variable
(let ((variable 'let-binding))
  (default-value 'variable))
  ⇒ let-binding
(let ((variable 'let-binding))
  (default-toplevel-value 'variable))
  ⇒ global-value
```

set-default-toplevel-value symbol value [Function]

This function sets the top-level default value of *symbol* to the specified *value*. This comes in handy when you want to set the global value of *symbol* regardless of whether your code runs in the context of *symbol*’s let-binding.

12.12 File Local Variables

A file can specify local variable values; Emacs uses these to create buffer-local bindings for those variables in the buffer visiting that file. See Section “Local Variables in Files” in *The GNU Emacs Manual*, for basic information about file-local variables. This section describes the functions and variables that affect how file-local variables are processed.

If a file-local variable could specify an arbitrary function or Lisp expression that would be called later, visiting a file could take over your Emacs. Emacs protects against this by

automatically setting only those file-local variables whose specified values are known to be safe. Other file-local variables are set only if the user agrees.

For additional safety, `read-circle` is temporarily bound to `nil` when Emacs reads file-local variables (see Section 20.3 [Input Functions], page 374). This prevents the Lisp reader from recognizing circular and shared Lisp structures (see Section 2.6 [Circular Objects], page 30).

`enable-local-variables`

[User Option]

This variable controls whether to process file-local variables. The possible values are:

`t` (the default)

Set the safe variables, and query (once) about any unsafe variables.

`:safe`

Set only the safe variables and do not query.

`:all`

Set all the variables and do not query.

`nil`

Don't set any variables.

anything else

Query (once) about all the variables.

`inhibit-local-variables-regexp`

[Variable]

This is a list of regular expressions. If a file has a name matching an element of this list, then it is not scanned for any form of file-local variable. For examples of why you might want to use this, see Section 24.2.2 [Auto Major Mode], page 531.

`permanently-enabled-local-variables`

[Variable]

Some local variable settings will, by default, be heeded even if `enable-local-variables` is `nil`. By default, this is only the case for the `lexical-binding` local variable setting, but this can be controlled by using this variable, which is a list of symbols.

`hack-local-variables` &optional `handle-mode`

[Function]

This function parses, and binds or evaluates as appropriate, any local variables specified by the contents of the current buffer. The variable `enable-local-variables` has its effect here. However, this function does not look for the ‘`mode:`’ local variable in the ‘`-*-`’ line. `set-auto-mode` does that, also taking `enable-local-variables` into account (see Section 24.2.2 [Auto Major Mode], page 531).

This function works by walking the alist stored in `file-local-variables-alist` and applying each local variable in turn. It calls `before-hack-local-variables-hook` and `hack-local-variables-hook` before and after applying the variables, respectively. It only calls the before-hook if the alist is non-`nil`; it always calls the other hook. This function ignores a ‘`mode`’ element if it specifies the same major mode as the buffer already has.

If the optional argument `handle-mode` is `t`, then all this function does is return a symbol specifying the major mode, if the ‘`-*-`’ line or the local variables list specifies one, and `nil` otherwise. It does not set the mode or any other file-local variable. If `handle-mode` has any value other than `nil` or `t`, any settings of ‘`mode`’ in the ‘`-*-`’ line or the local variables list are ignored, and the other settings are applied. If `handle-mode` is `nil`, all the file local variables are set.

file-local-variables-alist [Variable]

This buffer-local variable holds the alist of file-local variable settings. Each element of the alist is of the form `(var . value)`, where `var` is a symbol of the local variable and `value` is its value. When Emacs visits a file, it first collects all the file-local variables into this alist, and then the `hack-local-variables` function applies them one by one.

before-hack-local-variables-hook [Variable]

Emacs calls this hook immediately before applying file-local variables stored in `file-local-variables-alist`.

hack-local-variables-hook [Variable]

Emacs calls this hook immediately after it finishes applying file-local variables stored in `file-local-variables-alist`.

You can specify safe values for a variable with a `safe-local-variable` property. The property has to be a function of one argument; any value is safe if the function returns `non-nil` given that value. Many commonly-encountered file variables have `safe-local-variable` properties; these include `fill-column`, `fill-prefix`, and `indent-tabs-mode`. For boolean-valued variables that are safe, use `booleanp` as the property value.

If you want to define `safe-local-variable` properties for variables defined in C source code, add the names and the properties of those variables to the list in the “Safe local variables” section of `files.el`.

When defining a user option using `defcustom`, you can set its `safe-local-variable` property by adding the arguments `:safe function` to `defcustom` (see Section 15.3 [Variable Definitions], page 280). However, a safety predicate defined using `:safe` will only be known once the package that contains the `defcustom` is loaded, which is often too late. As an alternative, you can use the autoload cookie (see Section 16.5 [Autoload], page 304) to assign the option its safety predicate, like this:

```
;;;autoload (put 'var 'safe-local-variable 'pred)
```

The safe value definitions specified with `autoload` are copied into the package’s autoloads file (`loaddefs.el` for most packages bundled with Emacs), and are known to Emacs since the beginning of a session.

safe-local-variable-values [User Option]

This variable provides another way to mark some variable values as safe. It is a list of cons cells `(var . val)`, where `var` is a variable name and `val` is a value which is safe for that variable.

When Emacs asks the user whether or not to obey a set of file-local variable specifications, the user can choose to mark them as safe. Doing so adds those variable/value pairs to `safe-local-variable-values`, and saves it to the user’s custom file.

ignored-local-variable-values [User Option]

If there are some values of particular local variables that you always want to ignore completely, you can use this variable. Its value has the same form as `safe-local-variable-values`; a file-local variable setting to the value that appears in the list will always be ignored when processing the local variables specified by the file. As with

that variable, when Emacs queries the user about whether to obey file-local variables, the user can choose to ignore their particular values permanently, and that will alter this variable and save it to the user's custom file. Variable-value pairs that appear in this variable take precedence over the same pairs in `safe-local-variable-values`.

safe-local-variable-p *sym val* [Function]

This function returns non-`nil` if it is safe to give *sym* the value *val*, based on the above criteria.

Some variables are considered *risky*. If a variable is risky, it is never entered automatically into `safe-local-variable-values`; Emacs always queries before setting a risky variable, unless the user explicitly allows a value by customizing `safe-local-variable-values` directly.

Any variable whose name has a non-`nil` `risky-local-variable` property is considered risky. When you define a user option using `defcustom`, you can set its `risky-local-variable` property by adding the arguments `:risky value` to `defcustom` (see Section 15.3 [Variable Definitions], page 280). In addition, any variable whose name ends in any of ‘`-command`’, ‘`-frame-alist`’, ‘`-function`’, ‘`-functions`’, ‘`-hook`’, ‘`-hooks`’, ‘`-form`’, ‘`-forms`’, ‘`-map`’, ‘`-map-alist`’, ‘`-mode-alist`’, ‘`-program`’, or ‘`-predicate`’ is automatically considered risky. The variables ‘`font-lock-keywords`’, ‘`font-lock-keywords`’ followed by a digit, and ‘`font-lock-syntactic-keywords`’ are also considered risky.

risky-local-variable-p *sym* [Function]

This function returns non-`nil` if *sym* is a risky variable, based on the above criteria.

ignored-local-variables [Variable]

This variable holds a list of variables that should not be given local values by files. Any value specified for one of these variables is completely ignored.

The ‘`Eval:`’ “variable” is also a potential loophole, so Emacs normally asks for confirmation before handling it.

enable-local-eval [User Option]

This variable controls processing of ‘`Eval:`’ in ‘`-*-`’ lines or local variables lists in files being visited. A value of `t` means process them unconditionally; `nil` means ignore them; anything else means ask the user what to do for each file. The default value is `maybe`.

safe-local-eval-forms [User Option]

This variable holds a list of expressions that are safe to evaluate when found in the ‘`Eval:`’ “variable” in a file local variables list.

If the expression is a function call and the function has a `safe-local-eval-function` property, the property value determines whether the expression is safe to evaluate. The property value can be a predicate to call to test the expression, a list of such predicates (it's safe if any predicate succeeds), or `t` (always safe provided the arguments are constant).

Text properties are also potential loopholes, since their values could include functions to call. So Emacs discards all text properties from string values specified for file-local variables.

12.13 Directory Local Variables

A directory can specify local variable values common to all files in that directory; Emacs uses these to create buffer-local bindings for those variables in buffers visiting any file in that directory. This is useful when the files in the directory belong to some *project* and therefore share the same local variables.

There are two different methods for specifying directory local variables: by putting them in a special file, or by defining a *project class* for that directory.

dir-locals-file [Constant]

This constant is the name of the file where Emacs expects to find the directory-local variables. The name of the file is `.dir-locals.el`³. A file by that name in a directory causes Emacs to apply its settings to any file in that directory or any of its subdirectories (optionally, you can exclude subdirectories; see below). If some of the subdirectories have their own `.dir-locals.el` files, Emacs uses the settings from the deepest file it finds starting from the file's directory and moving up the directory tree. This constant is also used to derive the name of a second dir-locals file `.dir-locals-2.el`. If this second dir-locals file is present, then that is loaded in addition to `.dir-locals.el`. This is useful when `.dir-locals.el` is under version control in a shared repository and cannot be used for personal customizations. The file specifies local variables as a specially formatted list; see Section “Per-directory Local Variables” in *The GNU Emacs Manual*, for more details.

hack-dir-local-variables [Function]

This function reads the `.dir-locals.el` file and stores the directory-local variables in `file-local-variables-alist` that is local to the buffer visiting any file in the directory, without applying them. It also stores the directory-local settings in `dir-locals-class-alist`, where it defines a special class for the directory in which `.dir-locals.el` file was found. This function works by calling `dir-locals-set-class-variables` and `dir-locals-set-directory-class`, described below.

hack-dir-local-variables-non-file-buffer [Function]

This function looks for directory-local variables, and immediately applies them in the current buffer. It is intended to be called in the mode commands for non-file buffers, such as Dired buffers, to let them obey directory-local variable settings. For non-file buffers, Emacs looks for directory-local variables in `default-directory` and its parent directories.

dir-locals-set-class-variables class variables [Function]

This function defines a set of variable settings for the named `class`, which is a symbol. You can later assign the class to one or more directories, and Emacs will apply those variable settings to all files in those directories. The list in `variables` can be of one of the two forms: `(major-mode . alist)` or `(directory . list)`. With the first form, if the file's buffer turns on a mode that is derived from `major-mode`, then all the variables in the associated `alist` are applied; `alist` should be of the form `(name . value)`. A special value `nil` for `major-mode` means the settings are applicable to any mode. In

³ The MS-DOS version of Emacs uses `_dir-locals.el` instead, due to limitations of the DOS filesystems.

alist, you can use a special name: `subdirs`. If the associated value is `nil`, the *alist* is only applied to files in the relevant directory, not to those in any subdirectories.

With the second form of `variables`, if `directory` is the initial substring of the file's directory, then `list` is applied recursively by following the above rules; `list` should be of one of the two forms accepted by this function in `variables`.

`dir-locals-set-directory-class` *directory class &optional mtime* [Function]

This function assigns `class` to all the files in `directory` and its subdirectories. Thereafter, all the variable settings specified for `class` will be applied to any visited file in `directory` and its children. `class` must have been already defined by `dir-locals-set-class-variables`.

Emacs uses this function internally when it loads directory variables from a `.dir-locals.el` file. In that case, the optional argument `mtime` holds the file modification time (as returned by `file-attributes`). Emacs uses this time to check stored local variables are still valid. If you are assigning a class directly, not via a file, this argument should be `nil`.

`dir-locals-class-alist` [Variable]

This *alist* holds the class symbols and the associated variable settings. It is updated by `dir-locals-set-class-variables`.

`dir-locals-directory-cache` [Variable]

This *alist* holds directory names, their assigned class names, and modification times of the associated directory local variables file (if there is one). The function `dir-locals-set-directory-class` updates this list.

`enable-dir-local-variables` [Variable]

If `nil`, directory-local variables are ignored. This variable may be useful for modes that want to ignore directory-locals while still respecting file-local variables (see Section 12.12 [File Local Variables], page 213).

12.14 Connection Local Variables

Connection-local variables provide a general mechanism for different variable settings in buffers with a remote connection (see Section “Remote Files” in *The GNU Emacs Manual*). They are bound and set depending on the remote connection a buffer is dedicated to.

12.14.1 Connection Local Profiles

Emacs uses connection-local profiles to store the variable settings to apply to particular connections. You can then associate these with remote connections by defining the criteria when they should apply, using `connection-local-set-profiles`.

`connection-local-set-profile-variables` *profile variables* [Function]

This function defines a set of variable settings for the connection `profile`, which is a symbol. You can later assign the connection profile to one or more remote connections, and Emacs will apply those variable settings to all process buffers for those connections.

The list in `variables` is an *alist* of the form `(name . value)`. Example:

```
(connection-local-set-profile-variables
  'remote-bash
  '((shell-file-name . "/bin/bash")
    (shell-command-switch . "-c")
    (shell-interactive-switch . "-i")
    (shell-login-switch . "-l")))

(connection-local-set-profile-variables
  'remote-ksh
  '((shell-file-name . "/bin/ksh")
    (shell-command-switch . "-c")
    (shell-interactive-switch . "-i")
    (shell-login-switch . "-l")))

(connection-local-set-profile-variables
  'remote-null-device
  '((null-device . "/dev/null")))
```

If you want to append variable settings to an existing profile, you could use the function `connection-local-get-profile-variables` in order to retrieve the existing settings, like

```
(connection-local-set-profile-variables
  'remote-bash
  (append
    (connection-local-get-profile-variables 'remote-bash)
    '((shell-command-dont-erase-buffer . t))))
```

`connection-local-profile-alist` [User Option]

This alist holds the connection profile symbols and the associated variable settings. It is updated by `connection-local-set-profile-variables`.

`connection-local-set-profiles` *criteria &rest profiles* [Function]

This function assigns *profiles*, which are symbols, to all remote connections identified by *criteria*. *criteria* is a plist identifying a connection and the application using this connection. Property names might be `:application`, `:protocol`, `:user` and `:machine`. The property value of `:application` is a symbol, all other property values are strings. All properties are optional; if *criteria* is `nil`, it always applies. Example:

```
(connection-local-set-profiles
  '(:application tramp :protocol "ssh" :machine "localhost")
  'remote-bash 'remote-null-device)

(connection-local-set-profiles
  '(:application tramp :protocol "sudo"
    :user "root" :machine "localhost")
  'remote-ksh 'remote-null-device)
```

If *criteria* is `nil`, it applies for all remote connections. Therefore, the example above would be equivalent to

```
(connection-local-set-profiles
  '(:application tramp :protocol "ssh" :machine "localhost")
  'remote-bash)

(connection-local-set-profiles
  '(:application tramp :protocol "sudo"
    :user "root" :machine "localhost")
  'remote-ksh)

(connection-local-set-profiles
  nil 'remote-null-device)
```

Any connection profile of *profiles* must have been already defined by `connection-local-set-profile-variables`.

`connection-local-criteria-alist` [User Option]

This alist contains connection criteria and their assigned profile names. The function `connection-local-set-profiles` updates this list.

12.14.2 Applying Connection Local Variables

When writing connection-aware code, you'll need to collect, and possibly apply, any connection-local variables. There are several ways to do this, as described below.

`hack-connection-local-variables criteria` [Function]

This function collects applicable connection-local variables associated with *criteria* in `connection-local-variables-alist`, without applying them. Example:

```
(hack-connection-local-variables
  '(:application tramp :protocol "ssh" :machine "localhost"))

connection-local-variables-alist
  ⇒ ((null-device . "/dev/null")
      (shell-login-switch . "-l")
      (shell-interactive-switch . "-i")
      (shell-command-switch . "-c")
      (shell-file-name . "/bin/bash"))
```

`hack-connection-local-variables-apply criteria` [Function]

This function looks for connection-local variables according to *criteria*, and immediately applies them in the current buffer.

`with-connection-local-application-variables application &rest body` [Macro]

Apply all connection-local variables for *application*, which are specified by `default-directory`.

After that, *body* is executed, and the connection-local variables are unwound. Example:

```
(connection-local-set-profile-variables
  'my-remote-perl
  '((perl-command-name . "/usr/local/bin/perl5")
    (perl-command-switch . "-e %s")))
```

```
(connection-local-set-profiles
  '(:application my-app :protocol "ssh" :machine "remotehost")
  'my-remote-perl)

(let ((default-directory "/ssh:remotehost:/working/dir/"))
  (with-connection-local-application-variables 'my-app
    do something useful))
```

connection-local-default-application [Variable]

The default application, a symbol, to be applied in `with-connection-local-variables`. It defaults to `tramp`, but you can let-bind it to change the application temporarily (see Section 12.3 [Local Variables], page 190).

This variable must not be changed globally.

with-connection-local-variables &rest body [Macro]

This is equivalent to `with-connection-local-application-variables`, but uses `connection-local-default-application` for the application.

setq-connection-local [symbol form]... [Macro]

This macro sets each `symbol` connection-locally to the result of evaluating the corresponding `form`, using the connection-local profile specified in `connection-local-profile-name-for-setq`; if the profile name is `nil`, this macro will just set the variables normally, as with `setq` (see Section 12.8 [Setting Variables], page 198).

For example, you can use this macro in combination with `with-connection-local-variables` or `with-connection-local-application-variables` to lazily initialize connection-local settings:

```
(defvar my-app-variable nil)

(connection-local-set-profile-variables
  'my-app-connection-default-profile
  '((my-app-variable . nil)))

(connection-local-set-profiles
  '(:application my-app)
  'my-app-connection-default-profile)

(defun my-app-get-variable ()
  (with-connection-local-application-variables 'my-app
    (or my-app-variable
        (setq-connection-local my-app-variable
          do something useful))))
```

connection-local-profile-name-for-setq [Variable]

The connection-local profile name, a symbol, to use when setting variables via `setq-connection-local`. This is let-bound in the body of `with-connection-local-variables`, but you can also let-bind it yourself if you'd like to set variables on a different profile.

This variable must not be changed globally.

enable-connection-local-variables [Variable]

If `nil`, connection-local variables are ignored. This variable shall be changed temporarily only in special modes.

12.15 Variable Aliases

It is sometimes useful to make two variables synonyms, so that both variables always have the same value, and changing either one also changes the other. Whenever you change the name of a variable—either because you realize its old name was not well chosen, or because its meaning has partly changed—it can be useful to keep the old name as an *alias* of the new one for compatibility. You can do this with `defvaralias`.

defvaralias new-alias base-variable &optional docstring [Function]

This function defines the symbol `new-alias` as a variable alias for symbol `base-variable`. This means that retrieving the value of `new-alias` returns the value of `base-variable`, and changing the value of `new-alias` changes the value of `base-variable`. The two aliased variable names always share the same value and the same bindings.

If the `docstring` argument is non-`nil`, it specifies the documentation for `new-alias`; otherwise, the alias gets the same documentation as `base-variable` has, if any, unless `base-variable` is itself an alias, in which case `new-alias` gets the documentation of the variable at the end of the chain of aliases.

This function returns `base-variable`.

Variable aliases are convenient for replacing an old name for a variable with a new name. `make-obsolete-variable` declares that the old name is obsolete and therefore that it may be removed at some stage in the future.

make-obsolete-variable obsolete-name current-name when &optional access-type [Function]

This function makes the byte compiler warn that the variable `obsolete-name` is obsolete. If `current-name` is a symbol, it is the variable's new name; then the warning message says to use `current-name` instead of `obsolete-name`. If `current-name` is a string, this is the message and there is no replacement variable. `when` should be a string indicating when the variable was first made obsolete (usually a version number string).

The optional argument `access-type`, if non-`nil`, should specify the kind of access that will trigger obsolescence warnings; it can be either `get` or `set`.

You can make two variables synonyms and declare one obsolete at the same time using the macro `define-obsolete-variable-alias`.

define-obsolete-variable-alias obsolete-name current-name when &optional docstring [Macro]

This macro marks the variable `obsolete-name` as obsolete and also makes it an alias for the variable `current-name`. It is equivalent to the following:

```
(defvaralias obsolete-name current-name docstring)
(make-obsolete-variable obsolete-name current-name when)
```

This macro evaluates all its parameters, and both *obsolete-name* and *current-name* should be symbols, so a typical usage would look like:

```
(define-obsolete-variable-alias 'foo-thing 'bar-thing "27.1")
```

indirect-variable variable [Function]

This function returns the variable at the end of the chain of aliases of *variable*. If *variable* is not a symbol, or if *variable* is not defined as an alias, the function returns *variable*.

This function signals a *cyclic-variable-indirection* error if there is a loop in the chain of symbols.

```
(defvaralias 'foo 'bar)
(indirect-variable 'foo)
  ⇒ bar
(indirect-variable 'bar)
  ⇒ bar
(setq bar 2)
bar
  ⇒ 2
foo
  ⇒ 2
(setq foo 0)
bar
  ⇒ 0
foo
  ⇒ 0
```

12.16 Variables with Restricted Values

Ordinary Lisp variables can be assigned any value that is a valid Lisp object. However, certain Lisp variables are not defined in Lisp, but in C. Most of these variables are defined in the C code using DEFVAR_LISP. Like variables defined in Lisp, these can take on any value. However, some variables are defined using DEFVAR_INT or DEFVAR_BOOL. See [Writing Emacs Primitives], page 1358, in particular the description of functions of the type *syms_of_filename*, for a brief discussion of the C implementation.

Variables of type DEFVAR_BOOL can only take on the values *nil* or *t*. Attempting to assign them any other value will set them to *t*:

```
(let ((display-hourglass 5))
  display-hourglass)
  ⇒ t
```

byte-boolean-vars [Variable]

This variable holds a list of all variables of type DEFVAR_BOOL.

Variables of type DEFVAR_INT can take on only integer values. Attempting to assign them any other value will result in an error:

```
(setq undo-limit 1000.0)
error Wrong type argument: integerp, 1000.0
```

12.17 Generalized Variables

A *generalized variable* or *place form* is one of the many places in Lisp memory where values can be stored using the `setf` macro (see Section 12.17.1 [Setting Generalized Variables], page 224). The simplest place form is a regular Lisp variable. But the CARS and CDRS of lists, elements of arrays, properties of symbols, and many other locations are also places where Lisp values get stored.

Generalized variables are analogous to lvalues in the C language, where ‘`x = a[i]`’ gets an element from an array and ‘`a[i] = x`’ stores an element using the same notation. Just as certain forms like `a[i]` can be lvalues in C, there is a set of forms that can be generalized variables in Lisp.

12.17.1 The `setf` Macro

The `setf` macro is the most basic way to operate on generalized variables. The `setf` form is like `setq`, except that it accepts arbitrary place forms in the first (left) argument of each pair rather than just symbols. For example, `(setf (car a) b)` sets the car of `a` to `b`, doing the same operation as `(setcar a b)`, but without you having to use two separate functions for setting and accessing this type of place.

`setf [place form]...` [Macro]

This macro evaluates *form* and stores its value in *place*, which must be a valid generalized variable form. If there are several *place* and *form* pairs, the assignments are done sequentially just as with `setq`. `setf` returns the value of the last *form*.

The following Lisp forms are the forms in Emacs that will work as generalized variables, and so may appear in the *place* argument of `setf`:

- A symbol. In other words, `(setf x y)` is exactly equivalent to `(setq x y)`, and `setq` itself is strictly speaking redundant given that `setf` exists. Most programmers will continue to prefer `setq` for setting simple variables, though, for stylistic and historical reasons. The macro `(setf x y)` actually expands to `(setq x y)`, so there is no performance penalty for using it in compiled code.
- A call to any of the following standard Lisp functions:

<code>aref</code>	<code>cddr</code>	<code>symbol-function</code>
<code>car</code>	<code>elt</code>	<code>symbol-plist</code>
<code>caar</code>	<code>get</code>	<code>symbol-value</code>
<code>cadr</code>	<code>gethash</code>	
<code>cdr</code>	<code>nth</code>	
<code>cdar</code>	<code>nthcdr</code>	

- A call to any of the following Emacs-specific functions:

<code>alist-get</code>	<code>overlay-start</code>
<code>default-value</code>	<code>overlay-get</code>
<code>face-background</code>	<code>process-buffer</code>
<code>face-font</code>	<code>process-filter</code>
<code>face-foreground</code>	<code>process-get</code>
<code>face-stipple</code>	<code>process-sentinel</code>
<code>face-underline-p</code>	<code>terminal-parameter</code>
<code>file-modes</code>	<code>window-buffer</code>
<code>frame-parameter</code>	<code>window-dedicated-p</code>
<code>frame-parameters</code>	<code>window-display-table</code>
<code>get-register</code>	<code>window-hscroll</code>

getenv	window-parameter
keymap-parent	window-point
match-data	window-start
overlay-end	

- A call of the form (`substring subplace n [m]`), where `subplace` is itself a valid generalized variable whose current value is a string, and where the value stored is also a string. The new string is spliced into the specified part of the destination string. For example:

```
(setq a (list "hello" "world"))
  ⇒ ("hello" "world")
(cadr a)
  ⇒ "world"
(substring (cadr a) 2 4)
  ⇒ "rl"
(setf (substring (cadr a) 2 4) "o")
  ⇒ "o"
(cadr a)
  ⇒ "wood"
a
  ⇒ ("hello" "wood")
```

- The `if` and `cond` conditionals will work as generalized variables. For instance, this will set either the `foo` or the `bar` variable to `zot`:

```
(setf (if (zerop (random 2))
    foo
    bar)
  'zot)
```

`setf` signals an error if you pass a `place` form that it does not know how to handle.

Note that for `nthcdr`, the list argument of the function must itself be a valid `place` form. For example, (`(setf (nthcdr 0 foo) 7)`) will set `foo` itself to 7.

The macros `push` (see Section 5.5 [List Variables], page 85) and `pop` (see Section 5.3 [List Elements], page 79) can manipulate generalized variables, not just lists. (`pop place`) removes and returns the first element of the list stored in `place`. It is analogous to (`prog1 (car place) (setf place (cdr place))`), except that it takes care to evaluate all subforms only once. (`push x place`) inserts `x` at the front of the list stored in `place`. It is analogous to (`(setf place (cons x place))`), except for evaluation of the subforms. Note that `push` and `pop` on an `nthcdr` place can be used to insert or delete at any position in a list.

The `cl-lib` library defines various extensions for generalized variables, including additional `setf` places. See Section “Generalized Variables” in *Common Lisp Extensions*.

12.17.2 Defining new `setf` forms

This section describes how to define new forms that `setf` can operate on.

`gv-define-simple-setter name setter &optional fix-return` [Macro]

This macro enables you to easily define `setf` methods for simple cases. `name` is the name of a function, macro, or special form. You can use this macro whenever `name` has

a directly corresponding setter function that updates it, e.g., `(gv-define-simple-setter car setcar)`.

This macro translates a call of the form

```
(setf (name args...) value)
```

into

```
(setter args... value)
```

Such a `setf` call is documented to return `value`. This is no problem with, e.g., `car` and `setcar`, because `setcar` returns the value that it set. If your setter function does not return `value`, use a non-nil value for the `fix-return` argument of `gv-define-simple-setter`. This expands into something equivalent to

```
(let ((temp value))
  (setter args... temp)
  temp)
```

so ensuring that it returns the correct result.

`gv-define-setter name arglist &rest body`

[Macro]

This macro allows for more complex `setf` expansions than the previous form. You may need to use this form, for example, if there is no simple setter function to call, or if there is one but it requires different arguments to the place form.

This macro expands the form `(setf (name args...) value)` by first binding the `setf` argument forms `(value args...)` according to `arglist`, and then executing `body`. `body` should return a Lisp form that does the assignment, and finally returns the value that was set. An example of using this macro is:

```
(gv-define-setter caar (val x) `(setcar (car ,x) ,val))
```

`gv-define-expander name handler`

[Macro]

For more control over the expansion, the `gv-define-expander` macro can be used. For instance, a settable `substring` could be implemented this way:

```
(gv-define-expander substring
  (lambda (do place from &optional to)
    (gv-letplace (getter setter) place
      (macroexp-let2* (from to)
        (funcall do `(substring ,getter ,from ,to)
          (lambda (v)
            (macroexp-let2* (v)
              `(progn
                ,(funcall setter `(cl--set-substring
                  ,getter ,from ,to ,v))
                ,v)))))))
```

`gv-letplace (getter setter) place &rest body`

[Macro]

The macro `gv-letplace` can be useful in defining macros that perform similarly to `setf`; for example, the `incf` macro of Common Lisp could be implemented this way:

```
(defmacro incf (place &optional n)
  (gv-letplace (getter setter) place
```

```
(macroexp-let2* ((v (or n 1)))
  (funcall setter `(+ ,v ,getter))))
```

getter will be bound to a copyable expression that returns the value of *place*. *setter* will be bound to a function that takes an expression *v* and returns a new expression that sets *place* to *v*. *body* should return a Emacs Lisp expression manipulating *place* via *getter* and *setter*.

Consult the source file `gv.el` for more details.

`make-obsolete-generalized-variable` *obsolete-name* *current-name* [Function]
when

This function makes the byte compiler warn that the generalized variable *obsolete-name* is obsolete. If *current-name* is a symbol, then the warning message says to use *current-name* instead of *obsolete-name*. If *current-name* is a string, this is the message. *when* should be a string indicating when the variable was first made obsolete (usually a version number string).

Common Lisp note: Common Lisp defines another way to specify the `setf` behavior of a function, namely `setf` functions, whose names are lists (`(setf name)`) rather than symbols. For example, `(defun (setf foo) ...)` defines the function that is used when `setf` is applied to `foo`. Emacs does not support this. It is a compile-time error to use `setf` on a form that has not already had an appropriate expansion defined. In Common Lisp, this is not an error since the function `(setf func)` might be defined later.

12.18 Multisession Variables

When you set a variable to a value and then close Emacs and restart it, that value won't be automatically restored. Users usually set normal variables in their startup files, or use Customize (see Chapter 15 [Customization], page 277) to set user options permanently, and various packages have various files where they store the data (e.g., Gnus stores this in `.newsrsrc.eld` and the URL library stores cookies in `~/.emacs.d/url/cookies`).

For things in between these two extremes (i.e., configuration which goes in the startup file, and massive application state that goes into separate files), Emacs provides a facility to replicate data between sessions called *multisession variables*. (This facility may not be available on all systems.) To give you an idea of how these are meant to be used, here's a small example:

```
(define-multisession-variable foo 0)
(defun my-adder (num)
  (interactive "nAdd number: ")
  (setf (multisession-value foo)
    (+ (multisession-value foo) num))
  (message "The new number is: %s" (multisession-value foo)))
```

This defines the variable `foo` and binds it to a special multisession object which is initialized with the value '0' (if the variable doesn't already exist from a previous session). The `my-adder` command queries the user for a number, adds this to the old (possibly saved value), and then saves the new value.

This facility isn't meant to be used for huge data structures, but should be performant for most values.

define-multisession-variable *name initial-value &optional doc &rest args* [Macro]

This macro defines *name* as a multisession variable, and gives it the *initial-value* if this variable hasn't been assigned a value earlier. *doc* is the doc string, and several keyword arguments can be used in *args*:

:package package-symbol

This keyword says that a multisession variable belongs to the package specified by *package-symbol*. The combination of *package-symbol* and *name* has to be unique. If *package-symbol* isn't given, this will default to the first "segment" of the *name* symbol's name, which is the part of its name up to and excluding the first '-'. For instance, if *name* is `foo` and *package-symbol* isn't given, *package-symbol* will default to `foo`.

:synchronized bool

Multisession variables can be *synchronized* if *bool* is non-`nil`. This means that if there're two concurrent Emacs instances running, and the other Emacs changes the multisession variable `foo`, the current Emacs instance will retrieve that modified data when accessing the value. If *synchronized* is `nil` or missing, this won't happen, and the values in all Emacs sessions using the variable will be independent of each other.

:storage storage

Use the specified *storage* method. This can be either `sqlite` (in Emacs compiled with SQLite support) or `files`. If not given, this defaults to the value of the `multisession-storage` variable, described below.

multisession-value *variable* [Function]

This function returns the current value of *variable*. If this variable hasn't been accessed before in this Emacs session, or if it's changed externally, it will be read in from external storage. If not, the current value in this session is returned as is. It is an error to call this function for a *variable* that is not a multisession variable.

Values retrieved via `multisession-value` may or may not be `eq` to each other, but they will always be `equal`.

This is a generalized variable (see Section 12.17 [Generalized Variables], page 224), so the way to update such a variable is to say, for instance:

```
(setf (multisession-value foo-bar) 'zot)
```

Only Emacs Lisp values that have a readable print syntax (see Section 2.1 [Printed Representation], page 8) can be saved this way.

If the multisession variable is synchronized, setting it may update the value first. For instance:

```
(cl-incf (multisession-value foo-bar))
```

This first checks whether the value has changed in a different Emacs instance, retrieves that value, and then adds 1 to that value and stores it. But note that this is done without locking, so if many instances are updating the value at the same time, it's unpredictable which instance "wins".

multisession-delete object [Function]

This function deletes *object* and its value from its persistent storage.

make-multisession [Function]

You can also make persistent values that aren't tied to a specific variable, but are tied to an explicit package and key.

```
(setq foo (make-multisession :package "mail"
                               :key "friends"))
  (setf (multisession-value foo) 'everybody)
```

This supports the same keywords as `define-multisession-variable`, but also supports a `:initial-value` keyword, which specifies the default value.

multisession-storage [User Option]

This variable controls how the multisession variables are stored. Its value defaults to `files`, which means that the values are stored in a one-file-per-variable structure inside the directory specified by `multisession-directory`. If this value is `sqlite` instead, the values are stored in an SQLite database; this is only available if Emacs was built with SQLite support.

multisession-directory [User Option]

The multisession variables are stored under this directory, which defaults to `multisession/` subdirectory of the `user-emacs-directory`, which is typically `~/.emacs.d/multisession/`.

list-multisession-values [Command]

This command pops up a buffer listing all the multisession variables, and enters a special mode `multisession-edit-mode` which allows you to delete them and edit their values.

13 Functions

A Lisp program is composed mainly of Lisp functions. This chapter explains what functions are, how they accept arguments, and how to define them.

13.1 What Is a Function?

In a general sense, a function is a rule for carrying out a computation given input values called *arguments*. The result of the computation is called the *value* or *return value* of the function. The computation can also have side effects, such as lasting changes in the values of variables or the contents of data structures (see [Definition of side effect], page 145). A *pure function* is a function which, in addition to having no side effects, always returns the same value for the same combination of arguments, regardless of external factors such as machine type or system state.

In most computer languages, every function has a name. But in Lisp, a function in the strictest sense has no name: it is an object which can *optionally* be associated with a symbol (e.g., `car`) that serves as the function name. See Section 13.3 [Function Names], page 236. When a function has been given a name, we usually also refer to that symbol as a “function” (e.g., we refer to “the function `car`”). In this manual, the distinction between a function name and the function object itself is usually unimportant, but we will take note wherever it is relevant.

Certain function-like objects, called *special forms* and *macros*, also accept arguments to carry out computations. However, as explained below, these are not considered functions in Emacs Lisp.

Here are important terms for functions and function-like objects:

lambda expression

A function (in the strict sense, i.e., a function object) which is written in Lisp. These are described in the following section.

primitive A function which is callable from Lisp but is actually written in C. Primitives are also called *built-in functions*, or *subrs*. Examples include functions like `car` and `append`. In addition, all special forms (see below) are also considered primitives.

Usually, a function is implemented as a primitive because it is a fundamental part of Lisp (e.g., `car`), or because it provides a low-level interface to operating system services, or because it needs to run fast. Unlike functions defined in Lisp, primitives can be modified or added only by changing the C sources and recompiling Emacs. See Section E.7 [Writing Emacs Primitives], page 1356.

special form

A primitive that is like a function but does not evaluate all of its arguments in the usual way. It may evaluate only some of the arguments, or may evaluate them in an unusual order, or several times. Examples include `if`, `and`, and `while`. See Section 10.1.7 [Special Forms], page 149.

macro A construct defined in Lisp, which differs from a function in that it translates a Lisp expression into another expression which is to be evaluated instead of the

original expression. Macros enable Lisp programmers to do the sorts of things that special forms can do. See Chapter 14 [Macros], page 268.

command An object which can be invoked via the `command-execute` primitive, usually due to the user typing in a key sequence *bound* to that command. See Section 22.3 [Interactive Call], page 432. A command is usually a function; if the function is written in Lisp, it is made into a command by an `interactive` form in the function definition (see Section 22.2 [Defining Commands], page 424). Commands that are functions can also be called from Lisp expressions, just like other functions.

Keyboard macros (strings and vectors) are commands also, even though they are not functions. See Section 22.16 [Keyboard Macros], page 478. We say that a symbol is a command if its function cell contains a command (see Section 9.1 [Symbol Components], page 133); such a *named command* can be invoked with `M-x`.

closure A function object that is much like a lambda expression, except that it also encloses an environment of lexical variable bindings. See Section 13.10 [Closures], page 249.

byte-code function

A function that has been compiled by the byte compiler. See Section 2.4.16 [Byte-Code Type], page 24.

autoload object

A place-holder for a real function. If the autoload object is called, Emacs loads the file containing the definition of the real function, and then calls the real function. See Section 16.5 [Autoload], page 304.

You can use the function `functionp` to test if an object is a function:

functionp *object* [Function]

This function returns `t` if *object* is any kind of function, i.e., can be passed to `funcall`. Note that `functionp` returns `t` for symbols that are function names, and returns `nil` for symbols that are macros or special forms.

If *object* is not a function, this function ordinarily returns `nil`. However, the representation of function objects is complicated, and for efficiency reasons in rare cases this function can return `t` even when *object* is not a function.

It is also possible to find out how many arguments an arbitrary function expects:

func-arity *function* [Function]

This function provides information about the argument list of the specified *function*. The returned value is a cons cell of the form `(min . max)`, where *min* is the minimum number of arguments, and *max* is either the maximum number of arguments, or the symbol `many` for functions with `&rest` arguments, or the symbol `unevalled` if *function* is a special form.

Note that this function might return inaccurate results in some situations, such as the following:

- Functions defined using `apply-partially` (see Section 13.5 [Calling Functions], page 239).

- Functions that are advised using `advice-add` (see Section 13.12.2 [Advising Named Functions], page 255).
- Functions that determine the argument list dynamically, as part of their code.

Unlike `functionp`, the next three functions do *not* treat a symbol as its function definition.

subrp object [Function]

This function returns `t` if *object* is a built-in function (i.e., a Lisp primitive).

```
(subrp 'message) ; message is a symbol,  
⇒ nil ; not a subr object.  
(subrp (symbol-function 'message))  
⇒ t
```

byte-code-function-p object [Function]

This function returns `t` if *object* is a byte-code function. For example:

```
(byte-code-function-p (symbol-function 'next-line))  
⇒ t
```

compiled-function-p object [Function]

This function returns `t` if *object* is a function object that is not in the form of ELisp source code but something like machine code or byte code instead. More specifically it returns `t` if the function is built-in (a.k.a. “primitive”, see Section 13.1 [What Is a Function], page 230), or byte-compiled (see Chapter 17 [Byte Compilation], page 316), or natively-compiled (see Chapter 18 [Native Compilation], page 327), or a function loaded from a dynamic module (see Section 16.11 [Dynamic Modules], page 314).

subr-arity subr [Function]

This works like `func-arity`, but only for built-in functions and without symbol indirection. It signals an error for non-built-in functions. We recommend to use `func-arity` instead.

13.2 Lambda Expressions

A lambda expression is a function object written in Lisp. Here is an example:

```
(lambda (x)  
  "Return the hyperbolic cosine of X."  
  (* 0.5 (+ (exp x) (exp (- x)))))
```

In Emacs Lisp, such a list is a valid expression which evaluates to a function object.

A lambda expression, by itself, has no name; it is an *anonymous function*. Although lambda expressions can be used this way (see Section 13.7 [Anonymous Functions], page 243), they are more commonly associated with symbols to make *named functions* (see Section 13.3 [Function Names], page 236). Before going into these details, the following subsections describe the components of a lambda expression and what they do.

13.2.1 Components of a Lambda Expression

A lambda expression is a list that looks like this:

```
(lambda (arg-variables...)
```

```
[documentation-string]
[interactive-declaration]
body-forms...)
```

The first element of a lambda expression is always the symbol `lambda`. This indicates that the list represents a function. The reason functions are defined to start with `lambda` is so that other lists, intended for other uses, will not accidentally be valid as functions.

The second element is a list of symbols—the argument variable names (see Section 13.2.3 [Argument List], page 234). This is called the *lambda list*. When a Lisp function is called, the argument values are matched up against the variables in the lambda list, which are given local bindings with the values provided. See Section 12.3 [Local Variables], page 190.

The documentation string is a Lisp string object placed within the function definition to describe the function for the Emacs help facilities. See Section 13.2.4 [Function Documentation], page 235.

The interactive declaration is a list of the form (`interactive code-string`). This declares how to provide arguments if the function is used interactively. Functions with this declaration are called *commands*; they can be called using `M-x` or bound to a key. Functions not intended to be called in this way should not have interactive declarations. See Section 22.2 [Defining Commands], page 424, for how to write an interactive declaration.

The rest of the elements are the *body* of the function: the Lisp code to do the work of the function (or, as a Lisp programmer would say, “a list of Lisp forms to evaluate”). The value returned by the function is the value returned by the last element of the body.

13.2.2 A Simple Lambda Expression Example

Consider the following example:

```
(lambda (a b c) (+ a b c))
```

We can call this function by passing it to `funcall`, like this:

```
(funcall (lambda (a b c) (+ a b c))
         1 2 3)
```

This call evaluates the body of the lambda expression with the variable `a` bound to 1, `b` bound to 2, and `c` bound to 3. Evaluation of the body adds these three numbers, producing the result 6; therefore, this call to the function returns the value 6.

Note that the arguments can be the results of other function calls, as in this example:

```
(funcall (lambda (a b c) (+ a b c))
         1 (* 2 3) (- 5 4))
```

This evaluates the arguments 1, `(* 2 3)`, and `(- 5 4)` from left to right. Then it applies the lambda expression to the argument values 1, 6 and 1 to produce the value 8.

As these examples show, you can use a form with a lambda expression as its CAR to make local variables and give them values. In the old days of Lisp, this technique was the only way to bind and initialize local variables. But nowadays, it is clearer to use the special form `let` for this purpose (see Section 12.3 [Local Variables], page 190). Lambda expressions are mainly used as anonymous functions for passing as arguments to other functions (see Section 13.7 [Anonymous Functions], page 243), or stored as symbol function definitions to produce named functions (see Section 13.3 [Function Names], page 236).

13.2.3 Features of Argument Lists

Our simple sample function, `(lambda (a b c) (+ a b c))`, specifies three argument variables, so it must be called with three arguments: if you try to call it with only two arguments or four arguments, you get a `wrong-number-of-arguments` error (see Section 11.7.3 [Errors], page 179).

It is often convenient to write a function that allows certain arguments to be omitted. For example, the function `substring` accepts three arguments—a string, the start index and the end index—but the third argument defaults to the *length* of the string if you omit it. It is also convenient for certain functions to accept an indefinite number of arguments, as the functions `list` and `+ do`.

To specify optional arguments that may be omitted when a function is called, simply include the keyword `&optional` before the optional arguments. To specify a list of zero or more extra arguments, include the keyword `&rest` before one final argument.

Thus, the complete syntax for an argument list is as follows:

```
(required-vars...
  [&optional optional-vars...]]
  [&rest rest-var])
```

The square brackets indicate that the `&optional` and `&rest` clauses, and the variables that follow them, are optional.

A call to the function requires one actual argument for each of the *required-vars*. There may be actual arguments for zero or more of the *optional-vars*, and there cannot be any actual arguments beyond that unless the lambda list uses `&rest`. In that case, there may be any number of extra actual arguments.

If actual arguments for the optional and rest variables are omitted, then they always default to `nil`. There is no way for the function to distinguish between an explicit argument of `nil` and an omitted argument. However, the body of the function is free to consider `nil` an abbreviation for some other meaningful value. This is what `substring` does; `nil` as the third argument to `substring` means to use the length of the string supplied.

Common Lisp note: Common Lisp allows the function to specify what default value to use when an optional argument is omitted; Emacs Lisp always uses `nil`. Emacs Lisp does not support `supplied-p` variables that tell you whether an argument was explicitly passed.

For example, an argument list that looks like this:

```
(a b &optional c d &rest e)
```

binds `a` and `b` to the first two actual arguments, which are required. If one or two more arguments are provided, `c` and `d` are bound to them respectively; any arguments after the first four are collected into a list and `e` is bound to that list. Thus, if there are only two arguments, `c`, `d` and `e` are `nil`; if two or three arguments, `d` and `e` are `nil`; if four arguments or fewer, `e` is `nil`. Note that exactly five arguments with an explicit `nil` argument provided for `e` will cause that `nil` argument to be passed as a list with one element, `(nil)`, as with any other single value for `e`.

There is no way to have required arguments following optional ones—it would not make sense. To see why this must be so, suppose that `c` in the example were optional and `d` were required. Suppose three actual arguments are given; which variable would the third

argument be for? Would it be used for the *c*, or for *d*? One can argue for both possibilities. Similarly, it makes no sense to have any more arguments (either required or optional) after a `&rest` argument.

Here are some examples of argument lists and proper calls:

```
(funcall (lambda (n) (1+ n))          ; One required:  
        1)                      ; requires exactly one argument.  
    ⇒ 2  
(funcall (lambda (n &optional n1)    ; One required and one optional:  
        (if n1 (+ n n1) (1+ n))) ; 1 or 2 arguments.  
        1 2)  
    ⇒ 3  
(funcall (lambda (n &rest ns)      ; One required and one rest:  
        (+ n (apply '+ ns)))     ; 1 or more arguments.  
        1 2 3 4 5)  
    ⇒ 15
```

13.2.4 Documentation Strings of Functions

A lambda expression may optionally have a *documentation string* just after the lambda list. This string does not affect execution of the function; it is a kind of comment, but a systematized comment which actually appears inside the Lisp world and can be used by the Emacs help facilities. See Chapter 25 [Documentation], page 595, for how the documentation string is accessed.

It is a good idea to provide documentation strings for all the functions in your program, even those that are called only from within your program. Documentation strings are like comments, except that they are easier to access.

The first line of the documentation string should stand on its own, because `apropos` displays just this first line. It should consist of one or two complete sentences that summarize the function's purpose.

The start of the documentation string is usually indented in the source file, but since these spaces come before the starting double-quote, they are not part of the string. Some people make a practice of indenting any additional lines of the string so that the text lines up in the program source. *That is a mistake*. The indentation of the following lines is inside the string; what looks nice in the source code will look ugly when displayed by the help commands.

You may wonder how the documentation string could be optional, since there are required components of the function that follow it (the body). Since evaluation of a string returns that string, without any side effects, it has no effect if it is not the last form in the body. Thus, in practice, there is no confusion between the first form of the body and the documentation string; if the only body form is a string then it serves both as the return value and as the documentation.

The last line of the documentation string can specify calling conventions different from the actual function arguments. Write text like this:

```
\(fn arglist)
```

following a blank line, at the beginning of the line, with no newline following it inside the documentation string. (The ‘\’ is used to avoid confusing the Emacs motion commands.)

The calling convention specified in this way appears in help messages in place of the one derived from the actual arguments of the function.

This feature is particularly useful for macro definitions, since the arguments written in a macro definition often do not correspond to the way users think of the parts of the macro call.

Do not use this feature if you want to deprecate the calling convention and favor the one you advertise by the above specification. Instead, use the `advertised-calling-convention` declaration (see Section 13.15 [Declare Form], page 263) or `set-advertised-calling-convention` (see Section 13.13 [Obsolete Functions], page 260), because these two will cause the byte compiler emit a warning message when it compiles Lisp programs which use the deprecated calling convention.

Documentation strings are usually static, but occasionally it can be necessary to generate them dynamically. In some cases you can do so by writing a macro which generates at compile time the code of the function, including the desired documentation string. But you can also generate the docstring dynamically by writing `(:documentation form)` instead of the documentation string. This will evaluate `form` at run-time when the function is defined and use it as the documentation string¹. You can also compute the documentation string on the fly when it is requested, by setting the `function-documentation` property of the function's symbol to a Lisp form that evaluates to a string.

For example:

```
(defun adder (x)
  (lambda (y)
    (:documentation (format "Add %S to the argument Y." x))
    (+ x y)))
(defalias 'adder5 (adder 5))
(documentation 'adder5)
⇒ "Add 5 to the argument Y.

(put 'adder5 'function-documentation
      '(concat (documentation (symbol-function 'adder5) 'raw)
              " Consulted at " (format-time-string "%H:%M:%S")))
(documentation 'adder5)
⇒ "Add 5 to the argument Y. Consulted at 15:52:13"
(documentation 'adder5)
⇒ "Add 5 to the argument Y. Consulted at 15:52:18"
```

13.3 Naming a Function

A symbol can serve as the name of a function. This happens when the symbol's *function cell* (see Section 9.1 [Symbol Components], page 133) contains a function object (e.g., a lambda expression). Then the symbol itself becomes a valid, callable function, equivalent to the function object in its function cell.

The contents of the function cell are also called the symbol's *function definition*. The procedure of using a symbol's function definition in place of the symbol is called *symbol*

¹ This only works in code using `lexical-binding`.

function indirection; see Section 10.1.4 [Function Indirection], page 147. If you have not given a symbol a function definition, its function cell is said to be *void*, and it cannot be used as a function.

In practice, nearly all functions have names, and are referred to by their names. You can create a named Lisp function by defining a lambda expression and putting it in a function cell (see Section 13.9 [Function Cells], page 248). However, it is more common to use the `defun` macro, described in the next section.

We give functions names because it is convenient to refer to them by their names in Lisp expressions. Also, a named Lisp function can easily refer to itself—it can be recursive. Furthermore, primitives can only be referred to textually by their names, since primitive function objects (see Section 2.4.15 [Primitive Function Type], page 24) have no read syntax.

A function need not have a unique name. A given function object *usually* appears in the function cell of only one symbol, but this is just a convention. It is easy to store it in several symbols using `fset`; then each of the symbols is a valid name for the same function.

Note that a symbol used as a function name may also be used as a variable; these two uses of a symbol are independent and do not conflict. (This is not the case in some dialects of Lisp, like Scheme.)

By convention, if a function’s symbol consists of two names separated by ‘`--`’, the function is intended for internal use and the first part names the file defining the function. For example, a function named `vc-git--rev-parse` is an internal function defined in `vc-git.el`. Internal-use functions written in C have names ending in ‘`-internal`’, e.g., `bury-buffer-internal`. Emacs code contributed before 2018 may follow other internal-use naming conventions, which are being phased out.

13.4 Defining Functions

We usually give a name to a function when it is first created. This is called *defining a function*, and we usually do it with the `defun` macro. This section also describes other ways to define a function.

`defun name args [doc] [declare] [interactive] body...` [Macro]

`defun` is the usual way to define new Lisp functions. It defines the symbol `name` as a function with argument list `args` (see Section 13.2.3 [Argument List], page 234) and body forms given by `body`. Neither `name` nor `args` should be quoted.

`doc`, if present, should be a string specifying the function’s documentation string (see Section 13.2.4 [Function Documentation], page 235). `declare`, if present, should be a `declare` form specifying function metadata (see Section 13.15 [Declare Form], page 263). `interactive`, if present, should be an `interactive` form specifying how the function is to be called interactively (see Section 22.3 [Interactive Call], page 432).

The return value of `defun` is undefined.

Here are some examples:

```
(defun foo () 5)
(foo)
⇒ 5
```

```
(defun bar (a &optional b &rest c)
  (list a b c))
(bar 1 2 3 4 5)
  ⇒ (1 2 (3 4 5))
(bar 1)
  ⇒ (1 nil nil)
(bar)
[error] Wrong number of arguments.

(defun capitalize-backwards ()
  "Upcase the last letter of the word at point."
  (interactive)
  (backward-word 1)
  (forward-word 1)
  (backward-char 1)
  (capitalize-word 1))
```

Most Emacs functions are part of the source code of Lisp programs, and are defined when the Emacs Lisp reader reads the program source before executing it. However, you can also define functions dynamically at run time, e.g., by generating `defun` calls when your program's code is executed. If you do this, be aware that Emacs's Help commands, such as `C-h f`, which present in the `*Help*` buffer a button to jump to the function's definition, might be unable to find the source code because generating a function dynamically usually looks very different from the usual static calls to `defun`. You can make the job of finding the code which generates such functions easier by using the `definition-name` property, see Section 9.4.2 [Standard Properties], page 139.

Be careful not to redefine existing functions unintentionally. `defun` redefines even primitive functions such as `car` without any hesitation or notification. Emacs does not prevent you from doing this, because redefining a function is sometimes done deliberately, and there is no way to distinguish deliberate redefinition from unintentional redefinition.

`defalias name definition &optional doc` [Function]

This function defines the symbol `name` as a function, with definition `definition`. `definition` can be any valid Lisp function or macro, or a special form (see Section 10.1.7 [Special Forms], page 149), or a keymap (see Chapter 23 [Keymaps], page 480), or a vector or string (a keyboard macro). The return value of `defalias` is *undefined*.

If `doc` is non-`nil`, it becomes the function documentation of `name`. Otherwise, any documentation provided by `definition` is used.

Internally, `defalias` normally uses `fset` to set the definition. If `name` has a `defalias-fset-function` property, however, the associated value is used as a function to call in place of `fset`.

The proper place to use `defalias` is where a specific function or macro name is being defined—especially where that name appears explicitly in the source file being loaded. This is because `defalias` records which file defined the function, just like `defun` (see Section 16.9 [Unloading], page 313).

By contrast, in programs that manipulate function definitions for other purposes, it is better to use `fset`, which does not keep such records. See Section 13.9 [Function Cells], page 248.

function-alias-p *object* &**optional** *noerror* [Function]

Checks whether *object* is a function alias. If it is, it returns a list of symbols representing the function alias chain, else `nil`. For instance, if `a` is an alias for `b`, and `b` is an alias for `c`:

```
(function-alias-p 'a)
⇒ (b c)
```

If there's a loop in the definitions, an error will be signaled. If *noerror* is non-`nil`, the non-looping parts of the chain is returned instead.

You cannot create a new primitive function with `defun` or `defalias`, but you can use them to change the function definition of any symbol, even one such as `car` or `x-popup-menu` whose normal definition is a primitive. However, this is risky: for instance, it is next to impossible to redefine `car` without breaking Lisp completely. Redefining an obscure function such as `x-popup-menu` is less dangerous, but it still may not work as you expect. If there are calls to the primitive from C code, they call the primitive's C definition directly, so changing the symbol's definition will have no effect on them.

See also `defsubst`, which defines a function like `defun` and tells the Lisp compiler to perform inline expansion on it. See Section 13.14 [Inline Functions], page 261.

To undefine a function name, use `fmakunbound`. See Section 13.9 [Function Cells], page 248.

13.5 Calling Functions

Defining functions is only half the battle. Functions don't do anything until you *call* them, i.e., tell them to run. Calling a function is also known as *invocation*.

The most common way of invoking a function is by evaluating a list. For example, evaluating the list `(concat "a" "b")` calls the function `concat` with arguments `"a"` and `"b"`. See Chapter 10 [Evaluation], page 145, for a description of evaluation.

When you write a list as an expression in your program, you specify which function to call, and how many arguments to give it, in the text of the program. Usually that's just what you want. Occasionally you need to compute at run time which function to call. To do that, use the function `funcall`. When you also need to determine at run time how many arguments to pass, use `apply`.

funcall *function* &**rest** *arguments* [Function]

`funcall` calls *function* with *arguments*, and returns whatever *function* returns.

Since `funcall` is a function, all of its arguments, including *function*, are evaluated before `funcall` is called. This means that you can use any expression to obtain the function to be called. It also means that `funcall` does not see the expressions you write for the *arguments*, only their values. These values are *not* evaluated a second time in the act of calling *function*; the operation of `funcall` is like the normal procedure for calling a function, once its arguments have already been evaluated.

The argument *function* must be either a Lisp function or a primitive function. Special forms and macros are not allowed, because they make sense only when given the unevaluated argument expressions. `funcall` cannot provide these because, as we saw above, it never knows them in the first place.

If you need to use `funcall` to call a command and make it behave as if invoked interactively, use `funcall-interactively` (see Section 22.3 [Interactive Call], page 432).

```
(setq f 'list)
      ⇒ list
(funcall f 'x 'y 'z)
      ⇒ (x y z)
(funcall f 'x 'y '(z))
      ⇒ (x y (z))
(funcall 'and t nil)
[error] Invalid function: #<subr and>
```

Compare these examples with the examples of `apply`.

`apply` *function &rest arguments*

[Function]

`apply` calls *function* with *arguments*, just like `funcall` but with one difference: the last of *arguments* is a list of objects, which are passed to *function* as separate arguments, rather than a single list. We say that `apply` *spreads* this list so that each individual element becomes an argument.

`apply` with a single argument is special: the first element of the argument, which must be a non-empty list, is called as a function with the remaining elements as individual arguments. Passing two or more arguments will be faster.

`apply` returns the result of calling *function*. As with `funcall`, *function* must either be a Lisp function or a primitive function; special forms and macros do not make sense in `apply`.

```
(setq f 'list)
      ⇒ list
(apply f 'x 'y 'z)
[error] Wrong type argument: listp, z
(apply '+ 1 2 '(3 4))
      ⇒ 10
(apply '+ '(1 2 3 4))
      ⇒ 10

(apply 'append '((a b c) nil (x y z) nil))
      ⇒ (a b c x y z)

(apply '(+ 3 4))
      ⇒ 7
```

For an interesting example of using `apply`, see [Definition of `mapcar`], page 242.

Sometimes it is useful to fix some of the function's arguments at certain values, and leave the rest of arguments for when the function is actually called. The act of fixing some

of the function's arguments is called *partial application* of the function². The result is a new function that accepts the rest of arguments and calls the original function with all the arguments combined.

Here's how to do partial application in Emacs Lisp:

apply-partially *func &rest args*

[Function]

This function returns a new function which, when called, will call *func* with the list of arguments composed from *args* and additional arguments specified at the time of the call. If *func* accepts *n* arguments, then a call to **apply-partially** with *m* $\leq n$ arguments will produce a new function of *n - m* arguments³.

Here's how we could define the built-in function `1+`, if it didn't exist, using **apply-partially** and `+`, another built-in function⁴:

```
(defalias '1+ (apply-partially '+ 1)
  "Increment argument by one.")
(1+ 10)
⇒ 11
```

It is common for Lisp functions to accept functions as arguments or find them in data structures (especially in hook variables and property lists) and call them using `funcall` or `apply`. Functions that accept function arguments are often called *functionals*.

Sometimes, when you call a functional, it is useful to supply a no-op function as the argument. Here are three different kinds of no-op functions:

identity *argument*

[Function]

This function returns *argument* and has no side effects.

ignore *&rest arguments*

[Function]

This function ignores any *arguments* and returns `nil`.

always *&rest arguments*

[Function]

This function ignores any *arguments* and returns `t`.

Some functions are user-visible *commands*, which can be called interactively (usually by a key sequence). It is possible to invoke such a command exactly as though it was called interactively, by using the `call-interactively` function. See Section 22.3 [Interactive Call], page 432.

13.6 Mapping Functions

A *mapping function* applies a given function (*not* a special form or macro) to each element of a list or other collection. Emacs Lisp has several such functions; this section describes `mapcar`, `mapc`, `mapconcat`, and `mapcan`, which map over a list. See [Definition of mapatoms],

² This is related to, but different from *currying*, which transforms a function that takes multiple arguments in such a way that it can be called as a chain of functions, each one with a single argument.

³ If the number of arguments that *func* can accept is unlimited, then the new function will also accept an unlimited number of arguments, so in that case **apply-partially** doesn't reduce the number of arguments that the new function could accept.

⁴ Note that unlike the built-in function, this version accepts any number of arguments.

page 137, for the function `mapatoms` which maps over the symbols in an obarray. See [Definition of maphash], page 130, for the function `maphash` which maps over key/value associations in a hash table.

These mapping functions do not allow char-tables because a char-table is a sparse array whose nominal range of indices is very large. To map over a char-table in a way that deals properly with its sparse nature, use the function `map-char-table` (see Section 6.6 [Char-Tables], page 119).

mapcar *function sequence*

[Function]

`mapcar` applies *function* to each element of *sequence* in turn, and returns a list of the results.

The argument *sequence* can be any kind of sequence except a char-table; that is, a list, a vector, a bool-vector, or a string. The result is always a list. The length of the result is the same as the length of *sequence*. For example:

```
(mapcar #'car '((a b) (c d) (e f)))
      ⇒ (a c e)
(mapcar #'1+ [1 2 3])
      ⇒ (2 3 4)
(mapcar #'string "abc")
      ⇒ ("a" "b" "c")

;; Call each function in my-hooks.
(mapcar 'funcall my-hooks)

(defun mapcar* (function &rest args)
  "Apply FUNCTION to successive cars of all ARGS.
Return the list of results."
  ;; If no list is exhausted,
  (if (not (memq nil args))
      ;; apply function to CARS.
      (cons (apply function (mapcar #'car args))
            (apply #'mapcar* function
                   ;; Recurse for rest of elements.
                   (mapcar #'cdr args)))))

(mapcar* #'cons '(a b c) '(1 2 3 4))
      ⇒ ((a . 1) (b . 2) (c . 3))
```

mapcan *function sequence*

[Function]

This function applies *function* to each element of *sequence*, like `mapcar`, but instead of collecting the results into a list, it returns a single list with all the elements of the results (which must be lists), by altering the results (using `nconc`; see Section 5.6.3 [Rearrangement], page 90). Like with `mapcar`, *sequence* can be of any type except a char-table.

```
;; Contrast this:
(mapcar #'list '(a b c d))
⇒ ((a) (b) (c) (d))
;; with this:
(mapcan #'list '(a b c d))
⇒ (a b c d)
```

mapc *function sequence*

[Function]

mapc is like **mapcar** except that *function* is used for side-effects only—the values it returns are ignored, not collected into a list. **mapc** always returns *sequence*.

mapconcat *function sequence &optional separator*

[Function]

mapconcat applies *function* to each element of *sequence*; the results, which must be sequences of characters (strings, vectors, or lists), are concatenated into a single string return value. Between each pair of result sequences, **mapconcat** inserts the characters from *separator*, which also must be a string, or a vector or list of characters; a **nil** value is treated as the empty string. See Chapter 6 [Sequences Arrays Vectors], page 102.

The argument *function* must be a function that can take one argument and returns a sequence of characters: a string, a vector, or a list. The argument *sequence* can be any kind of sequence except a char-table; that is, a list, a vector, a bool-vector, or a string.

```
(mapconcat #'symbol-name
           '(The cat in the hat)
           " ")
⇒ "The cat in the hat"

(mapconcat (lambda (x) (format "%c" (1+ x)))
           "HAL-8000")
⇒ "IBM.9111"
```

13.7 Anonymous Functions

Although functions are usually defined with **defun** and given names at the same time, it is sometimes convenient to use an explicit lambda expression—an *anonymous function*. Anonymous functions are valid wherever function names are. They are often assigned as variable values, or as arguments to functions; for instance, you might pass one as the *function* argument to **mapcar**, which applies that function to each element of a list (see Section 13.6 [Mapping Functions], page 241). See [describe-symbols example], page 597, for a realistic example of this.

When defining a lambda expression that is to be used as an anonymous function, you can in principle use any method to construct the list. But typically you should use the **lambda** macro, or the **function** special form, or the **#'** read syntax:

lambda *args [doc] [interactive] body...*

[Macro]

This macro returns an anonymous function with argument list *args*, documentation string *doc* (if any), interactive spec *interactive* (if any), and body forms given by *body*.

Under dynamic binding, this macro effectively makes `lambda` forms self-quoting: evaluating a form whose CAR is `lambda` yields the form itself:

```
(lambda (x) (* x x))
⇒ (lambda (x) (* x x))
```

Note that when evaluating under lexical binding the result is a closure object (see Section 13.10 [Closures], page 249).

The `lambda` form has one other effect: it tells the Emacs evaluator and byte-compiler that its argument is a function, by using `function` as a subroutine (see below).

`function function-object` [Special Form]

This special form returns *function-object* without evaluating it. In this, it is similar to `quote` (see Section 10.2 [Quoting], page 151). But unlike `quote`, it also serves as a note to the Emacs evaluator and byte-compiler that *function-object* is intended to be used as a function. Assuming *function-object* is a valid lambda expression, this has two effects:

- When the code is byte-compiled, *function-object* is compiled into a byte-code function object (see Chapter 17 [Byte Compilation], page 316).
- When lexical binding is enabled, *function-object* is converted into a closure. See Section 13.10 [Closures], page 249.

When *function-object* is a symbol and the code is byte compiled, the byte-compiler will warn if that function is not defined or might not be known at run time.

The read syntax #' is a short-hand for using `function`. The following forms are all equivalent:

```
(lambda (x) (* x x))
(function (lambda (x) (* x x)))
#'(lambda (x) (* x x))
```

In the following example, we define a `change-property` function that takes a function as its third argument, followed by a `double-property` function that makes use of `change-property` by passing it an anonymous function:

```
(defun change-property (symbol prop function)
  (let ((value (get symbol prop)))
    (put symbol prop (funcall function value)))

(defun double-property (symbol prop)
  (change-property symbol prop (lambda (x) (* 2 x))))
```

Note that we do not quote the `lambda` form.

If you compile the above code, the anonymous function is also compiled. This would not happen if, say, you had constructed the anonymous function by quoting it as a list:

```
(defun double-property (symbol prop)
  (change-property symbol prop '(lambda (x) (* 2 x))))
```

In that case, the anonymous function is kept as a lambda expression in the compiled code. The byte-compiler cannot assume this list is a function, even though it looks like one, since it does not know that `change-property` intends to use it as a function.

13.8 Generic Functions

Functions defined using `defun` have a hard-coded set of assumptions about the types and expected values of their arguments. For example, a function that was designed to handle values of its argument that are either numbers or lists of numbers will fail or signal an error if called with a value of any other type, such as a vector or a string. This happens because the implementation of the function is not prepared to deal with types other than those assumed during the design.

By contrast, object-oriented programs use *polymorphic functions*: a set of specialized functions having the same name, each one of which was written for a certain specific set of argument types. Which of the functions is actually called is decided at run time based on the types of the actual arguments.

Emacs provides support for polymorphism. Like other Lisp environments, notably Common Lisp and its Common Lisp Object System (CLOS), this support is based on *generic functions*. The Emacs generic functions closely follow CLOS, including use of similar names, so if you have experience with CLOS, the rest of this section will sound very familiar.

A generic function specifies an abstract operation, by defining its name and list of arguments, but (usually) no implementation. The actual implementation for several specific classes of arguments is provided by *methods*, which should be defined separately. Each method that implements a generic function has the same name as the generic function, but the method's definition indicates what kinds of arguments it can handle by *specializing* the arguments defined by the generic function. These *argument specializers* can be more or less specific; for example, a `string` type is more specific than a more general type, such as `sequence`.

Note that, unlike in message-based OO languages, such as C++ and Simula, methods that implement generic functions don't belong to a class, they belong to the generic function they implement.

When a generic function is invoked, it selects the applicable methods by comparing the actual arguments passed by the caller with the argument specializers of each method. A method is applicable if the actual arguments of the call are compatible with the method's specializers. If more than one method is applicable, they are combined using certain rules, described below, and the combination then handles the call.

`cl-defgeneric name arguments [documentation]` [Macro]
`[options-and-methods...]` &`rest body`

This macro defines a generic function with the specified `name` and `arguments`. If `body` is present, it provides the default implementation. If `documentation` is present (it should always be), it specifies the documentation string for the generic function, in the form `(:documentation docstring)`. The optional `options-and-methods` can be one of the following forms:

`(declare declarations)`

A declare form, as described in Section 13.15 [Declare Form], page 263.

`(:argument-precedence-order &rest args)`

This form affects the sorting order for combining applicable methods. Normally, when two methods are compared during combination, method arguments are examined left to right, and the first method whose argument

specializer is more specific will come before the other one. The order defined by this form overrides that, and the arguments are examined according to their order in this form, and not left to right.

`(:method [qualifiers...] args &rest body)`

This form defines a method like `cl-defmethod` does.

`cl-defmethod name [extra] [qualifier] arguments [&context (expr spec)...] &rest [docstring] body` [Macro]

This macro defines a particular implementation for the generic function called `name`. The implementation code is given by `body`. If present, `docstring` is the documentation string for the method. The `arguments` list, which must be identical in all the methods that implement a generic function, and must match the argument list of that function, provides argument specializers of the form `(arg spec)`, where `arg` is the argument name as specified in the `cl-defgeneric` call, and `spec` is one of the following specializer forms:

`type` This specializer requires the argument to be of the given `type`, one of the types from the type hierarchy described below.

`(eql object)`

This specializer requires the argument be `eql` to the given `object`.

`(head object)`

The argument must be a cons cell whose `car` is `eql` to `object`.

`struct-type`

The argument must be an instance of a class named `struct-type` defined with `cl-defstruct` (see Section “Structures” in *Common Lisp Extensions for GNU Emacs Lisp*), or of one of its child classes.

Method definitions can make use of a new argument-list keyword, `&context`, which introduces extra specializers that test the environment at the time the method is run. This keyword should appear after the list of required arguments, but before any `&rest` or `&optional` keywords. The `&context` specializers look much like regular argument specializers—`(expr spec)`—except that `expr` is an expression to be evaluated in the current context, and the `spec` is a value to compare against. For example, `&context (overwrite-mode (eql t))` will make the method applicable only when `overwrite-mode` is turned on. The `&context` keyword can be followed by any number of context specializers. Because the context specializers are not part of the generic function’s argument signature, they may be omitted in methods that don’t require them.

The type specializer, `(arg type)`, can specify one of the *system types* in the following list. When a parent type is specified, an argument whose type is any of its more specific child types, as well as grand-children, grand-grand-children, etc. will also be compatible.

`integer` Parent type: `number`.

`number`

`null` Parent type: `symbol`

```

symbol
string      Parent type: array.
array       Parent type: sequence.
cons        Parent type: list.
list        Parent type: sequence.

marker
overlay
float       Parent type: number.

window-configuration
process

window
subr

compiled-function
buffer

char-table
    Parent type: array.

bool-vector
    Parent type: array.

vector      Parent type: array.

frame

hash-table
font-spec
font-entity
font-object

```

The optional *extra* element, expressed as ‘`:extra string`’, allows you to add more methods, distinguished by *string*, for the same specializers and qualifiers.

The optional *qualifier* allows combining several applicable methods. If it is not present, the defined method is a *primary* method, responsible for providing the primary implementation of the generic function for the specialized arguments. You can also define *auxiliary methods*, by using one of the following values as *qualifier*:

- :before** This auxiliary method will run before the primary method. More accurately, all the `:before` methods will run before the primary, in the most-specific-first order.
- :after** This auxiliary method will run after the primary method. More accurately, all such methods will run after the primary, in the most-specific-last order.
- :around** This auxiliary method will run *instead* of the primary method. The most specific of such methods will be run before any other method. Such methods normally use `cl-call-next-method`, described below, to invoke the other auxiliary or primary methods.

Functions defined using `cl-defmethod` cannot be made interactive, i.e. commands (see Section 22.2 [Defining Commands], page 424), by adding the `interactive` form to them. If you need a polymorphic command, we recommend defining a normal command that calls a polymorphic function defined via `cl-defgeneric` and `cl-defmethod`.

Each time a generic function is called, it builds the *effective method* which will handle this invocation by combining the applicable methods defined for the function. The process of finding the applicable methods and producing the effective method is called *dispatch*. The applicable methods are those all of whose specializers are compatible with the actual arguments of the call. Since all of the arguments must be compatible with the specializers, they all determine whether a method is applicable. Methods that explicitly specialize more than one argument are called *multiple-dispatch methods*.

The applicable methods are sorted into the order in which they will be combined. The method whose left-most argument specializer is the most specific one will come first in the order. (Specifying `:argument-precedence-order` as part of `cl-defmethod` overrides that, as described above.) If the method body calls `cl-call-next-method`, the next most-specific method will run. If there are applicable `:around` methods, the most-specific of them will run first; it should call `cl-call-next-method` to run any of the less specific `:around` methods. Next, the `:before` methods run in the order of their specificity, followed by the primary method, and lastly the `:after` methods in the reverse order of their specificity.

`cl-call-next-method &rest args`

[Function]

When invoked from within the lexical body of a primary or an `:around` auxiliary method, call the next applicable method for the same generic function. Normally, it is called with no arguments, which means to call the next applicable method with the same arguments that the calling method was invoked. Otherwise, the specified arguments are used instead.

`cl-next-method-p`

[Function]

This function, when called from within the lexical body of a primary or an `:around` auxiliary method, returns `non-nil` if there is a next method to call.

13.9 Accessing Function Cell Contents

The *function definition* of a symbol is the object stored in the function cell of the symbol. The functions described here access, test, and set the function cell of symbols.

See also the function `indirect-function`. See [Definition of `indirect-function`], page 148.

`symbol-function symbol`

[Function]

This returns the object in the function cell of *symbol*. It does not check that the returned object is a legitimate function.

If the function cell is void, the return value is `nil`. To distinguish between a function cell that is void and one set to `nil`, use `fboundp` (see below).

```
(defun bar (n) (+ n 2))
  (symbol-function 'bar)
    ⇒ (lambda (n) (+ n 2))
  (fset 'baz 'bar)
    ⇒ bar
```

```
(symbol-function 'baz)
⇒ bar
```

If you have never given a symbol any function definition, we say that that symbol's function cell is *void*. In other words, the function cell does not have any Lisp object in it. If you try to call the symbol as a function, Emacs signals a **void-function** error.

Note that *void* is not the same as **nil** or the symbol **void**. The symbols **nil** and **void** are Lisp objects, and can be stored into a function cell just as any other object can be (and **void** can be a valid function if you define it with **defun**). A void function cell contains no object whatsoever.

You can test the voidness of a symbol's function definition with **fboundp**. After you have given a symbol a function definition, you can make it void once more using **fmakunbound**.

fboundp *symbol* [Function]

This function returns **t** if the symbol has an object in its function cell, **nil** otherwise. It does not check that the object is a legitimate function.

fmakunbound *symbol* [Function]

This function makes *symbol*'s function cell void, so that a subsequent attempt to access this cell will cause a **void-function** error. It returns *symbol*. (See also **makunbound**, in Section 12.4 [Void Variables], page 193.)

```
(defun foo (x) x)
(foo 1)
⇒ 1
(fmakunbound 'foo)
⇒ foo
(foo 1)
[error] Symbol's function definition is void: foo
```

fset *symbol* *definition* [Function]

This function stores *definition* in the function cell of *symbol*. The result is *definition*. Normally *definition* should be a function or the name of a function, but this is not checked. The argument *symbol* is an ordinary evaluated argument.

The primary use of this function is as a subroutine by constructs that define or alter functions, like **defun** or **advice-add** (see Section 13.12 [Advising Functions], page 252). You can also use it to give a symbol a function definition that is not a function, e.g., a keyboard macro (see Section 22.16 [Keyboard Macros], page 478):

```
;; Define a named keyboard macro.
(fset 'kill-two-lines "\^u2\^k")
⇒ "\^u2\^k"
```

If you wish to use **fset** to make an alternate name for a function, consider using **defalias** instead. See [Definition of defalias], page 238.

13.10 Closures

As explained in Section 12.10 [Variable Scoping], page 201, Emacs can optionally enable lexical binding of variables. When lexical binding is enabled, any named function that you

create (e.g., with `defun`), as well as any anonymous function that you create using the `lambda` macro or the `function` special form or the `#'` syntax (see Section 13.7 [Anonymous Functions], page 243), is automatically converted into a *closure*.

A closure is a function that also carries a record of the lexical environment that existed when the function was defined. When it is invoked, any lexical variable references within its definition use the retained lexical environment. In all other respects, closures behave much like ordinary functions; in particular, they can be called in the same way as ordinary functions.

See Section 12.10.3 [Lexical Binding], page 203, for an example of using a closure.

Currently, an Emacs Lisp closure object is represented by a list with the symbol `closure` as the first element, a list representing the lexical environment as the second element, and the argument list and body forms as the remaining elements:

```
;; lexical binding is enabled.
(lambda (x) (* x x))
⇒ (closure (t) (x) (* x x))
```

However, the fact that the internal structure of a closure is exposed to the rest of the Lisp world is considered an internal implementation detail. For this reason, we recommend against directly examining or altering the structure of closure objects.

13.11 Open Closures

Traditionally, functions are opaque objects which offer no other functionality but to call them. (Emacs Lisp functions aren't fully opaque since you can extract some info out of them such as their docstring, their arglist, or their interactive spec, but they are still mostly opaque.) This is usually what we want, but occasionally we need functions to expose a bit more information about themselves.

Open closures, or *OClosures* for short, are function objects which carry additional type information and expose some information about themselves in the form of slots which you can access via accessor functions.

OClosures are defined in two steps: first you use `oclosure-define` to define a new OClosure type by specifying the slots carried by the OClosures of this type, and then you use `oclosure-lambda` to create an OClosure object of a given type.

Let's say we want to define keyboard macros, i.e. interactive functions which re-execute a sequence of key events (see Section 22.16 [Keyboard Macros], page 478). You could do it with a plain function as follows:

```
(defun kbd-macro (key-sequence)
  (lambda (&optional arg)
    (interactive "P")
    (execute-kbd-macro key-sequence arg)))
```

But with such a definition there is no easy way to extract the `key-sequence` from that function, for example to print it.

We can solve this problem using OClosures as follows. First we define the type of our keyboard macros (to which we decided to add a `counter` slot while at it):

```
(oclosure-define kbd-macro
```

```
"Keyboard macro."
keys (counter :mutable t))
```

After which we can rewrite our `kbd-macro` function:

```
(defun kbd-macro (key-sequence)
  (oclosure-lambda (kbd-macro (keys key-sequence) (counter 0))
    (&optional arg)
    (interactive "P")
    (execute-kbd-macro keys arg)
    (setq counter (1+ counter))))
```

As you can see, the `keys` and `counter` slots of the OClosure can be accessed as local variables from within the body of the OClosure. But we can now also access them from outside of the body of the OClosure, for example to describe a keyboard macro:

```
(defun describe-kbd-macro (km)
  (if (not (eq 'kbd-macro (oclosure-type km)))
    (message "Not a keyboard macro")
    (let ((keys (kbd-macro--keys km))
          (counter (kbd-macro--counter km)))
      (message "Keys=%S, called %d times" keys counter))))
```

Where `kbd-macro--keys` and `kbd-macro--counter` are accessor functions generated by the `oclosure-define` macro for oclosures whose type is `kbd-macro`.

`oclosure-define oname &optional docstring &rest slots`

[Macro]

This macro defines a new OClosure type along with accessor functions for its `slots`. `oname` can be a symbol (the name of the new type), or a list of the form `(oname . type-props)`, in which case `type-props` is a list of additional properties of this oclosure type. `slots` is a list of slot descriptions where each slot can be either a symbol (the name of the slot) or it can be of the form `(slot-name . slot-props)`, where `slot-props` is a property list of the corresponding slot `slot-name`. The OClosure type's properties specified by `type-props` can include the following:

`(:predicate pred-name)`

This requests creation of a predicate function named `pred-name`. This function will be used to recognize OClosures of the type `oname`. If this type property is not specified, `oclosure-define` will generate a default name for the predicate.

`(:parent otype)`

This makes type `otype` of OClosures be the parent of the type `oname`. The OClosures of type `oname` inherit the `slots` defined by their parent type.

`(:copier copier-name copier-args)`

This causes the definition of a functional update function, known as the `copier`, which takes an OClosure of type `oname` as its first argument and returns a copy of it with the slots named in `copier-args` modified to contain the value passed in the corresponding argument in the actual call to `copier-name`.

For each slot in *slots*, the `oclosure-define` macro creates an accessor function named `oname--slot-name`; these can be used to access the values of the slots. The slot definitions in *slots* can specify the following properties of the slots:

:mutable val

By default, slots are immutable, but if you specify the `:mutable` property with a non-`nil` value, the slot can be mutated, for example with `setf` (see Section 12.17.1 [Setting Generalized Variables], page 224).

:type val-type

This specifies the type of the values expected to appear in the slot.

oclosure-lambda (type . slots) arglist &rest body [Macro]

This macro creates an anonymous OClosure of type *type*, which should have been defined with `oclosure-define`. *slots* should be a list of elements of the form `(slot-name expr)`. At run time, each *expr* is evaluated, in order, after which the OClosure is created with its slots initialized with the resulting values.

When called as a function (see Section 13.5 [Calling Functions], page 239), the OClosure created by this macro will accept arguments according to *arglist* and will execute the code in *body*. *body* can refer to the value of any of its slot directly as if it were a local variable that had been captured by static scoping.

oclosure-type object [Function]

This function returns the OClosure type (a symbol) of *object* if it is an OClosure, and `nil` otherwise.

One other function related to OClosures is `oclosure-interactive-form`, which allows some types of OClosures to compute their interactive forms dynamically. See Section 22.2.1 [Using Interactive], page 424.

13.12 Advising Emacs Lisp Functions

When you need to modify a function defined in another library, or when you need to modify a hook like `foo-function`, a process filter, or basically any variable or object field which holds a function value, you can use the appropriate setter function, such as `fset` or `defun` for named functions, `setq` for hook variables, or `set-process-filter` for process filters, but those are often too blunt, completely throwing away the previous value.

The *advice* feature lets you add to the existing definition of a function, by *advising the function*. This is a cleaner method than redefining the whole function.

Emacs's advice system provides two sets of primitives for that: the core set, for function values held in variables and object fields (with the corresponding primitives being `add-function` and `remove-function`) and another set layered on top of it for named functions (with the main primitives being `advice-add` and `advice-remove`).

As a trivial example, here's how to add advice that'll modify the return value of a function every time it's called:

```
(defun my-double (x)
  (* x 2))
(defun my-increase (x)
```

```
(+ x 1)
(advice-add 'my-double :filter-return #'my-increase)
```

After adding this advice, if you call `my-double` with ‘3’, the return value will be ‘7’. To remove this advice, say

```
(advice-remove 'my-double #'my-increase)
```

A more advanced example would be to trace the calls to the process filter of a process `proc`:

```
(defun my-tracing-function (proc string)
  (message "Proc %S received %S" proc string)

  (add-function :before (process-filter proc) #'my-tracing-function))
```

This will cause the process’s output to be passed to `my-tracing-function` before being passed to the original process filter. `my-tracing-function` receives the same arguments as the original function. When you’re done with it, you can revert to the untraced behavior with:

```
(remove-function (process-filter proc) #'my-tracing-function)
```

Similarly, if you want to trace the execution of the function named `display-buffer`, you could use:

```
(defun his-tracing-function (orig-fun &rest args)
  (message "display-buffer called with args %S" args)
  (let ((res (apply orig-fun args)))
    (message "display-buffer returned %S" res)
    res))

(advice-add 'display-buffer :around #'his-tracing-function)
```

Here, `his-tracing-function` is called instead of the original function and receives the original function (additionally to that function’s arguments) as argument, so it can call it if and when it needs to. When you’re tired of seeing this output, you can revert to the untraced behavior with:

```
(advice-remove 'display-buffer #'his-tracing-function)
```

The arguments `:before` and `:around` used in the above examples specify how the two functions are composed, since there are many different ways to do it. The added function is also called a piece of *advice*.

13.12.1 Primitives to manipulate advices

`add-function where place function &optional props` [Macro]

This macro is the handy way to add the advice `function` to the function stored in `place` (see Section 12.17 [Generalized Variables], page 224).

`where` determines how `function` is composed with the existing function, e.g., whether `function` should be called before, or after the original function. See Section 13.12.3 [Advice Combinators], page 257, for the list of available ways to compose the two functions.

When modifying a variable (whose name will usually end with `-function`), you can choose whether `function` is used globally or only in the current buffer: if `place` is just

a symbol, then *function* is added to the global value of *place*. Whereas if *place* is of the form `(local symbol)`, where *symbol* is an expression which returns the variable name, then *function* will only be added in the current buffer. Finally, if you want to modify a lexical variable, you will have to use `(var variable)`.

Every function added with `add-function` can be accompanied by an association list of properties *props*. Currently only two of those properties have a special meaning:

name This gives a name to the advice, which `remove-function` can use to identify which function to remove. Typically used when *function* is an anonymous function.

depth This specifies how to order the advice, should several pieces of advice be present. By default, the depth is 0. A depth of 100 indicates that this piece of advice should be kept as deep as possible, whereas a depth of -100 indicates that it should stay as the outermost piece. When two pieces of advice specify the same depth, the most recently added one will be outermost.

For `:before` advice, being outermost means that this advice will be run first, before any other advice, whereas being innermost means that it will run right before the original function, with no other advice run between itself and the original function. Similarly, for `:after` advice innermost means that it will run right after the original function, with no other advice run in between, whereas outermost means that it will be run right at the end after all other advice. An innermost `:override` piece of advice will only override the original function and other pieces of advice will apply to it, whereas an outermost `:override` piece of advice will override not only the original function but all other advice applied to it as well.

If *function* is not interactive, then the combined function will inherit the interactive spec, if any, of the original function. Else, the combined function will be interactive and will use the interactive spec of *function*. One exception: if the interactive spec of *function* is a function (i.e., a `lambda` expression or an `fbound` symbol rather than an expression or a string), then the interactive spec of the combined function will be a call to that function with the interactive spec of the original function as sole argument. To interpret the spec received as argument, use `advice-eval-interactive-spec`.

Note: The interactive spec of *function* will apply to the combined function and should hence obey the calling convention of the combined function rather than that of *function*. In many cases, it makes no difference since they are identical, but it does matter for `:around`, `:filter-args`, and `:filter-return`, where *function* receives different arguments than the original function stored in *place*.

`remove-function place function`

[Macro]

This macro removes *function* from the function stored in *place*. This only works if *function* was added to *place* using `add-function`.

function is compared with functions added to *place* using `equal`, to try and make it work also with lambda expressions. It is additionally compared also with the `name` property of the functions added to *place*, which can be more reliable than comparing lambda expressions using `equal`.

`advice-function-member-p advice function-def` [Function]

Return non-nil if `advice` is already in `function-def`. Like for `remove-function` above, instead of `advice` being the actual function, it can also be the name of the piece of advice.

`advice-function-mapc f function-def` [Function]

Call the function `f` for every piece of advice that was added to `function-def`. `f` is called with two arguments: the advice function and its properties.

`advice-eval-interactive-spec spec` [Function]

Evaluate the interactive `spec` just like an interactive call to a function with such a `spec` would, and then return the corresponding list of arguments that was built. E.g., (`(advice-eval-interactive-spec "r\nP")`) will return a list of three elements, containing the boundaries of the region and the current prefix argument.

For instance, if you want to make the `C-x m (compose-mail)` command prompt for a ‘From:’ header, you could say something like this:

```
(defun my-compose-mail-advice (orig &rest args)
  "Read From: address interactively."
  (interactive
   (lambda (spec)
     (let* ((user-mail-address
            (completing-read "From: "
                             '("one.address@example.net"
                               "alternative.address@example.net"))))
       (from (message-make-from user-full-name
                                user-mail-address))
       (spec (advice-eval-interactive-spec spec)))
     ;; Put the From header into the OTHER-HEADERS argument.
     (push (cons 'From from) (nth 2 spec))
     spec)))
  (apply orig args))

(advice-add 'compose-mail :around #'my-compose-mail-advice)
```

13.12.2 Advising Named Functions

A common use of advice is for named functions and macros. You could just use `add-function` as in:

```
(add-function :around (symbol-function 'fun) #'his-tracing-function)
```

But you should use `advice-add` and `advice-remove` for that instead. This separate set of functions to manipulate pieces of advice applied to named functions, offers the following extra features compared to `add-function`: they know how to deal with macros and autoloaded functions, they let `describe-function` preserve the original docstring as well as document the added advice, and they let you add and remove advice before a function is even defined.

`advice-add` can be useful for altering the behavior of existing calls to an existing function without having to redefine the whole function. However, it can be a source of bugs, since existing callers to the function may assume the old behavior, and work incorrectly when the

behavior is changed by advice. Advice can also cause confusion in debugging, if the person doing the debugging does not notice or remember that the function has been modified by advice.

For these reasons, advice should be reserved for the cases where you cannot modify a function's behavior in any other way. If it is possible to do the same thing via a hook, that is preferable (see Section 24.1 [Hooks], page 524). If you simply want to change what a particular key does, it may be better to write a new command, and remap the old command's key bindings to the new one (see Section 23.14 [Remapping Commands], page 503).

If you are writing code for release, for others to use, try to avoid including advice in it. If the function you want to advise has no hook to do the job, please talk with the Emacs developers about adding a suitable hook. Especially, Emacs's own source files should not put advice on functions in Emacs. (There are currently a few exceptions to this convention, but we aim to correct them.) It is generally cleaner to create a new hook in `foo`, and make `bar` use the hook, than to have `bar` put advice in `foo`.

Special forms (see Section 10.1.7 [Special Forms], page 149) cannot be advised, however macros can be advised, in much the same way as functions. Of course, this will not affect code that has already been macro-expanded, so you need to make sure the advice is installed before the macro is expanded.

It is possible to advise a primitive (see Section 13.1 [What Is a Function], page 230), but one should typically *not* do so, for two reasons. Firstly, some primitives are used by the advice mechanism, and advising them could cause an infinite recursion. Secondly, many primitives are called directly from C, and such calls ignore advice; hence, one ends up in a confusing situation where some calls (occurring from Lisp code) obey the advice and other calls (from C code) do not.

define-advice *symbol* (where *lambda-list* &**optional** *name* *depth*) [Macro]
 &**rest** *body*

This macro defines a piece of advice and adds it to the function named *symbol*. The advice is an anonymous function if *name* is `nil` or a function named `symbol@name`. See **advice-add** for explanation of other arguments.

advice-add *symbol* where *function* &**optional** *props* [Function]

Add the advice *function* to the named function *symbol*. *where* and *props* have the same meaning as for **add-function** (see Section 13.12.1 [Core Advising Primitives], page 253).

advice-remove *symbol* *function* [Function]

Remove the advice *function* from the named function *symbol*. *function* can also be the **name** of a piece of advice.

advice-member-p *function* *symbol* [Function]

Return non-`nil` if the advice *function* is already in the named function *symbol*. *function* can also be the **name** of a piece of advice.

advice-mapc *function* *symbol* [Function]

Call *function* for every piece of advice that was added to the named function *symbol*. *function* is called with two arguments: the advice function and its properties.

13.12.3 Ways to compose advice

Here are the different possible values for the `where` argument of `add-function` and `advice-add`, specifying how the advice *function* and the original function should be composed.

`:before` Call *function* before the old function. Both functions receive the same arguments, and the return value of the composition is the return value of the old function. More specifically, the composition of the two functions behaves like:

```
(lambda (&rest r) (apply function r) (apply oldfun r))
```

`(add-function :before funvar function)` is comparable for single-function hooks to `(add-hook 'hookvar function)` for normal hooks.

`:after` Call *function* after the old function. Both functions receive the same arguments, and the return value of the composition is the return value of the old function. More specifically, the composition of the two functions behaves like:

```
(lambda (&rest r) (prog1 (apply oldfun r) (apply function r)))
```

`(add-function :after funvar function)` is comparable for single-function hooks to `(add-hook 'hookvar function 'append)` for normal hooks.

`:override` This completely replaces the old function with the new one. The old function can of course be recovered if you later call `remove-function`.

`:around` Call *function* instead of the old function, but provide the old function as an extra argument to *function*. This is the most flexible composition. For example, it lets you call the old function with different arguments, or many times, or within a let-binding, or you can sometimes delegate the work to the old function and sometimes override it completely. More specifically, the composition of the two functions behaves like:

```
(lambda (&rest r) (apply function oldfun r))
```

`:before-while` Call *function* before the old function and don't call the old function if *function* returns `nil`. Both functions receive the same arguments, and the return value of the composition is the return value of the old function. More specifically, the composition of the two functions behaves like:

```
(lambda (&rest r) (and (apply function r) (apply oldfun r)))
```

`(add-function :before-while funvar function)` is comparable for single-function hooks to `(add-hook 'hookvar function)` when *hookvar* is run via `run-hook-with-args-until-failure`.

`:before-until` Call *function* before the old function and only call the old function if *function* returns `nil`. More specifically, the composition of the two functions behaves like:

```
(lambda (&rest r) (or (apply function r) (apply oldfun r)))
```

`(add-function :before-until funvar function)` is comparable for single-function hooks to `(add-hook 'hookvar function)` when *hookvar* is run via `run-hook-with-args-until-success`.

:after-while

Call *function* after the old function and only if the old function returned non-*nil*. Both functions receive the same arguments, and the return value of the composition is the return value of *function*. More specifically, the composition of the two functions behaves like:

```
(lambda (&rest r) (and (apply oldfun r) (apply function r)))
(add-function :after-while funvar function) is comparable for
single-function hooks to (add-hook 'hookvar function 'append) when
hookvar is run via run-hook-with-args-until-failure.
```

:after-until

Call *function* after the old function and only if the old function returned *nil*. More specifically, the composition of the two functions behaves like:

```
(lambda (&rest r) (or (apply oldfun r) (apply function r)))
(add-function :after-until funvar function) is comparable for
single-function hooks to (add-hook 'hookvar function 'append) when
hookvar is run via run-hook-with-args-until-success.
```

:filter-args

Call *function* first and use the result (which should be a list) as the new arguments to pass to the old function. More specifically, the composition of the two functions behaves like:

```
(lambda (&rest r) (apply oldfun (funcall function r)))
```

:filter-return

Call the old function first and pass the result to *function*. More specifically, the composition of the two functions behaves like:

```
(lambda (&rest r) (funcall function (apply oldfun r)))
```

13.12.4 Adapting code using the old defadvice

A lot of code uses the old `defadvice` mechanism, which is largely made obsolete by the new `advice-add`, whose implementation and semantics is significantly simpler.

An old piece of advice such as:

```
(defadvice previous-line (before next-line-at-end
                                (&optional arg try-vscroll))
  "Insert an empty line when moving up from the top line."
  (if (and next-line-add-newlines (= arg 1)
         (save-excursion (beginning-of-line) (bobp)))
    (progn
      (beginning-of-line)
      (newline))))
```

could be translated in the new advice mechanism into a plain function:

```
(defun previous-line--next-line-at-end (&optional arg try-vscroll)
  "Insert an empty line when moving up from the top line."
  (if (and next-line-add-newlines (= arg 1)
         (save-excursion (beginning-of-line) (bobp))))
```

```
(progn
  (beginning-of-line)
  (newline))))
```

Obviously, this does not actually modify `previous-line`. For that the old advice needed:

```
(ad-activate 'previous-line)
```

whereas the new advice mechanism needs:

```
(advice-add 'previous-line :before #'previous-line--next-line-at-end)
```

Note that `ad-activate` had a global effect: it activated all pieces of advice enabled for that specified function. If you wanted to only activate or deactivate a particular piece, you needed to *enable* or *disable* it with `ad-enable-advice` and `ad-disable-advice`. The new mechanism does away with this distinction.

Around advice such as:

```
(defadvice foo (around foo-around)
  "Ignore case in `foo'."
  (let ((case-fold-search t))
    ad-do-it))
(ad-activate 'foo)
```

could translate into:

```
(defun foo--foo-around (orig-fun &rest args)
  "Ignore case in `foo'."
  (let ((case-fold-search t))
    (apply orig-fun args)))
(advice-add 'foo :around #'foo--foo-around)
```

Regarding the advice's *class*, note that the new `:before` is not quite equivalent to the old `before`, because in the old advice you could modify the function's arguments (e.g., with `ad-set-arg`), and that would affect the argument values seen by the original function, whereas in the new `:before`, modifying an argument via `setq` in the advice has no effect on the arguments seen by the original function. When porting `before` advice which relied on this behavior, you'll need to turn it into new `:around` or `:filter-args` advice instead.

Similarly old `after` advice could modify the returned value by changing `ad-return-value`, whereas new `:after` advice cannot, so when porting such old `after` advice, you'll need to turn it into new `:around` or `:filter-return` advice instead.

13.12.5 Advice and Byte Code

Not all functions can be reliably advised. The byte compiler may choose to replace a call to a function with a sequence of instructions that doesn't call the function you were interested in altering.

This usually happens due to one of the three following mechanisms:

`byte-compile` properties

If a function's symbol has a `byte-compile` property, that property will be used instead of the symbol's function definition. See Section 17.2 [Compilation Functions], page 316.

byte-optimize properties

If a function's symbol has a **byte-optimize** property, the byte compiler may rewrite the function arguments, or decide to use a different function altogether.

compiler-macro declare forms

A function can have a special **compiler-macro** declare form in its definition (see Section 13.15 [Declare Form], page 263) that defines an expander to call when compiling the function. The expander could then cause the produced byte-code not to call the original function.

13.13 Declaring Functions Obsolete

You can mark a named function as *obsolete*, meaning that it may be removed at some point in the future. This causes Emacs to warn that the function is obsolete whenever it byte-compiles code containing that function, and whenever it displays the documentation for that function. In all other respects, an obsolete function behaves like any other function.

The easiest way to mark a function as obsolete is to put a (**declare (obsolete ...)**) form in the function's **defun** definition. See Section 13.15 [Declare Form], page 263. Alternatively, you can use the **make-obsolete** function, described below.

A macro (see Chapter 14 [Macros], page 268) can also be marked obsolete with **make-obsolete**; this has the same effects as for a function. An alias for a function or macro can also be marked as obsolete; this makes the alias itself obsolete, not the function or macro which it resolves to.

make-obsolete *obsolete-name* *current-name* *when* [Function]

This function marks *obsolete-name* as obsolete. *obsolete-name* should be a symbol naming a function or macro, or an alias for a function or macro.

If *current-name* is a symbol, the warning message says to use *current-name* instead of *obsolete-name*. *current-name* does not need to be an alias for *obsolete-name*; it can be a different function with similar functionality. *current-name* can also be a string, which serves as the warning message. The message should begin in lower case, and end with a period. It can also be *nil*, in which case the warning message provides no additional details.

The argument *when* should be a string indicating when the function was first made obsolete—for example, a date or a release number.

define-obsolete-function-alias *obsolete-name* *current-name* *when* [Macro]
&optional *doc*

This convenience macro marks the function *obsolete-name* obsolete and also defines it as an alias for the function *current-name*. It is equivalent to the following:

```
(defalias obsolete-name current-name doc)
  (make-obsolete obsolete-name current-name when)
```

In addition, you can mark a particular calling convention for a function as obsolete:

set-advertised-calling-convention *function* *signature* *when* [Function]

This function specifies the argument list *signature* as the correct way to call *function*. This causes the Emacs byte compiler to issue a warning whenever it comes across an

Emacs Lisp program that calls *function* any other way (however, it will still allow the code to be byte compiled). *when* should be a string indicating when the variable was first made obsolete (usually a version number string).

For instance, in old versions of Emacs the `sit-for` function accepted three arguments, like this

```
(sit-for seconds milliseconds nodisp)
```

However, calling `sit-for` this way is considered obsolete (see Section 22.10 [Waiting], page 470). The old calling convention is deprecated like this:

```
(set-advertised-calling-convention
  'sit-for '(seconds &optional nodisp) "22.1")
```

The alternative to using this function is the `advertised-calling-convention` `declare` spec, see Section 13.15 [Declare Form], page 263.

13.14 Inline Functions

An *inline function* is a function that works just like an ordinary function, except for one thing: when you byte-compile a call to the function (see Chapter 17 [Byte Compilation], page 316), the function's definition is expanded into the caller.

The simple way to define an inline function, is to write `defsubst` instead of `defun`. The rest of the definition looks just the same, but using `defsubst` says to make it inline for byte compilation.

`defsubst name args [doc] [declare] [interactive] body... [Macro]`

This macro defines an inline function. Its syntax is exactly the same as `defun` (see Section 13.4 [Defining Functions], page 237).

Making a function inline often makes its function calls run faster. But it also has disadvantages. For one thing, it reduces flexibility; if you change the definition of the function, calls already inlined still use the old definition until you recompile them.

Another disadvantage is that making a large function inline can increase the size of compiled code both in files and in memory. Since the speed advantage of inline functions is greatest for small functions, you generally should not make large functions inline.

Also, inline functions do not behave well with respect to debugging, tracing, and advising (see Section 13.12 [Advising Functions], page 252). Since ease of debugging and the flexibility of redefining functions are important features of Emacs, you should not make a function inline, even if it's small, unless its speed is really crucial, and you've timed the code to verify that using `defun` actually has performance problems.

After an inline function is defined, its inline expansion can be performed later on in the same file, just like macros.

It's possible to use `defmacro` to define a macro to expand into the same code that an inline function would execute (see Chapter 14 [Macros], page 268). But the macro would be limited to direct use in expressions—a macro cannot be called with `apply`, `mapcar` and so on. Also, it takes some work to convert an ordinary function into a macro. To convert it into an inline function is easy; just replace `defun` with `defsubst`. Since each argument of an inline function is evaluated exactly once, you needn't worry about how many times the body uses the arguments, as you do for macros.

Alternatively, you can define a function by providing the code which will inline it as a compiler macro (see Section 13.15 [Declare Form], page 263). The following macros make this possible.

define-inline *name args [doc] [declare] body...* [Macro]

Define a function *name* by providing code that does its inlining, as a compiler macro. The function will accept the argument list *args* and will have the specified *body*.

If present, *doc* should be the function’s documentation string (see Section 13.2.4 [Function Documentation], page 235); *declare*, if present, should be a **declare** form (see Section 13.15 [Declare Form], page 263) specifying the function’s metadata.

Functions defined via **define-inline** have several advantages with respect to macros defined by **defsubst** or **defmacro**:

- They can be passed to **mapcar** (see Section 13.6 [Mapping Functions], page 241).
- They are more efficient.
- They can be used as *place forms* to store values (see Section 12.17 [Generalized Variables], page 224).
- They behave in a more predictable way than **cl-defsubst** (see Section “Argument Lists” in *Common Lisp Extensions for GNU Emacs Lisp*).

Like **defmacro**, a function inlined with **define-inline** inherits the scoping rules, either dynamic or lexical, from the call site. See Section 12.10 [Variable Scoping], page 201.

The following macros should be used in the body of a function defined by **define-inline**.

inline-quote *expression* [Macro]

Quote *expression* for **define-inline**. This is similar to the backquote (see Section 10.3 [Backquote], page 151), but quotes code and accepts only `,`, not `,@`.

inline-letvals (*bindings...*) *body...* [Macro]

This provides a convenient way to ensure that the arguments to an inlined function are evaluated exactly once, as well as to create local variables.

It’s similar to **let** (see Section 12.3 [Local Variables], page 190): It sets up local variables as specified by *bindings*, and then evaluates *body* with those bindings in effect.

Each element of *bindings* should be either a symbol or a list of the form `(var expr)`; the result is to evaluate *expr* and bind *var* to the result. However, when an element of *bindings* is just a symbol *var*, the result of evaluating *var* is re-bound to *var* (which is quite different from the way **let** works).

The tail of *bindings* can be either **nil** or a symbol which should hold a list of arguments, in which case each argument is evaluated, and the symbol is bound to the resulting list.

inline-const-p *expression* [Macro]

Return non-**nil** if the value of *expression* is already known.

inline-const-val *expression* [Macro]

Return the value of *expression*.

inline-error *format* &*rest args* [Macro]

Signal an error, formatting *args* according to *format*.

Here's an example of using **define-inline**:

```
(define-inline myaccessor (obj)
  (inline-letevals (obj)
    (inline-quote (if (foo-p ,obj) (aref (cdr ,obj) 3) (aref ,obj 2)))))
```

This is equivalent to

```
(defsubst myaccessor (obj)
  (if (foo-p obj) (aref (cdr obj) 3) (aref obj 2)))
```

13.15 The declare Form

declare is a special macro which can be used to add meta properties to a function or macro: for example, marking it as obsolete, or giving its forms a special TAB indentation convention in Emacs Lisp mode.

declare *specs...* [Macro]

This macro ignores its arguments and evaluates to **nil**; it has no run-time effect. However, when a **declare** form occurs in the *declare* argument of a **defun** or **defsubst** function definition (see Section 13.4 [Defining Functions], page 237) or a **defmacro** macro definition (see Section 14.4 [Defining Macros], page 270), it appends the properties specified by *specs* to the function or macro. This work is specially performed by **defun**, **defsubst**, and **defmacro**.

Each element in *specs* should have the form (*property args...*), which should not be quoted. These have the following effects:

(advertised-calling-convention *signature when*)

This acts like a call to **set-advertised-calling-convention** (see Section 13.13 [Obsolete Functions], page 260); *signature* specifies the correct argument list for calling the function or macro, and *when* should be a string indicating when the old argument list was first made obsolete.

(debug *edebug-form-spec*)

This is valid for macros only. When stepping through the macro with Edebug, use **edebug-form-spec**. See Section 19.2.15.1 [Instrumenting Macro Calls], page 358.

(doc-string *n*)

This is used when defining a function or macro which itself will be used to define entities like functions, macros, or variables. It indicates that the *n*th argument, if any, should be considered as a documentation string.

(indent *indent-spec*)

Indent calls to this function or macro according to *indent-spec*. This is typically used for macros, though it works for functions too. See Section 14.6 [Indenting Macros], page 275.

(interactive-only *value*)

Set the function's **interactive-only** property to *value*. See [The interactive-only property], page 424.

(obsolete *current-name* *when*)

Mark the function or macro as obsolete, similar to a call to `make-obsolete` (see Section 13.13 [Obsolete Functions], page 260). *current-name* should be a symbol (in which case the warning message says to use that instead), a string (specifying the warning message), or `nil` (in which case the warning message gives no extra details). *when* should be a string indicating when the function or macro was first made obsolete.

(compiler-macro *expander*)

This can only be used for functions, and tells the compiler to use *expander* as an optimization function. When encountering a call to the function, of the form (*function* *args...*), the macro expander will call *expander* with that form as well as with *args...*, and *expander* can either return a new expression to use instead of the function call, or it can return just the form unchanged, to indicate that the function call should be left alone.

When *expander* is a lambda form it should be written with a single argument (i.e., be of the form `(lambda (arg) body)`) because the function's formal arguments are automatically added to the lambda's list of arguments for you.

(gv-expander *expander*)

Declare *expander* to be the function to handle calls to the macro (or function) as a generalized variable, similarly to `gv-define-expander`. *expander* can be a symbol or it can be of the form `(lambda (arg) body)` in which case that function will additionally have access to the macro (or function)'s arguments.

(gv-setter *setter*)

Declare *setter* to be the function to handle calls to the macro (or function) as a generalized variable. *setter* can be a symbol in which case it will be passed to `gv-define-simple-setter`, or it can be of the form `(lambda (arg) body)` in which case that function will additionally have access to the macro (or function)'s arguments and it will be passed to `gv-define-setter`.

(completion *completion-predicate*)

Declare *completion-predicate* as a function to determine whether to include a function's symbol in the list of functions when asking for completions in `M-x`. This predicate function will only be called when `read-extended-command-predicate` is customized to `command-completion-default-include-p`; by default the value of `read-extended-command-predicate` is `nil` (see Section 22.3 [Interactive Call], page 432). The predicate *completion-predicate* is called with two arguments: the function's symbol and the current buffer.

(modes *modes*)

Specify that this command is meant to be applicable only to specified *modes*. See Section 22.2.4 [Command Modes], page 430.

`(interactive-args arg ...)`

Specify the arguments that should be stored for `repeat-command`. Each `arg` is on the form `argument-name form`.

`(pure val)`

If `val` is non-`nil`, this function is *pure* (see Section 13.1 [What Is a Function], page 230). This is the same as the `pure` property of the function’s symbol (see Section 9.4.2 [Standard Properties], page 139).

`(side-effect-free val)`

If `val` is non-`nil`, this function is free of side effects, so the byte compiler can ignore calls whose value is ignored. This is the same as the `side-effect-free` property of the function’s symbol, see Section 9.4.2 [Standard Properties], page 139.

`(speed n)` Specify the value of `native-comp-speed` in effect for native compilation of this function (see Section 18.2 [Native-Compilation Variables], page 330). This allows function-level control of the optimization level used for native code emitted for the function. In particular, if `n` is `-1`, native compilation of the function will emit bytecode instead of native code for the function.

`no-font-lock-keyword`

This is valid for macros only. Macros with this declaration are highlighted by font-lock (see Section 24.6 [Font Lock Mode], page 563) as normal functions, not specially as macros.

13.16 Telling the Compiler that a Function is Defined

Byte-compiling a file often produces warnings about functions that the compiler doesn’t know about (see Section 17.6 [Compiler Errors], page 321). Sometimes this indicates a real problem, but usually the functions in question are defined in other files which would be loaded if that code is run. For example, byte-compiling `simple.el` used to warn:

```
simple.el:8727:1:Warning: the function 'shell-mode' is not known to be
defined.
```

In fact, `shell-mode` is used only in a function that executes (`require 'shell`) before calling `shell-mode`, so `shell-mode` will be defined properly at run-time. When you know that such a warning does not indicate a real problem, it is good to suppress the warning. That makes new warnings which might mean real problems more visible. You do that with `declare-function`.

All you need to do is add a `declare-function` statement before the first use of the function in question:

```
(declare-function shell-mode "shell" ())
```

This says that `shell-mode` is defined in `shell.el` (the ‘`.el`’ can be omitted). The compiler takes for granted that that file really defines the function, and does not check.

The optional third argument specifies the argument list of `shell-mode`. In this case, it takes no arguments (`nil` is different from not specifying a value). In other cases, this might be something like (`file &optional overwrite`). You don’t have to specify the argument list, but if you do the byte compiler can check that the calls match the declaration.

declare-function *function file &optional arglist fileonly* [Macro]

Tell the byte compiler to assume that *function* is defined in the file *file*. The optional third argument *arglist* is either **t**, meaning the argument list is unspecified, or a list of formal parameters in the same style as **defun** (including the parentheses). An omitted *arglist* defaults to **t**, not **nil**; this is atypical behavior for omitted arguments, and it means that to supply a fourth but not third argument one must specify **t** for the third-argument placeholder instead of the usual **nil**. The optional fourth argument *fileonly* non-**nil** means check only that *file* exists, not that it actually defines *function*.

To verify that these functions really are declared where **declare-function** says they are, use **check-declare-file** to check all **declare-function** calls in one source file, or use **check-declare-directory** check all the files in and under a certain directory.

These commands find the file that ought to contain a function's definition using **locate-library**; if that finds no file, they expand the definition file name relative to the directory of the file that contains the **declare-function** call.

You can also say that a function is a primitive by specifying a file name ending in '**.c**' or '**.m**'. This is useful only when you call a primitive that is defined only on certain systems. Most primitives are always defined, so they will never give you a warning.

Sometimes a file will optionally use functions from an external package. If you prefix the filename in the **declare-function** statement with '**ext:**', then it will be checked if it is found, otherwise skipped without error.

There are some function definitions that '**check-declare**' does not understand (e.g., **defstruct** and some other macros). In such cases, you can pass a non-**nil** *fileonly* argument to **declare-function**, meaning to only check that the file exists, not that it actually defines the function. Note that to do this without having to specify an argument list, you should set the *arglist* argument to **t** (because **nil** means an empty argument list, as opposed to an unspecified one).

13.17 Determining whether a Function is Safe to Call

Some major modes, such as SES, call functions that are stored in user files. (See **ses**, for more information on SES.) User files sometimes have poor pedigrees—you can get a spreadsheet from someone you've just met, or you can get one through email from someone you've never met. So it is risky to call a function whose source code is stored in a user file until you have determined that it is safe.

unsafep *form &optional unsafep-vars* [Function]

Returns **nil** if *form* is a safe Lisp expression, or returns a list that describes why it might be unsafe. The argument *unsafep-vars* is a list of symbols known to have temporary bindings at this point; it is mainly used for internal recursive calls. The current buffer is an implicit argument, which provides a list of buffer-local bindings.

Being quick and simple, **unsafep** does a very light analysis and rejects many Lisp expressions that are actually safe. There are no known cases where **unsafep** returns **nil** for an unsafe expression. However, a safe Lisp expression can return a string with a **display** property, containing an associated Lisp expression to be executed after the string is inserted into a buffer. This associated expression can be a virus. In order to be safe, you must delete properties from all strings calculated by user code before inserting them into buffers.

13.18 Other Topics Related to Functions

Here is a table of several functions that do things related to function calling and function definitions. They are documented elsewhere, but we provide cross references here.

<code>apply</code>	See Section 13.5 [Calling Functions], page 239.
<code>autoload</code>	See Section 16.5 [Autoload], page 304.
<code>call-interactively</code>	See Section 22.3 [Interactive Call], page 432.
<code>called-interactively-p</code>	See Section 22.4 [Distinguish Interactive], page 435.
<code>commandp</code>	See Section 22.3 [Interactive Call], page 432.
<code>documentation</code>	See Section 25.2 [Accessing Documentation], page 596.
<code>eval</code>	See Section 10.4 [Eval], page 152.
<code>funcall</code>	See Section 13.5 [Calling Functions], page 239.
<code>function</code>	See Section 13.7 [Anonymous Functions], page 243.
<code>ignore</code>	See Section 13.5 [Calling Functions], page 239.
<code>indirect-function</code>	See Section 10.1.4 [Function Indirection], page 147.
<code>interactive</code>	See Section 22.2.1 [Using Interactive], page 424.
<code>interactive-p</code>	See Section 22.4 [Distinguish Interactive], page 435.
<code>mapatoms</code>	See Section 9.3 [Creating Symbols], page 135.
<code>mapcar</code>	See Section 13.6 [Mapping Functions], page 241.
<code>map-char-table</code>	See Section 6.6 [Char-Tables], page 119.
<code>mapconcat</code>	See Section 13.6 [Mapping Functions], page 241.
<code>undefined</code>	See Section 23.11 [Functions for Key Lookup], page 495.

14 Macros

Macros enable you to define new control constructs and other language features. A macro is defined much like a function, but instead of telling how to compute a value, it tells how to compute another Lisp expression which will in turn compute the value. We call this expression the *expansion* of the macro.

Macros can do this because they operate on the unevaluated expressions for the arguments, not on the argument values as functions do. They can therefore construct an expansion containing these argument expressions or parts of them.

If you are using a macro to do something an ordinary function could do, just for the sake of speed, consider using an inline function instead. See Section 13.14 [Inline Functions], page 261.

14.1 A Simple Example of a Macro

Suppose we would like to define a Lisp construct to increment a variable value, much like the `++` operator in C. We would like to write `(inc x)` and have the effect of `(setq x (1+ x))`. Here's a macro definition that does the job:

```
(defmacro inc (var)
  (list 'setq var (list '1+ var)))
```

When this is called with `(inc x)`, the argument `var` is the symbol `x`—*not* the *value* of `x`, as it would be in a function. The body of the macro uses this to construct the expansion, which is `(setq x (1+ x))`. Once the macro definition returns this expansion, Lisp proceeds to evaluate it, thus incrementing `x`.

macrop object [Function]
This predicate tests whether its argument is a macro, and returns `t` if so, `nil` otherwise.

14.2 Expansion of a Macro Call

A macro call looks just like a function call in that it is a list which starts with the name of the macro. The rest of the elements of the list are the arguments of the macro.

Evaluation of the macro call begins like evaluation of a function call except for one crucial difference: the macro arguments are the actual expressions appearing in the macro call. They are not evaluated before they are given to the macro definition. By contrast, the arguments of a function are results of evaluating the elements of the function call list.

Having obtained the arguments, Lisp invokes the macro definition just as a function is invoked. The argument variables of the macro are bound to the argument values from the macro call, or to a list of them in the case of a `&rest` argument. And the macro body executes and returns its value just as a function body does.

The second crucial difference between macros and functions is that the value returned by the macro body is an alternate Lisp expression, also known as the *expansion* of the macro. The Lisp interpreter proceeds to evaluate the expansion as soon as it comes back from the macro.

Since the expansion is evaluated in the normal manner, it may contain calls to other macros. It may even be a call to the same macro, though this is unusual.

Note that Emacs tries to expand macros when loading an uncompiled Lisp file. This is not always possible, but if it is, it speeds up subsequent execution. See Section 16.1 [How Programs Do Loading], page 298.

You can see the expansion of a given macro call by calling `macroexpand`.

macroexpand form &optional environment [Function]

This function expands *form*, if it is a macro call. If the result is another macro call, it is expanded in turn, until something which is not a macro call results. That is the value returned by `macroexpand`. If *form* is not a macro call to begin with, it is returned as given.

Note that `macroexpand` does not look at the subexpressions of *form* (although some macro definitions may do so). Even if they are macro calls themselves, `macroexpand` does not expand them.

The function `macroexpand` does not expand calls to inline functions. Normally there is no need for that, since a call to an inline function is no harder to understand than a call to an ordinary function.

If *environment* is provided, it specifies an alist of macro definitions that shadow the currently defined macros. Byte compilation uses this feature.

```
(defmacro inc (var)
  (list 'setq var (list '1+ var)))

(macroexpand '(inc r))
⇒ (setq r (1+ r))

(defmacro inc2 (var1 var2)
  (list 'progn (list 'inc var1) (list 'inc var2)))

(macroexpand '(inc2 r s))
⇒ (progn (inc r) (inc s)) ; inc not expanded here.
```

macroexpand-all form &optional environment [Function]

`macroexpand-all` expands macros like `macroexpand`, but will look for and expand all macros in *form*, not just at the top-level. If no macros are expanded, the return value is `eq` to *form*.

Repeating the example used for `macroexpand` above with `macroexpand-all`, we see that `macroexpand-all` does expand the embedded calls to `inc`:

```
(macroexpand-all '(inc2 r s))
⇒ (progn (setq r (1+ r)) (setq s (1+ s)))
```

macroexpand-1 form &optional environment [Function]

This function expands macros like `macroexpand`, but it only performs one step of the expansion: if the result is another macro call, `macroexpand-1` will not expand it.

14.3 Macros and Byte Compilation

You might ask why we take the trouble to compute an expansion for a macro and then evaluate the expansion. Why not have the macro body produce the desired results directly? The reason has to do with compilation.

When a macro call appears in a Lisp program being compiled, the Lisp compiler calls the macro definition just as the interpreter would, and receives an expansion. But instead of evaluating this expansion, it compiles the expansion as if it had appeared directly in the program. As a result, the compiled code produces the value and side effects intended for the macro, but executes at full compiled speed. This would not work if the macro body computed the value and side effects itself—they would be computed at compile time, which is not useful.

In order for compilation of macro calls to work, the macros must already be defined in Lisp when the calls to them are compiled. The compiler has a special feature to help you do this: if a file being compiled contains a `defmacro` form, the macro is defined temporarily for the rest of the compilation of that file.

Byte-compiling a file also executes any `require` calls at top-level in the file, so you can ensure that necessary macro definitions are available during compilation by requiring the files that define them (see Section 16.7 [Named Features], page 309). To avoid loading the macro definition files when someone *runs* the compiled program, write `eval-when-compile` around the `require` calls (see Section 17.5 [Eval During Compile], page 320).

14.4 Defining Macros

A Lisp macro object is a list whose CAR is `macro`, and whose CDR is a function. Expansion of the macro works by applying the function (with `apply`) to the list of *unevaluated* arguments from the macro call.

It is possible to use an anonymous Lisp macro just like an anonymous function, but this is never done, because it does not make sense to pass an anonymous macro to functionals such as `mapcar`. In practice, all Lisp macros have names, and they are almost always defined with the `defmacro` macro.

`defmacro name args [doc] [declare] body...` [Macro]

`defmacro` defines the symbol `name` (which should not be quoted) as a macro that looks like this:

```
(macro lambda args . body)
```

(Note that the CDR of this list is a lambda expression.) This macro object is stored in the function cell of `name`. The meaning of `args` is the same as in a function, and the keywords `&rest` and `&optional` may be used (see Section 13.2.3 [Argument List], page 234). Neither `name` nor `args` should be quoted. The return value of `defmacro` is undefined.

`doc`, if present, should be a string specifying the macro's documentation string. `declare`, if present, should be a `declare` form specifying metadata for the macro (see Section 13.15 [Declare Form], page 263). Note that macros cannot have interactive declarations, since they cannot be called interactively.

Macros often need to construct large list structures from a mixture of constants and nonconstant parts. To make this easier, use the ‘`’ syntax (see Section 10.3 [Backquote], page 151). For example:

```
(defmacro t-becomes-nil (variable)
  `(if (eq ,variable t)
       (setq ,variable nil)))

(t-becomes-nil foo)
  ≡ (if (eq foo t) (setq foo nil))
```

14.5 Common Problems Using Macros

Macro expansion can have counterintuitive consequences. This section describes some important consequences that can lead to trouble, and rules to follow to avoid trouble.

14.5.1 Wrong Time

The most common problem in writing macros is doing some of the real work prematurely—while expanding the macro, rather than in the expansion itself. For instance, one real package had this macro definition:

```
(defmacro my-set-buffer-multibyte (arg)
  (if (fboundp 'set-buffer-multibyte)
      (set-buffer-multibyte arg)))
```

With this erroneous macro definition, the program worked fine when interpreted but failed when compiled. This macro definition called `set-buffer-multibyte` during compilation, which was wrong, and then did nothing when the compiled package was run. The definition that the programmer really wanted was this:

```
(defmacro my-set-buffer-multibyte (arg)
  (if (fboundp 'set-buffer-multibyte)
      ` (set-buffer-multibyte ,arg)))
```

This macro expands, if appropriate, into a call to `set-buffer-multibyte` that will be executed when the compiled program is actually run.

14.5.2 Evaluating Macro Arguments Repeatedly

When defining a macro you must pay attention to the number of times the arguments will be evaluated when the expansion is executed. The following macro (used to facilitate iteration) illustrates the problem. This macro allows us to write a for-loop construct.

```
(defmacro for (var from init to final do &rest body)
  "Execute a simple \"for\" loop.
  For example, (for i from 1 to 10 do (print i))."
  (list 'let (list (list var init))
        (cons 'while
              (cons (list '<= var final)
                    (append body (list (list 'inc var)))))))
```

```
(for i from 1 to 3 do
  (setq square (* i i))
  (princ (format "\n%d %d" i square)))
→
(let ((i 1))
  (while (<= i 3)
    (setq square (* i i))
    (princ (format "\n%d %d" i square))
    (inc i)))

→ 1      1
→ 2      4
→ 3      9
⇒ nil
```

The arguments `from`, `to`, and `do` in this macro are syntactic sugar; they are entirely ignored. The idea is that you will write noise words (such as `from`, `to`, and `do`) in those positions in the macro call.

Here's an equivalent definition simplified through use of backquote:

```
(defmacro for (var from init to final do &rest body)
  "Execute a simple \"for\" loop.
For example, (for i from 1 to 10 do (print i))."
  `(let ((,var ,init))
     (while (<= ,var ,final)
       ,@body
       (inc ,var))))
```

Both forms of this definition (with backquote and without) suffer from the defect that `final` is evaluated on every iteration. If `final` is a constant, this is not a problem. If it is a more complex form, say `(long-complex-calculation x)`, this can slow down the execution significantly. If `final` has side effects, executing it more than once is probably incorrect.

A well-designed macro definition takes steps to avoid this problem by producing an expansion that evaluates the argument expressions exactly once unless repeated evaluation is part of the intended purpose of the macro. Here is a correct expansion for the `for` macro:

```
(let ((i 1)
      (max 3))
  (while (<= i max)
    (setq square (* i i))
    (princ (format "%d      %d" i square))
    (inc i)))
```

Here is a macro definition that creates this expansion:

```
(defmacro for (var from init to final do &rest body)
  "Execute a simple for loop: (for i from 1 to 10 do (print i))."
  `(let ((,var ,init)
        (max ,final))
    (while (<= ,var max)
      ,@body
      (inc ,var))))
```

Unfortunately, this fix introduces another problem, described in the following section.

14.5.3 Local Variables in Macro Expansions

The new definition of `for` has a new problem: it introduces a local variable named `max` which the user does not expect. This causes trouble in examples such as the following:

```
(let ((max 0))
  (for x from 0 to 10 do
    (let ((this (frob x)))
      (if (< max this)
          (setq max this)))))
```

The references to `max` inside the body of the `for`, which are supposed to refer to the user's binding of `max`, really access the binding made by `for`.

The way to correct this is to use an uninterned symbol instead of `max` (see Section 9.3 [Creating Symbols], page 135). The uninterned symbol can be bound and referred to just like any other symbol, but since it is created by `for`, we know that it cannot already appear in the user's program. Since it is not interned, there is no way the user can put it into the program later. It will never appear anywhere except where put by `for`. Here is a definition of `for` that works this way:

```
(defmacro for (var from init to final do &rest body)
  "Execute a simple for loop: (for i from 1 to 10 do (print i))."
  (let ((tempvar (make-symbol "max")))
    `(let ((,var ,init)
          (,tempvar ,final))
      (while (<= ,var ,tempvar)
        ,@body
        (inc ,var)))))
```

This creates an uninterned symbol named `max` and puts it in the expansion instead of the usual interned symbol `max` that appears in expressions ordinarily.

14.5.4 Evaluating Macro Arguments in Expansion

Another problem can happen if the macro definition itself evaluates any of the macro argument expressions, such as by calling `eval` (see Section 10.4 [Eval], page 152). You have to take into account that macro expansion may take place long before the code is executed, when the context of the caller (where the macro expansion will be evaluated) is not yet accessible.

Also, if your macro definition does not use `lexical-binding`, its formal arguments may hide the user's variables of the same name. Inside the macro body, the macro argument

binding is the most local binding of such variable, so any references inside the form being evaluated do refer to it. Here is an example:

```
(defmacro foo (a)
  (list 'setq (eval a) t))
(setq x 'b)
(foo x) ↪ (setq b t)
  ⇒ t           ; and b has been set.
;; but
(setq a 'c)
(foo a) ↪ (setq a t)
  ⇒ t           ; but this set a, not c.
```

It makes a difference whether the user's variable is named `a` or `x`, because `a` conflicts with the macro argument variable `a`.

Also, the expansion of `(foo x)` above will return something different or signal an error when the code is compiled, since in that case `(foo x)` is expanded during compilation, whereas the execution of `(setq x 'b)` will only take place later when the code is executed.

To avoid these problems, **don't evaluate an argument expression while computing the macro expansion**. Instead, substitute the expression into the macro expansion, so that its value will be computed as part of executing the expansion. This is how the other examples in this chapter work.

14.5.5 How Many Times is the Macro Expanded?

Occasionally problems result from the fact that a macro call is expanded each time it is evaluated in an interpreted function, but is expanded only once (during compilation) for a compiled function. If the macro definition has side effects, they will work differently depending on how many times the macro is expanded.

Therefore, you should avoid side effects in computation of the macro expansion, unless you really know what you are doing.

One special kind of side effect can't be avoided: constructing Lisp objects. Almost all macro expansions include constructed lists; that is the whole point of most macros. This is usually safe; there is just one case where you must be careful: when the object you construct is part of a quoted constant in the macro expansion.

If the macro is expanded just once, in compilation, then the object is constructed just once, during compilation. But in interpreted execution, the macro is expanded each time the macro call runs, and this means a new object is constructed each time.

In most clean Lisp code, this difference won't matter. It can matter only if you perform side-effects on the objects constructed by the macro definition. Thus, to avoid trouble, **avoid side effects on objects constructed by macro definitions**. Here is an example of how such side effects can get you into trouble:

```
(defmacro empty-object ()
  (list 'quote (cons nil nil)))
```

```
(defun initialize (condition)
  (let ((object (empty-object)))
    (if condition
        (setcar object condition))
    object))
```

If `initialize` is interpreted, a new list (`(nil)`) is constructed each time `initialize` is called. Thus, no side effect survives between calls. If `initialize` is compiled, then the macro `empty-object` is expanded during compilation, producing a single constant (`(nil)`) that is reused and altered each time `initialize` is called.

One way to avoid pathological cases like this is to think of `empty-object` as a funny kind of constant, not as a memory allocation construct. You wouldn't use `setcar` on a constant such as '`(nil)`', so naturally you won't use it on `(empty-object)` either.

14.6 Indenting Macros

Within a macro definition, you can use the `declare` form (see Section 14.4 [Defining Macros], page 270) to specify how TAB should indent calls to the macro. An indentation specification is written like this:

```
(declare (indent indent-spec))
```

This results in the `lisp-indent-function` property being set on the macro name.

Here are the possibilities for `indent-spec`:

- `nil` This is the same as no property—use the standard indentation pattern.
- `defun` Handle this function like a ‘`def`’ construct: treat the second line as the start of a *body*.

an integer, *number*

The first *number* arguments of the function are *distinguished* arguments; the rest are considered the body of the expression. A line in the expression is indented according to whether the first argument on it is distinguished or not. If the argument is part of the body, the line is indented `lisp-body-indent` more columns than the open-parenthesis starting the containing expression. If the argument is distinguished and is either the first or second argument, it is indented *twice* that many extra columns. If the argument is distinguished and not the first or second argument, the line uses the standard pattern.

a symbol, *symbol*

symbol should be a function name; that function is called to calculate the indentation of a line within this expression. The function receives two arguments:

- `pos` The position at which the line being indented begins.
- `state` The value returned by `parse-partial-sexp` (a Lisp primitive for indentation and nesting computation) when it parses up to the beginning of this line.

It should return either a number, which is the number of columns of indentation for that line, or a list whose car is such a number. The difference between returning a number and returning a list is that a number says that all following

lines at the same nesting level should be indented just like this one; a list says that following lines might call for different indentations. This makes a difference when the indentation is being computed by $C-M-q$; if the value is a number, $C-M-q$ need not recalculate indentation for the following lines until the end of the list.

15 Customization Settings

Users of Emacs can customize variables and faces without writing Lisp code, by using the Customize interface. See Section “Easy Customization” in *The GNU Emacs Manual*. This chapter describes how to define *customization items* that users can interact with through the Customize interface.

Customization items include customizable variables, which are defined with the `defcustom` macro; customizable faces, which are defined with `defface` (described separately in Section 41.12.2 [Defining Faces], page 1168); and *customization groups*, defined with `defgroup`, which act as containers for groups of related customization items.

15.1 Common Item Keywords

The customization declarations that we will describe in the next few sections—`defcustom`, `defgroup`, etc.—all accept keyword arguments (see Section 12.2 [Constant Variables], page 189) for specifying various information. This section describes keywords that apply to all types of customization declarations.

All of these keywords, except `:tag`, can be used more than once in a given item. Each use of the keyword has an independent effect. The keyword `:tag` is an exception because any given item can only display one name.

`:tag label`

Use *label*, a string, instead of the item’s name, to label the item in customization menus and buffers. **Don’t use a tag which is substantially different from the item’s real name; that would cause confusion.**

`:group group`

Put this customization item in group *group*. If this keyword is missing from a customization item, it’ll be placed in the same group that was last defined (in the current file).

When you use `:group` in a `defgroup`, it makes the new group a subgroup of *group*.

If you use this keyword more than once, you can put a single item into more than one group. Displaying any of those groups will show this item. Please don’t overdo this, since the result would be annoying.

`:link link-data`

Include an external link after the documentation string for this item. This is a sentence containing a button that references some other documentation.

There are several alternatives you can use for *link-data*:

`(custom-manual info-node)`

Link to an Info node; *info-node* is a string which specifies the node name, as in “`(emacs)Top`”. The link appears as ‘[Manual]’ in the customization buffer and enters the built-in Info reader on *info-node*.

`(info-link info-node)`

Like `custom-manual` except that the link appears in the customization buffer with the Info node name.

(url-link *url*)

Link to a web page; *url* is a string which specifies the URL. The link appears in the customization buffer as *url* and invokes the WWW browser specified by `browse-url-browser-function`.

(emacs-commentary-link *library*)

Link to the commentary section of a library; *library* is a string which specifies the library name. See Section D.8 [Library Headers], page 1343.

(emacs-library-link *library*)

Link to an Emacs Lisp library file; *library* is a string which specifies the library name.

(file-link *file*)

Link to a file; *file* is a string which specifies the name of the file to visit with `find-file` when the user invokes this link.

(function-link *function*)

Link to the documentation of a function; *function* is a string which specifies the name of the function to describe with `describe-function` when the user invokes this link.

(variable-link *variable*)

Link to the documentation of a variable; *variable* is a string which specifies the name of the variable to describe with `describe-variable` when the user invokes this link.

(face-link *face*)

Link to the documentation of a face; *face* is a string which specifies the name of the face to describe with `describe-face` when the user invokes this link.

(custom-group-link *group*)

Link to another customization group. Invoking it creates a new customization buffer for *group*.

You can specify the text to use in the customization buffer by adding `:tag name` after the first element of the *link-data*; for example, `(info-link :tag "foo" "(emacs)Top")` makes a link to the Emacs manual which appears in the buffer as ‘foo’.

You can use this keyword more than once, to add multiple links.

:load *file*

Load file *file* (a string) before displaying this customization item (see Chapter 16 [Loading], page 298). Loading is done with `load`, and only if the file is not already loaded.

:require *feature*

Execute `(require 'feature)` when your saved customizations set the value of this item. *feature* should be a symbol.

The most common reason to use `:require` is when a variable enables a feature such as a minor mode, and just setting the variable won't have any effect unless the code which implements the mode is loaded.

`:version version`

This keyword specifies that the item was first introduced in Emacs version *version*, or that its default value was changed in that version. The value *version* must be a string.

`:package-version '(package . version)`

This keyword specifies that the item was first introduced in *package* version *version*, or that its meaning or default value was changed in that version. This keyword takes priority over `:version`.

package should be the official name of the package, as a symbol (e.g., `MH-E`). *version* should be a string. If the package *package* is released as part of Emacs, *package* and *version* should appear in the value of `customize-package-emacs-version-alist`.

Packages distributed as part of Emacs that use the `:package-version` keyword must also update the `customize-package-emacs-version-alist` variable.

`customize-package-emacs-version-alist`

[Variable]

This alist provides a mapping for the versions of Emacs that are associated with versions of a package listed in the `:package-version` keyword. Its elements are:

`(package (pversion . eversion) ...)`

For each *package*, which is a symbol, there are one or more elements that contain a package version *pversion* with an associated Emacs version *eversion*. These versions are strings. For example, the `MH-E` package updates this alist with the following:

```
(add-to-list 'customize-package-emacs-version-alist
            '(MH-E ("6.0" . "22.1") ("6.1" . "22.1") ("7.0" . "22.1")
                  ("7.1" . "22.1") ("7.2" . "22.1") ("7.3" . "22.1")
                  ("7.4" . "22.1") ("8.0" . "22.1"))))
```

The value of *package* needs to be unique and it needs to match the *package* value appearing in the `:package-version` keyword. Since the user might see the value in an error message, a good choice is the official name of the package, such as `MH-E` or `Gnus`.

15.2 Defining Customization Groups

Each Emacs Lisp package should have one main customization group which contains all the options, faces and other groups in the package. If the package has a small number of options and faces, use just one group and put everything in it. When there are more than twenty or so options and faces, then you should structure them into subgroups, and put the subgroups under the package's main customization group. It is OK to put some of the options and faces in the package's main group alongside the subgroups.

The package's main or only group should be a member of one or more of the standard customization groups. (To display the full list of them, use `M-x customize`.) Choose one or more of them (but not too many), and add your group to each of them using the `:group` keyword.

The way to declare new customization groups is with `defgroup`.

`defgroup group members doc [keyword value]...` [Macro]

Declare *group* as a customization group containing *members*. Do not quote the symbol *group*. The argument *doc* specifies the documentation string for the group.

The argument *members* is a list specifying an initial set of customization items to be members of the group. However, most often *members* is `nil`, and you specify the group's members by using the `:group` keyword when defining those members.

If you want to specify group members through *members*, each element should have the form `(name widget)`. Here *name* is a symbol, and *widget* is a widget type for editing that symbol. Useful widgets are `custom-variable` for a variable, `custom-face` for a face, and `custom-group` for a group.

When you introduce a new group into Emacs, use the `:version` keyword in the `defgroup`; then you need not use it for the individual members of the group.

In addition to the common keywords (see Section 15.1 [Common Keywords], page 277), you can also use this keyword in `defgroup`:

`:prefix prefix`

If the name of an item in the group starts with *prefix*, and the customizable variable `custom-unlispify-remove-prefixes` is non-`nil`, the item's tag will omit *prefix*. A group can have any number of prefixes.

The variables, faces, and subgroups of a group are stored in the `custom-group` property of the group's symbol. See Section 9.4.1 [Symbol Plists], page 138. The value of that property is a list of pairs whose `car` is the symbol of the variable or the face or the subgroup, and the `cdr` is one of the corresponding symbols `custom-variable`, `custom-face`, or `custom-group`.

`custom-unlispify-remove-prefixes` [User Option]

If this variable is non-`nil`, the prefixes specified by a group's `:prefix` keyword are omitted from tag names, whenever the user customizes the group.

The default value is `nil`, i.e., the prefix-dropping feature is disabled. This is because discarding prefixes often leads to confusing names for options and faces.

15.3 Defining Customization Variables

Customizable variables, also called *user options*, are global Lisp variables whose values can be set through the Customize interface. Unlike other global variables, which are defined with `defvar` (see Section 12.5 [Defining Variables], page 194), customizable variables are defined using the `defcustom` macro. In addition to calling `defvar` as a subroutine, `defcustom` states how the variable should be displayed in the Customize interface, the values it is allowed to take, etc.

`defcustom option standard doc [keyword value]...` [Macro]

This macro declares *option* as a user option (i.e., a customizable variable). You should not quote *option*.

The argument *standard* is an expression that specifies the standard value for *option*. Evaluating the `defcustom` form evaluates *standard*, but does not necessarily bind the

option to that value. If *option* already has a default value, it is left unchanged. If the user has already saved a customization for *option*, the user's customized value is installed as the default value. Otherwise, the result of evaluating *standard* is installed as the default value.

Like `defvar`, this macro marks *option* as a special variable, meaning that it should always be dynamically bound. If *option* is already lexically bound, that lexical binding remains in effect until the binding construct exits. See Section 12.10 [Variable Scoping], page 201.

The expression *standard* can be evaluated at various other times, too—whenever the customization facility needs to know *option*'s standard value. So be sure to use an expression which is harmless to evaluate at any time.

The argument *doc* specifies the documentation string for the variable.

If a `defcustom` does not specify any `:group`, the last group defined with `defgroup` in the same file will be used. This way, most `defcustom` do not need an explicit `:group`. When you evaluate a `defcustom` form with *C-M-x* in Emacs Lisp mode (`eval-defun`), a special feature of `eval-defun` arranges to set the variable unconditionally, without testing whether its value is void. (The same feature applies to `defvar`, see Section 12.5 [Defining Variables], page 194.) Using `eval-defun` on a `defcustom` that is already defined calls the `:set` function (see below), if there is one.

If you put a `defcustom` in a pre-loaded Emacs Lisp file (see Section E.1 [Building Emacs], page 1346), the standard value installed at dump time might be incorrect, e.g., because another variable that it depends on has not been assigned the right value yet. In that case, use `custom-reevaluate-setting`, described below, to re-evaluate the standard value after Emacs starts up.

In addition to the keywords listed in Section 15.1 [Common Keywords], page 277, this macro accepts the following keywords:

`:type type`

Use *type* as the data type for this option. It specifies which values are legitimate, and how to display the value (see Section 15.4 [Customization Types], page 284). Every `defcustom` should specify a value for this keyword.

`:options value-list`

Specify the list of reasonable values for use in this option. The user is not restricted to using only these values, but they are offered as convenient alternatives.

This is meaningful only for certain types, currently including `hook`, `plist` and `alist`. See the definition of the individual types for a description of how to use `:options`.

Re-evaluating a `defcustom` form with a different `:options` value does not clear the values added by previous evaluations, or added by calls to `custom-add-frequent-value` (see below).

`:set setfunction`

Specify *setfunction* as the way to change the value of this option when using the Customize interface. The function *setfunction* should take two arguments,

a symbol (the option name) and the new value, and should do whatever is necessary to update the value properly for this option (which may not mean simply setting the option as a Lisp variable); preferably, though, it should not modify its value argument destructively. The default for *setfunction* is **set-default-toplevel-value**.

If defined, *setfunction* will also be called when evaluating a `defcustom` form with *C-M-x* in Emacs Lisp mode and when the *option*'s value is changed via the `setopt` macro (see Section 12.8 [Setting Variables], page 198).

If you specify this keyword, the variable's documentation string should describe how to do the same job in hand-written Lisp code, either by invoking *setfunction* directly or by using `setopt`.

`:get getfunction`

Specify *getfunction* as the way to extract the value of this option. The function *getfunction* should take one argument, a symbol, and should return whatever customize should use as the current value for that symbol (which need not be the symbol's Lisp value). The default is **default-toplevel-value**.

You have to really understand the workings of Custom to use `:get` correctly. It is meant for values that are treated in Custom as variables but are not actually stored in Lisp variables. It is almost surely a mistake to specify *getfunction* for a value that really is stored in a Lisp variable.

`:initialize function`

function should be a function used to initialize the variable when the `defcustom` is evaluated. It should take two arguments, the option name (a symbol) and the value. Here are some predefined functions meant for use in this way:

`custom-initialize-set`

Use the variable's `:set` function to initialize the variable, but do not reinitialize it if it is already non-void.

`custom-initialize-default`

Like `custom-initialize-set`, but use the function **set-default-toplevel-value** to set the variable, instead of the variable's `:set` function. This is the usual choice for a variable whose `:set` function enables or disables a minor mode; with this choice, defining the variable will not call the minor mode function, but customizing the variable will do so.

`custom-initialize-reset`

Always use the `:set` function to initialize the variable. If the variable is already non-void, reset it by calling the `:set` function using the current value (returned by the `:get` method). This is the default `:initialize` function.

`custom-initialize-changed`

Use the `:set` function to initialize the variable, if it is already set or has been customized; otherwise, just use **set-default-toplevel-value**.

custom-initialize-delay

This function behaves like `custom-initialize-set`, but it delays the actual initialization to the next Emacs start. This should be used in files that are preloaded (or for autoloaded variables), so that the initialization is done in the run-time context rather than the build-time context. This also has the side-effect that the (delayed) initialization is performed with the `:set` function. See Section E.1 [Building Emacs], page 1346.

:local value

If the `value` is `t`, mark `option` as automatically buffer-local; if the value is `permanent`, also set `options permanent-local` property to `t`. See Section 12.11.2 [Creating Buffer-Local], page 208.

:risky value

Set the variable's `risky-local-variable` property to `value` (see Section 12.12 [File Local Variables], page 213).

:safe function

Set the variable's `safe-local-variable` property to `function` (see Section 12.12 [File Local Variables], page 213).

:set-after variables

When setting variables according to saved customizations, make sure to set the variables `variables` before this one; i.e., delay setting this variable until after those others have been handled. Use `:set-after` if setting this variable won't work properly unless those other variables already have their intended values.

It is useful to specify the `:require` keyword for an option that turns on a certain feature. This causes Emacs to load the feature, if it is not already loaded, whenever the option is set. See Section 15.1 [Common Keywords], page 277. Here is an example:

```
(defcustom frobnicate-automatically nil
  "Non-nil means automatically frobnicate all buffers."
  :type 'boolean
  :require 'frobnicate-mode
  :group 'frobnicate)
```

If a customization item has a type such as `hook` or `alist`, which supports `:options`, you can add additional values to the list from outside the `defcustom` declaration by calling `custom-add-frequent-value`. For example, if you define a function `my-lisp-mode-initialization` intended to be called from `emacs-lisp-mode-hook`, you might want to add that to the list of reasonable values for `emacs-lisp-mode-hook`, but not by editing its definition. You can do it thus:

```
(custom-add-frequent-value 'emacs-lisp-mode-hook
  'my-lisp-mode-initialization)
```

custom-add-frequent-value symbol value

[Function]

For the customization option `symbol`, add `value` to the list of reasonable values.

The precise effect of adding a value depends on the customization type of `symbol`.

Since evaluating a `defcustom` form does not clear values added previously, Lisp programs can use this function to add values for user options not yet defined.

Internally, `defcustom` uses the symbol property `standard-value` to record the expression for the standard value, `saved-value` to record the value saved by the user with the customization buffer, and `customized-value` to record the value set by the user with the customization buffer, but not saved. See Section 9.4 [Symbol Properties], page 138. In addition, there's `themed-value`, which is used to record the value set by a theme (see Section 15.6 [Custom Themes], page 295). These properties are lists, the car of which is an expression that evaluates to the value.

`custom-reevaluate-setting symbol` [Function]

This function re-evaluates the standard value of `symbol`, which should be a user option declared via `defcustom`. If the variable was customized, this function re-evaluates the saved value instead. Then it sets the user option to that value (using the option's `:set` property if that is defined).

This is useful for customizable options that are defined before their value could be computed correctly. For example, during startup Emacs calls this function for some user options that were defined in pre-loaded Emacs Lisp files, but whose initial values depend on information available only at run-time.

`custom-variable-p arg` [Function]

This function returns `non-nil` if `arg` is a customizable variable. A customizable variable is either a variable that has a `standard-value` or `custom-autoload` property (usually meaning it was declared with `defcustom`), or an alias for another customizable variable.

15.4 Customization Types

When you define a user option with `defcustom`, you must specify its *customization type*. That is a Lisp object which describes (1) which values are legitimate and (2) how to display the value in the customization buffer for editing.

You specify the customization type in `defcustom` with the `:type` keyword. The argument of `:type` is evaluated, but only once when the `defcustom` is executed, so it isn't useful for the value to vary. Normally we use a quoted constant. For example:

```
(defcustom diff-command "diff"
  "The command to use to run diff."
  :type '(string)
  :group 'diff)
```

In general, a customization type is a list whose first element is a symbol, one of the customization type names defined in the following sections. After this symbol come a number of arguments, depending on the symbol. Between the type symbol and its arguments, you can optionally write keyword-value pairs (see Section 15.4.4 [Type Keywords], page 291).

Some type symbols do not use any arguments; those are called *simple types*. For a simple type, if you do not use any keyword-value pairs, you can omit the parentheses around the type symbol. For example just `string` as a customization type is equivalent to `(string)`.

All customization types are implemented as widgets; see Section “Introduction” in *The Emacs Widget Library*, for details.

15.4.1 Simple Types

This section describes all the simple customization types. For several of these customization types, the customization widget provides inline completion with *C-M-i* or *M-TAB*.

- sexp** The value may be any Lisp object that can be printed and read back. You can use **sexp** as a fall-back for any option, if you don't want to take the time to work out a more specific type to use.
- integer** The value must be an integer.
- natnum** The value must be a nonnegative integer.
- number** The value must be a number (floating point or integer).
- float** The value must be floating point.
- string** The value must be a string. The customization buffer shows the string without delimiting “” characters or ‘`’ quotes.
- regexp** Like **string** except that the string must be a valid regular expression.
- character**
The value must be a character code. A character code is actually an integer, but this type shows the value by inserting the character in the buffer, rather than by showing the number.
- file** The value must be a file name. The widget provides completion.
- (file :must-match t)**
The value must be a file name for an existing file. The widget provides completion.
- directory**
The value must be a directory. The widget provides completion.
- hook** The value must be a list of functions. This customization type is used for hook variables. You can use the **:options** keyword in a hook variable's **defcustom** to specify a list of functions recommended for use in the hook; See Section 15.3 [Variable Definitions], page 280.
- symbol** The value must be a symbol. It appears in the customization buffer as the symbol name. The widget provides completion.
- function** The value must be either a lambda expression or a function name. The widget provides completion for function names.
- variable** The value must be a variable name. The widget provides completion.
- face** The value must be a symbol which is a face name. The widget provides completion.
- boolean** The value is boolean—either **nil** or **t**. Note that by using **choice** and **const** together (see the next section), you can specify that the value must be **nil** or **t**, but also specify the text to describe each value in a way that fits the specific meaning of the alternative.

key The value is a valid key according to *key-valid-p*, and suitable for use with, for example `keymap-set`.

key-sequence

The value is a key sequence. The customization buffer shows the key sequence using the same syntax as the `kbd` function. See Section 23.1 [Key Sequences], page 480. This is a legacy type; use `key` instead.

coding-system

The value must be a coding-system name, and you can do completion with `M-TAB`.

color

The value must be a valid color name. The widget provides completion for color names, as well as a sample and a button for selecting a color name from a list of color names shown in a `*Colors*` buffer.

fringe-bitmap

The value must be a valid fringe bitmap name. The widget provides completion.

15.4.2 Composite Types

When none of the simple types is appropriate, you can use composite types, which build new types from other types or from specified data. The specified types or data are called the *arguments* of the composite type. The composite type normally looks like this:

`(constructor arguments...)`

but you can also add keyword-value pairs before the arguments, like this:

`(constructor {keyword value}... arguments...)`

Here is a table of constructors and how to use them to write composite types:

(cons car-type cdr-type)

The value must be a cons cell, its CAR must fit *car-type*, and its CDR must fit *cdr-type*. For example, `(cons string symbol)` is a customization type which matches values such as `("foo" . foo)`.

In the customization buffer, the CAR and CDR are displayed and edited separately, each according to their specified type.

(list element-types...)

The value must be a list with exactly as many elements as the *element-types* given; and each element must fit the corresponding *element-type*.

For example, `(list integer string function)` describes a list of three elements; the first element must be an integer, the second a string, and the third a function.

In the customization buffer, each element is displayed and edited separately, according to the type specified for it.

(group element-types...)

This works like `list` except for the formatting of text in the Custom buffer. `list` labels each element value with its tag; `group` does not.

(vector element-types...)

Like `list` except that the value must be a vector instead of a list. The elements work the same as in `list`.

```
(alist :key-type key-type :value-type value-type)
```

The value must be a list of cons-cells, the CAR of each cell representing a key of customization type *key-type*, and the CDR of the same cell representing a value of customization type *value-type*. The user can add and delete key/value pairs, and edit both the key and the value of each pair.

If omitted, *key-type* and *value-type* default to `sexp`.

The user can add any key matching the specified key type, but you can give some keys a preferential treatment by specifying them with the `:options` (see Section 15.3 [Variable Definitions], page 280). The specified keys will always be shown in the customize buffer (together with a suitable value), with a checkbox to include or exclude or disable the key/value pair from the alist. The user will not be able to edit the keys specified by the `:options` keyword argument.

The argument to the `:options` keywords should be a list of specifications for reasonable keys in the alist. Ordinarily, they are simply atoms, which stand for themselves. For example:

```
:options '("foo" "bar" "baz")
```

specifies that there are three known keys, namely "foo", "bar" and "baz", which will always be shown first.

You may want to restrict the value type for specific keys, for example, the value associated with the "bar" key can only be an integer. You can specify this by using a list instead of an atom in the list. The first element will specify the key, like before, while the second element will specify the value type. For example:

```
:options '("foo" ("bar" integer) "baz")
```

Finally, you may want to change how the key is presented. By default, the key is simply shown as a `const`, since the user cannot change the special keys specified with the `:options` keyword. However, you may want to use a more specialized type for presenting the key, like `function-item` if you know it is a symbol with a function binding. This is done by using a customization type specification instead of a symbol for the key.

```
:options '("foo"
          ((function-item some-function) integer)
          "baz")
```

Many alists use lists with two elements, instead of cons cells. For example,

```
(defcustom list-alist
  '(("foo" 1) ("bar" 2) ("baz" 3))
  "Each element is a list of the form (KEY VALUE).")
```

instead of

```
(defcustom cons-alist
  '(("foo" . 1) ("bar" . 2) ("baz" . 3))
  "Each element is a cons-cell (KEY . VALUE).")
```

Because of the way lists are implemented on top of cons cells, you can treat `list-alist` in the example above as a cons cell alist, where the value type is a list with a single element containing the real value.

```
(defcustom list-alist '(("foo" 1) ("bar" 2) ("baz" 3))
```

```
"Each element is a list of the form (KEY VALUE)."
:type '(alist :value-type (group integer)))
```

The `group` widget is used here instead of `list` only because the formatting is better suited for the purpose.

Similarly, you can have alists with more values associated with each key, using variations of this trick:

```
(defcustom person-data '(("brian" 50 t)
                         ("dorith" 55 nil)
                         ("ken" 52 t))
  "Alist of basic info about people.
  Each element has the form (NAME AGE MALE-FLAG)."
  :type '(alist :value-type (group integer boolean)))
```

`(plist :key-type key-type :value-type value-type)`

This customization type is similar to `alist` (see above), except that (i) the information is stored as a property list, (see Section 5.9 [Property Lists], page 99), and (ii) `key-type`, if omitted, defaults to `symbol` rather than `sexp`.

`(choice alternative-types...)`

The value must fit one of `alternative-types`. For example, `(choice integer string)` allows either an integer or a string.

In the customization buffer, the user selects an alternative using a menu, and can then edit the value in the usual way for that alternative.

Normally the strings in this menu are determined automatically from the choices; however, you can specify different strings for the menu by including the `:tag` keyword in the alternatives. For example, if an integer stands for a number of spaces, while a string is text to use verbatim, you might write the customization type this way,

```
(choice (integer :tag "Number of spaces")
       (string :tag "Literal text"))
```

so that the menu offers ‘Number of spaces’ and ‘Literal text’.

In any alternative for which `nil` is not a valid value, other than a `const`, you should specify a valid default for that alternative using the `:value` keyword. See Section 15.4.4 [Type Keywords], page 291.

If some values are covered by more than one of the alternatives, customize will choose the first alternative that the value fits. This means you should always list the most specific types first, and the most general last. Here’s an example of proper usage:

```
(choice (const :tag "Off" nil)
       symbol (sexp :tag "Other"))
```

This way, the special value `nil` is not treated like other symbols, and symbols are not treated like other Lisp expressions.

`(radio element-types...)`

This is similar to `choice`, except that the choices are displayed using radio buttons rather than a menu. This has the advantage of displaying documentation

for the choices when applicable and so is often a good choice for a choice between constant functions (`function-item` customization types).

(`const value`)

The value must be `value`—nothing else is allowed.

The main use of `const` is inside of `choice`. For example, `(choice integer (const nil))` allows either an integer or `nil`.

`:tag` is often used with `const`, inside of `choice`. For example,

```
(choice (const :tag "Yes" t)
       (const :tag "No" nil)
       (const :tag "Ask" foo))
```

describes a variable for which `t` means yes, `nil` means no, and `foo` means “ask”.

(`other value`)

This alternative can match any Lisp value, but if the user chooses this alternative, that selects the value `value`.

The main use of `other` is as the last element of `choice`. For example,

```
(choice (const :tag "Yes" t)
       (const :tag "No" nil)
       (other :tag "Ask" foo))
```

describes a variable for which `t` means yes, `nil` means no, and anything else means “ask”. If the user chooses ‘Ask’ from the menu of alternatives, that specifies the value `foo`; but any other value (not `t`, `nil` or `foo`) displays as ‘Ask’, just like `foo`.

(`function-item function`)

Like `const`, but used for values which are functions. This displays the documentation string as well as the function name. The documentation string is either the one you specify with `:doc`, or `function`’s own documentation string.

(`variable-item variable`)

Like `const`, but used for values which are variable names. This displays the documentation string as well as the variable name. The documentation string is either the one you specify with `:doc`, or `variable`’s own documentation string.

(`set types...`)

The value must be a list, and each element of the list must match one of the `types` specified.

This appears in the customization buffer as a checklist, so that each of `types` may have either one corresponding element or none. It is not possible to specify two different elements that match the same one of `types`. For example, `(set integer symbol)` allows one integer and/or one symbol in the list; it does not allow multiple integers or multiple symbols. As a result, it is rare to use nonspecific types such as `integer` in a `set`.

Most often, the `types` in a `set` are `const` types, as shown here:

```
(set (const :bold) (const :italic))
```

Sometimes they describe possible elements in an alist:

```
(set (cons :tag "Height" (const height) integer))
```

```
(cons :tag "Width" (const width) integer))
```

That lets the user specify a height value optionally and a width value optionally.

(repeat element-type)

The value must be a list and each element of the list must fit the type *element-type*. This appears in the customization buffer as a list of elements, with ‘[INS]’ and ‘[DEL]’ buttons for adding more elements or removing elements.

(restricted-sexp :match-alternatives criteria)

This is the most general composite type construct. The value may be any Lisp object that satisfies one of *criteria*. *criteria* should be a list, and each element should be one of these possibilities:

- A predicate—that is, a function of one argument that returns either `nil` or `non-nil` according to the argument. Using a predicate in the list says that objects for which the predicate returns `non-nil` are acceptable.
- A quoted constant—that is, '*object*'. This sort of element in the list says that *object* itself is an acceptable value.

For example,

```
(restricted-sexp :match-alternatives
                (integerp 't 'nil))
```

allows integers, `t` and `nil` as legitimate values.

The customization buffer shows all legitimate values using their read syntax, and the user edits them textually.

Here is a table of the keywords you can use in keyword-value pairs in a composite type:

:tag tag Use *tag* as the name of this alternative, for user communication purposes. This is useful for a type that appears inside of a `choice`.

:match-alternatives criteria

Use *criteria* to match possible values. This is used only in `restricted-sexp`.

:args argument-list

Use the elements of *argument-list* as the arguments of the type construct. For instance, `(const :args (foo))` is equivalent to `(const foo)`. You rarely need to write `:args` explicitly, because normally the arguments are recognized automatically as whatever follows the last keyword-value pair.

15.4.3 Splicing into Lists

The `:inline` feature lets you splice a variable number of elements into the middle of a `list` or `vector` customization type. You use it by adding `:inline t` to a type specification which is contained in a `list` or `vector` specification.

Normally, each entry in a `list` or `vector` type specification describes a single element type. But when an entry contains `:inline t`, the value it matches is merged directly into the containing sequence. For example, if the entry matches a list with three elements, those become three elements of the overall sequence. This is analogous to ‘`,@`’ in a backquote construct (see Section 10.3 [Backquote], page 151).

For example, to specify a list whose first element must be `baz` and whose remaining arguments should be zero or more of `foo` and `bar`, use this customization type:

```
(list (const baz) (set :inline t (const foo) (const bar)))
```

This matches values such as `(baz)`, `(baz foo)`, `(baz bar)` and `(baz foo bar)`.

When the element-type is a `choice`, you use `:inline` not in the `choice` itself, but in (some of) the alternatives of the `choice`. For example, to match a list which must start with a file name, followed either by the symbol `t` or two strings, use this customization type:

```
(list file
      (choice (const t)
              (list :inline t string string)))
```

If the user chooses the first alternative in the choice, then the overall list has two elements and the second element is `t`. If the user chooses the second alternative, then the overall list has three elements and the second and third must be strings.

The widgets can specify predicates to say whether an inline value matches the widget with the `:match-inline` element.

15.4.4 Type Keywords

You can specify keyword-argument pairs in a customization type after the type name symbol. Here are the keywords you can use, and their meanings:

`:value default`

Provide a default value.

If `nil` is not a valid value for the alternative, then it is essential to specify a valid default with `:value`.

If you use this for a type that appears as an alternative inside of `choice`; it specifies the default value to use, at first, if and when the user selects this alternative with the menu in the customization buffer.

Of course, if the actual value of the option fits this alternative, it will appear showing the actual value, not `default`.

`:format format-string`

This string will be inserted in the buffer to represent the value corresponding to the type. The following '%' escapes are available for use in `format-string`:

`'%[button%]'`

Display the text `button` marked as a button. The `:action` attribute specifies what the button will do if the user invokes it; its value is a function which takes two arguments—the widget which the button appears in, and the event.

There is no way to specify two different buttons with different actions.

`'%{sample%}'`

Show `sample` in a special face specified by `:sample-face`.

`'%v'`

Substitute the item's value. How the value is represented depends on the kind of item, and (for variables) on the customization type.

‘%d’	Substitute the item’s documentation string.
‘%h’	Like ‘%d’, but if the documentation string is more than one line, add a button to control whether to show all of it or just the first line.
‘%t’	Substitute the tag here. You specify the tag with the :tag keyword.
‘%%’	Display a literal ‘%’.
:action action	Perform <i>action</i> if the user clicks on a button.
:button-face face	Use the face <i>face</i> (a face name or a list of face names) for button text displayed with ‘%[...]’.
:button-prefix prefix	
:button-suffix suffix	These specify the text to display before and after a button. Each can be:
nil	No text is inserted.
a string	The string is inserted literally.
a symbol	The symbol’s value is used.
:tag tag	Use <i>tag</i> (a string) as the tag for the value (or part of the value) that corresponds to this type.
:doc doc	Use <i>doc</i> as the documentation string for this value (or part of the value) that corresponds to this type. In order for this to work, you must specify a value for :format, and use ‘%d’ or ‘%h’ in that value. The usual reason to specify a documentation string for a type is to provide more information about the meanings of alternatives inside a choice type or the parts of some other composite type.
:help-echo motion-doc	When you move to this item with <code>widget-forward</code> or <code>widget-backward</code> , it will display the string <i>motion-doc</i> in the echo area. In addition, <i>motion-doc</i> is used as the mouse <code>help-echo</code> string and may actually be a function or form evaluated to yield a help string. If it is a function, it is called with one argument, the widget.
:match function	Specify how to decide whether a value matches the type. The corresponding value, <i>function</i> , should be a function that accepts two arguments, a widget and a value; it should return non-nil if the value is acceptable.
:match-inline function	Specify how to decide whether an inline value matches the type. The corresponding value, <i>function</i> , should be a function that accepts two arguments, a widget and an inline value; it should return non-nil if the value is acceptable. See Section 15.4.3 [Splicing into Lists], page 290, for more information about inline values.

:validate function

Specify a validation function for input. *function* takes a widget as an argument, and should return `nil` if the widget's current value is valid for the widget. Otherwise, it should return the widget containing the invalid data, and set that widget's `:error` property to a string explaining the error.

:type-error string

string should be a string that describes why a value doesn't match the type, as determined by the `:match` function. When the `:match` function returns `nil`, the widget's `:error` property will be set to *string*.

15.4.5 Defining New Types

In the previous sections we have described how to construct elaborate type specifications for `defcustom`. In some cases you may want to give such a type specification a name. The obvious case is when you are using the same type for many user options: rather than repeat the specification for each option, you can give the type specification a name, and use that name each `defcustom`. The other case is when a user option's value is a recursive data structure. To make it possible for a datatype to refer to itself, it needs to have a name.

Since custom types are implemented as widgets, the way to define a new customize type is to define a new widget. We are not going to describe the widget interface here in details, see Section “Introduction” in *The Emacs Widget Library*, for that. Instead we are going to demonstrate the minimal functionality needed for defining new customize types by a simple example.

```
(define-widget 'binary-tree-of-string 'lazy
  "A binary tree made of cons-cells and strings."
  :offset 4
  :tag "Node"
  :type '(choice (string :tag "Leaf" :value "")
                 (cons :tag "Interior"
                       :value ("" . "")
                       binary-tree-of-string
                       binary-tree-of-string)))"

(defcustom foo-bar ""
  "Sample variable holding a binary tree of strings."
  :type 'binary-tree-of-string)
```

The function to define a new widget is called `define-widget`. The first argument is the symbol we want to make a new widget type. The second argument is a symbol representing an existing widget, the new widget is going to be defined in terms of difference from the existing widget. For the purpose of defining new customization types, the `lazy` widget is perfect, because it accepts a `:type` keyword argument with the same syntax as the keyword argument to `defcustom` with the same name. The third argument is a documentation string for the new widget. You will be able to see that string with the *M-x widget-browse RET binary-tree-of-string RET* command.

After these mandatory arguments follow the keyword arguments. The most important is `:type`, which describes the data type we want to match with this widget. Here a

`binary-tree-of-string` is described as being either a string, or a cons-cell whose car and cdr are themselves both `binary-tree-of-string`. Note the reference to the widget type we are currently in the process of defining. The `:tag` attribute is a string to name the widget in the user interface, and the `:offset` argument is there to ensure that child nodes are indented four spaces relative to the parent node, making the tree structure apparent in the customization buffer.

The `defcustom` shows how the new widget can be used as an ordinary customization type.

The reason for the name `lazy` is that the other composite widgets convert their inferior widgets to internal form when the widget is instantiated in a buffer. This conversion is recursive, so the inferior widgets will convert *their* inferior widgets. If the data structure is itself recursive, this conversion is an infinite recursion. The `lazy` widget prevents the recursion: it converts its `:type` argument only when needed.

15.5 Applying Customizations

The following functions are responsible for installing the user's customization settings for variables and faces, respectively. When the user invokes ‘Save for future sessions’ in the Customize interface, that takes effect by writing a `custom-set-variables` and/or a `custom-set-faces` form into the custom file, to be evaluated the next time Emacs starts.

`custom-set-variables &rest args` [Function]

This function installs the variable customizations specified by `args`. Each argument in `args` should have the form

(`var expression [now [request [comment]]]`)

`var` is a variable name (a symbol), and `expression` is an expression which evaluates to the desired customized value.

If the `defcustom` form for `var` has been evaluated prior to this `custom-set-variables` call, `expression` is immediately evaluated, and the variable's value is set to the result. Otherwise, `expression` is stored into the variable's `saved-value` property, to be evaluated when the relevant `defcustom` is called (usually when the library defining that variable is loaded into Emacs).

The `now`, `request`, and `comment` entries are for internal use only, and may be omitted. `now`, if non-`nil`, means to set the variable's value now, even if the variable's `defcustom` form has not been evaluated. `request` is a list of features to be loaded immediately (see Section 16.7 [Named Features], page 309). `comment` is a string describing the customization.

`custom-set-faces &rest args` [Function]

This function installs the face customizations specified by `args`. Each argument in `args` should have the form

(`face spec [now [comment]]]`)

`face` is a face name (a symbol), and `spec` is the customized face specification for that face (see Section 41.12.2 [Defining Faces], page 1168).

The `now` and `comment` entries are for internal use only, and may be omitted. `now`, if non-`nil`, means to install the face specification now, even if the `defface` form has not been evaluated. `comment` is a string describing the customization.

15.6 Custom Themes

Custom themes are collections of settings that can be enabled or disabled as a unit. See Section “Custom Themes” in *The GNU Emacs Manual*. Each Custom theme is defined by an Emacs Lisp source file, which should follow the conventions described in this section. (Instead of writing a Custom theme by hand, you can also create one using a Customize-like interface; see Section “Creating Custom Themes” in *The GNU Emacs Manual*.)

A Custom theme file should be named `foo-theme.el`, where `foo` is the theme name. The first Lisp form in the file should be a call to `deftheme`, and the last form should be a call to `provide-theme`.

deftheme *theme* &**optional** *doc* &**rest** *properties* [Macro]

This macro declares *theme* (a symbol) as the name of a Custom theme. The optional argument *doc* should be a string describing the theme; this is the description shown when the user invokes the `describe-theme` command or types `?` in the ‘*Custom Themes*’ buffer. The remaining arguments *properties* are used pass a property list with theme attributes.

The following attributes are supported:

:family A symbol designating what “family” a theme belongs to. A *family* of themes is a set of similar themes that differ by minor aspects, such as face colors that are meant for the light vs dark background of the frame.

:kind A symbol. If a theme is enabled and this property has the value `color-scheme`, then the `theme-choose-variant` command will look for other available themes that belong to the same family in order to switch the themes. Other values are currently unspecified and should not be used.

:background-mode

A symbol, either `light` or `dark`. This attribute is currently unused, but should still be specified.

Two special theme names are disallowed (using them causes an error): `user` is a dummy theme that stores the user’s direct customization settings, and `changed` is a dummy theme that stores changes made outside of the Customize system.

provide-theme *theme* [Macro]

This macro declares that the theme named *theme* has been fully specified.

In between `deftheme` and `provide-theme` are Lisp forms specifying the theme settings: usually a call to `custom-theme-set-variables` and/or a call to `custom-theme-set-faces`.

custom-theme-set-variables *theme* &**rest** *args* [Function]

This function specifies the Custom theme *theme*’s variable settings. *theme* should be a symbol. Each argument in *args* should be a list of the form

`(var expression [now [request [comment]]])`

where the list entries have the same meanings as in `custom-set-variables`. See Section 15.5 [Applying Customizations], page 294.

custom-theme-set-faces *theme* &*rest args* [Function]

This function specifies the Custom theme *theme*'s face settings. *theme* should be a symbol. Each argument in *args* should be a list of the form

(*face spec* [*now* [*comment*]])

where the list entries have the same meanings as in **custom-set-faces**. See Section 15.5 [Applying Customizations], page 294.

In theory, a theme file can also contain other Lisp forms, which would be evaluated when loading the theme, but that is bad form. To protect against loading themes containing malicious code, Emacs displays the source file and asks for confirmation from the user before loading any non-built-in theme for the first time. As such, themes are not ordinarily byte-compiled, and source files usually take precedence when Emacs is looking for a theme to load.

The following functions are useful for programmatically enabling and disabling themes:

custom-theme-p *theme* [Function]

This function return a non-**nil** value if *theme* (a symbol) is the name of a Custom theme (i.e., a Custom theme which has been loaded into Emacs, whether or not the theme is enabled). Otherwise, it returns **nil**.

custom-known-themes [Variable]

The value of this variable is a list of themes loaded into Emacs. Each theme is represented by a Lisp symbol (the theme name). The default value of this variable is a list containing two dummy themes: (**user changed**). The **changed** theme stores settings made before any Custom themes are applied (e.g., variables set outside of Customize). The **user** theme stores settings the user has customized and saved. Any additional themes declared with the **deftheme** macro are added to the front of this list.

load-theme *theme* &**optional** *no-confirm* *no-enable* [Command]

This function loads the Custom theme named *theme* from its source file, looking for the source file in the directories specified by the variable **custom-theme-load-path**. See Section “Custom Themes” in *The GNU Emacs Manual*. It also enables the theme (unless the optional argument *no-enable* is non-**nil**), causing its variable and face settings to take effect. It prompts the user for confirmation before loading the theme, unless the optional argument *no-confirm* is non-**nil**.

require-theme *feature* &**optional** *noerror* [Function]

This function searches **custom-theme-load-path** for a file that provides *feature* and then loads it. This is like the function **require** (see Section 16.7 [Named Features], page 309), except it searches **custom-theme-load-path** instead of **load-path** (see Section 16.3 [Library Search], page 301). This can be useful in Custom themes that need to load supporting Lisp files when **require** is unsuitable for that.

If *feature*, which should be a symbol, is not already present in the current Emacs session according to **featurep**, then **require-theme** searches for a file named *feature* with an added ‘.elc’ or ‘.el’ suffix, in that order, in the directories specified by **custom-theme-load-path**.

If a file providing *feature* is successfully found and loaded, then `require-theme` returns *feature*. The optional argument `noerror` determines what happens if the search or loading fails. If it is `nil`, the function signals an error; otherwise, it returns `nil`. If the file loads successfully but does not provide *feature*, then `require-theme` signals an error; this cannot be suppressed.

`enable-theme theme` [Command]

This function enables the Custom theme named *theme*. It signals an error if no such theme has been loaded.

`disable-theme theme` [Command]

This function disables the Custom theme named *theme*. The theme remains loaded, so that a subsequent call to `enable-theme` will re-enable it.

16 Loading

Loading a file of Lisp code means bringing its contents into the Lisp environment in the form of Lisp objects. Emacs finds and opens the file, reads the text, evaluates each form, and then closes the file. Such a file is also called a *Lisp library*.

The load functions evaluate all the expressions in a file just as the `eval-buffer` function evaluates all the expressions in a buffer. The difference is that the load functions read and evaluate the text in the file as found on disk, not the text in an Emacs buffer.

The loaded file must contain Lisp expressions, either as source code or as byte-compiled code. Each form in the file is called a *top-level form*. There is no special format for the forms in a loadable file; any form in a file may equally well be typed directly into a buffer and evaluated there. (Indeed, most code is tested this way.) Most often, the forms are function definitions and variable definitions.

Emacs can also load compiled dynamic modules: shared libraries that provide additional functionality for use in Emacs Lisp programs, just like a package written in Emacs Lisp would. When a dynamic module is loaded, Emacs calls a specially-named initialization function which the module needs to implement, and which exposes the additional functions and variables to Emacs Lisp programs.

For on-demand loading of external libraries which are known in advance to be required by certain Emacs primitives, see Section 42.21 [Dynamic Libraries], page 1299.

16.1 How Programs Do Loading

Emacs Lisp has several interfaces for loading. For example, `autoload` creates a placeholder object for a function defined in a file; trying to call the autoloading function loads the file to get the function's real definition (see Section 16.5 [Autoload], page 304). `require` loads a file if it isn't already loaded (see Section 16.7 [Named Features], page 309). Ultimately, all these facilities call the `load` function to do the work.

load *filename* &**optional** *missing-ok* *nomessage* *nosuffix* *must-suffix* [Function]
 This function finds and opens a file of Lisp code, evaluates all the forms in it, and closes the file.

To find the file, `load` first looks for a file named *filename.elc*, that is, for a file whose name is *filename* with the extension '`.elc`' appended. If such a file exists, and Emacs was compiled with native-compilation support (see Chapter 18 [Native Compilation], page 327), `load` attempts to find a corresponding '`.eln`' file, and if found, loads it instead of *filename.elc*. Otherwise, it loads *filename.elc* (and starts a background native compilation to produce the missing '`.eln`' file, followed by loading that file). If there is no *filename.elc*, then `load` looks for a file named *filename.el*. If that file exists, it is loaded. If Emacs was compiled with support for dynamic modules (see Section 16.11 [Dynamic Modules], page 314), `load` next looks for a file named *filename.ext*, where *ext* is a system-dependent file-name extension of shared libraries ('`.so`' on GNU and Unix systems). Finally, if neither of those names is found, `load` looks for a file named *filename* with nothing appended, and loads it if it exists. (The `load` function is not clever about looking at *filename*. In the perverse case of a file named *foo.el.el*, evaluation of (`(load "foo.el")`) will indeed find it.)

If Auto Compression mode is enabled, as it is by default, then if `load` can not find a file, it searches for a compressed version of the file before trying other file names. It decompresses and loads it if it exists. It looks for compressed versions by appending each of the suffixes in `jka-compr-load-suffixes` to the file name. The value of this variable must be a list of strings. Its standard value is ("`.gz`").

If the optional argument `nosuffix` is `non-nil`, then `load` does not try the suffixes '`.elc`' and '`.el`'. In this case, you must specify the precise file name you want, except that, if Auto Compression mode is enabled, `load` will still use `jka-compr-load-suffixes` to find compressed versions. By specifying the precise file name and using `t` for `nosuffix`, you can prevent file names like `foo.el.el` from being tried.

If the optional argument `must-suffix` is `non-nil`, then `load` insists that the file name used must end in either '`.el`' or '`.elc`' (possibly extended with a compression suffix) or the shared-library extension, unless it contains an explicit directory name.

If the option `load-prefer-newer` is `non-nil`, then when searching suffixes, `load` selects whichever version of a file ('`.elc`', '`.el`', etc.) has been modified most recently. In this case, `load` doesn't load the '`.eln`' natively-compiled file even if it exists.

If `filename` is a relative file name, such as `foo` or `baz/foo.bar`, `load` searches for the file using the variable `load-path`. It appends `filename` to each of the directories listed in `load-path`, and loads the first file it finds whose name matches. The current default directory is tried only if it is specified in `load-path`, where `nil` stands for the default directory. `load` tries all three possible suffixes in the first directory in `load-path`, then all three suffixes in the second directory, and so on. See Section 16.3 [Library Search], page 301.

Whatever the name under which the file is eventually found, and the directory where Emacs found it, Emacs sets the value of the variable `load-file-name` to that file's name.

If you get a warning that `foo.elc` is older than `foo.el`, it means you should consider recompiling `foo.el`. See Chapter 17 [Byte Compilation], page 316.

When loading a source file (not compiled), `load` performs character set translation just as Emacs would do when visiting the file. See Section 34.10 [Coding Systems], page 976.

When loading an uncompiled file, Emacs tries to expand any macros that the file contains (see Chapter 14 [Macros], page 268). We refer to this as *eager macro expansion*. Doing this (rather than deferring the expansion until the relevant code runs) can significantly speed up the execution of uncompiled code. Sometimes, this macro expansion cannot be done, owing to a cyclic dependency. In the simplest example of this, the file you are loading refers to a macro defined in another file, and that file in turn requires the file you are loading. Emacs will issue an error about ('Eager macro-expansion skipped due to cycle...') giving details of the problem. You have to restructure your code so that this does not happen. Loading a compiled file does not cause macroexpansion, because this should already have happened during compilation. See Section 14.3 [Compiling Macros], page 270.

Messages like 'Loading foo...' and 'Loading foo...done' appear in the echo area during loading unless `nomessage` is `non-nil`. If a natively-compiled '`.eln`' file is loaded, the message says so.

Any unhandled errors while loading a file terminate loading. If the load was done for the sake of `autoload`, any function definitions made during the loading are undone. If `load` can't find the file to load, then normally it signals a `file-error` (with 'Cannot open load file *filename*'). But if `missing-ok` is non-`nil`, then `load` just returns `nil`.

You can use the variable `load-read-function` to specify a function for `load` to use instead of `read` for reading expressions. See below.

`load` returns `t` if the file loads successfully.

`load-file` *filename*

[Command]

This command loads the file *filename*. If *filename* is a relative file name, then the current default directory is assumed. This command does not use `load-path`, and does not append suffixes. However, it does look for compressed versions (if Auto Compression Mode is enabled). Use this command if you wish to specify precisely the file name to load.

`load-library` *library*

[Command]

This command loads the library named *library*. It is equivalent to `load`, except for the way it reads its argument interactively. See Section "Lisp Libraries" in *The GNU Emacs Manual*.

`load-in-progress`

[Variable]

This variable is non-`nil` if Emacs is in the process of loading a file, and it is `nil` otherwise.

`load-file-name`

[Variable]

When Emacs is in the process of loading a file, this variable's value is the name of that file, as Emacs found it during the search described earlier in this section.

`load-read-function`

[Variable]

This variable specifies an alternate expression-reading function for `load` and `eval-region` to use instead of `read`. The function should accept one argument, just as `read` does.

By default, this variable's value is `read`. See Section 20.3 [Input Functions], page 374.

Instead of using this variable, it is cleaner to use another, newer feature: to pass the function as the `read-function` argument to `eval-region`. See [Eval], page 153.

For information about how `load` is used in building Emacs, see Section E.1 [Building Emacs], page 1346.

16.2 Load Suffixes

We now describe some technical details about the exact suffixes that `load` tries.

`load-suffixes`

[Variable]

This is a list of suffixes indicating (compiled or source) Emacs Lisp files. It should not include the empty string. `load` uses these suffixes in order when it appends Lisp suffixes to the specified file name. The standard value is `("\".elc\" \" .el")` which produces the behavior described in the previous section.

load-file-rep-suffixes

[Variable]

This is a list of suffixes that indicate representations of the same file. This list should normally start with the empty string. When `load` searches for a file it appends the suffixes in this list, in order, to the file name, before searching for another file.

Enabling Auto Compression mode appends the suffixes in `jka-compr-load-suffixes` to this list and disabling Auto Compression mode removes them again. The standard value of `load-file-rep-suffixes` if Auto Compression mode is disabled is (""). Given that the standard value of `jka-compr-load-suffixes` is (".`.gz`"), the standard value of `load-file-rep-suffixes` if Auto Compression mode is enabled is ("".`.gz`).

get-load-suffixes

[Function]

This function returns the list of all suffixes that `load` should try, in order, when its `must-suffix` argument is non-`nil`. This takes both `load-suffixes` and `load-file-rep-suffixes` into account. If `load-suffixes`, `jka-compr-load-suffixes` and `load-file-rep-suffixes` all have their standard values, this function returns (".`.elc`" ".`.elc.gz`" ".`.el`" ".`.el.gz`") if Auto Compression mode is enabled and (".`.elc`" ".`.el`") if Auto Compression mode is disabled.

To summarize, `load` normally first tries the suffixes in the value of (`get-load-suffixes`) and then those in `load-file-rep-suffixes`. If `nosuffix` is non-`nil`, it skips the former group, and if `must-suffix` is non-`nil`, it skips the latter group.

load-prefer-newer

[User Option]

If this option is non-`nil`, then rather than stopping at the first suffix that exists, `load` tests them all, and uses whichever file is the newest.

16.3 Library Search

When Emacs loads a Lisp library, it searches for the library in a list of directories specified by the variable `load-path`.

load-path

[Variable]

The value of this variable is a list of directories to search when loading files with `load`. Each element is a string (which must be a directory) or `nil` (which stands for the current working directory).

When Emacs starts up, it sets up the value of `load-path` in several steps. First, it looks for the directory containing its own Lisp files, using default locations set when Emacs was compiled. It saves this directory in `lisp-directory`. Normally, this is a directory where the `*.elc` files are installed, something like

```
"/usr/local/share/emacs/version/lisp"
```

where `version` is the Emacs version. (In this and the following examples, replace `/usr/local` with the prefix appropriate for your Emacs installation.) This directory and its subdirectories contain the standard Lisp files that come with Emacs. If Emacs cannot find its own Lisp files, it will not start correctly.

If you run Emacs from the directory where it was built—that is, an executable that has not been installed yet—Emacs instead initializes `lisp-directory` using the `lisp` subdirectory of the directory containing the sources from which it was built.

Emacs then initializes `load-path` with this `lisp-directory`. If you built Emacs in a separate directory from the sources, it also adds the `lisp` subdirectory of the build directory.

All of these directories are stored in the above two variables as absolute file names.

Unless you start Emacs with the `--no-site-lisp` option, it then adds two more `site-lisp` directories to the front of `load-path`. These are intended for locally installed Lisp files, and are normally of the form:

```
"/usr/local/share/emacs/version/site-lisp"
```

and

```
"/usr/local/share/emacs/site-lisp"
```

The first one is for locally installed files for the current Emacs *version*; the second is for locally installed files meant for use with any installed Emacs version. (If Emacs is running uninstalled, it also adds `site-lisp` subdirectories from the source and build directories, if they exist. However, normally the source and build directories do not contain `site-lisp` subdirectories.)

If the environment variable `EMACSLOADPATH` is set, it modifies the above initialization procedure. Emacs initializes `load-path` based on the value of the environment variable.

The syntax of `EMACSLOADPATH` is the same as used for `PATH`; directories are separated by ‘`:`’ (or ‘`;`’, on some operating systems). Here is an example of how to set `EMACSLOADPATH` variable (from a `sh`-style shell):

```
export EMACSLOADPATH=/home/foo/.emacs.d/lisp:
```

An empty element in the value of the environment variable, whether trailing (as in the above example, note the trailing ‘`:`’), leading, or embedded, is replaced by the default value of `load-path` as determined by the standard initialization procedure. If there are no such empty elements, then `EMACSLOADPATH` specifies the entire `load-path`. You must include either an empty element, or the explicit path to the directory containing the standard Lisp files, else Emacs will not function. (Another way to modify `load-path` is to use the `-L` command-line option when starting Emacs; see below.)

For each directory in `load-path`, Emacs then checks to see if it contains a file `subdirs.el`, and if so, loads it. The `subdirs.el` file is created when Emacs is built/installed, and contains code that causes Emacs to add any subdirectories of those directories to `load-path`. Both immediate subdirectories and subdirectories multiple levels down are added. But it excludes subdirectories whose names do not start with a letter or digit, and subdirectories named `RCS` or `CVS`, and subdirectories containing a file named `.nosearch`.

Next, Emacs adds any extra load directories that you specify using the `-L` command-line option (see Section “Action Arguments” in *The GNU Emacs Manual*). It also adds the directories where optional packages are installed, if any (see Section 43.1 [Packaging Basics], page 1303).

It is common to add code to one’s init file (see Section 42.1.2 [Init File], page 1258) to add one or more directories to `load-path`. For example:

```
(push "~/emacs.d/lisp" load-path)
```

See Section 5.5 [List Variables], page 85, for the description of `push`.

Dumping Emacs uses a special value of `load-path`. If you use a `site-load.el` or `site-init.el` file to customize the dumped Emacs (see Section E.1 [Building Emacs], page 1346), any changes to `load-path` that these files make will be lost after dumping.

lisp-directory

[Variable]

This variable holds a string naming the directory which holds Emacs's own `*.el` and `*.elc` files. This is usually the place where those files are located in the Emacs installation tree, unless Emacs is run from its build directory in which case it points to the `lisp` subdirectory in the source directory from which Emacs was built.

locate-library library &optional nosuffix path interactive-call [Command]

This command finds the precise file name for library `library`. It searches for the library in the same way `load` does, and the argument `nosuffix` has the same meaning as in `load`: don't add suffixes `'.elc'` or `'.el'` to the specified name `library`.

If the `path` is non-`nil`, that list of directories is used instead of `load-path`.

When `locate-library` is called from a program, it returns the file name as a string. When the user runs `locate-library` interactively, the argument `interactive-call` is `t`, and this tells `locate-library` to display the file name in the echo area.

list-load-path-shadows &optional stringp

[Command]

This command shows a list of *shadowed* Emacs Lisp files. A shadowed file is one that will not normally be loaded, despite being in a directory on `load-path`, due to the existence of another similarly-named file in a directory earlier on `load-path`.

For instance, suppose `load-path` is set to

```
("/opt/emacs/site-lisp" "/usr/share/emacs/29.1/lisp")
```

and that both these directories contain a file named `foo.el`. Then `(require 'foo)` never loads the file in the second directory. Such a situation might indicate a problem in the way Emacs was installed.

When called from Lisp, this function prints a message listing the shadowed files, instead of displaying them in a buffer. If the optional argument `stringp` is non-`nil`, it instead returns the shadowed files as a string.

If Emacs was compiled with support for native compilation (see Chapter 18 [Native Compilation], page 327), then when a `'.elc'` byte-compiled file is found by searching `load-path`, Emacs will try to look for a corresponding `'.eln'` file holding the corresponding natively-compiled code. The natively-compiled files are looked up in the directories listed by the `native-comp-eln-load-path`.

native-comp-eln-load-path

[Variable]

This variable holds a list of directories where Emacs looks for natively-compiled `'.eln'` files. File names in the list that are not absolute are interpreted as relative to `invocation-directory` (see Section 42.3 [System Environment], page 1265). The last directory in the list is the system directory, i.e. the directory with `'.eln'` files installed by the Emacs build and installation procedure. In each of the directories in the list, Emacs looks for `'.eln'` files in a subdirectory whose name is constructed from the Emacs version and an 8-character hash that depends on the current native-compilation ABI; the name of this subdirectory is stored in the variable `comp-native-version-dir`.

16.4 Loading Non-ASCII Characters

When Emacs Lisp programs contain string constants with non-ASCII characters, these can be represented within Emacs either as unibyte strings or as multibyte strings (see Section 34.1 [Text Representations], page 963). Which representation is used depends on how the file is read into Emacs. If it is read with decoding into multibyte representation, the text of the Lisp program will be multibyte text, and its string constants will be multibyte strings. If a file containing Latin-1 characters (for example) is read without decoding, the text of the program will be unibyte text, and its string constants will be unibyte strings. See Section 34.10 [Coding Systems], page 976.

In most Emacs Lisp programs, the fact that non-ASCII strings are multibyte strings should not be noticeable, since inserting them in unibyte buffers converts them to unibyte automatically. However, if this does make a difference, you can force a particular Lisp file to be interpreted as unibyte by writing ‘`coding: raw-text`’ in a local variables section. With that designator, the file will unconditionally be interpreted as unibyte. This can matter when making key bindings to non-ASCII characters written as `?vliteral`.

16.5 Autoload

The `autoload` facility lets you register the existence of a function or macro, but put off loading the file that defines it. The first call to the function automatically loads the proper library, in order to install the real definition and other associated code, then runs the real definition as if it had been loaded all along. Autoloading can also be triggered by looking up the documentation of the function or macro (see Section 25.1 [Documentation Basics], page 595), and completion of variable and function names (see Section 16.5.1 [Autoload by Prefix], page 307, below).

There are two ways to set up an autoloaded function: by calling `autoload`, and by writing a “magic” comment in the source before the real definition. `autoload` is the low-level primitive for autoloading; any Lisp program can call `autoload` at any time. Magic comments are the most convenient way to make a function autoload, for packages installed along with Emacs. These comments do nothing on their own, but they serve as a guide for the command `loaddefs-generate`, which constructs calls to `autoload` and arranges to execute them when Emacs is built.

`autoload` *function* *filename* &optional** *docstring* *interactive* *type*** [Function]

This function defines the function (or macro) named *function* so as to load automatically from *filename*. The string *filename* specifies the file to load to get the real definition of *function*.

If *filename* does not contain either a directory name, or the suffix `.el` or `.elc`, this function insists on adding one of these suffixes, and it will not load from a file whose name is just *filename* with no added suffix. (The variable `load-suffixes` specifies the exact required suffixes.)

The argument *docstring* is the documentation string for the function. Specifying the documentation string in the call to `autoload` makes it possible to look at the documentation without loading the function’s real definition. Normally, this should be identical to the documentation string in the function definition itself. If it isn’t, the function definition’s documentation string takes effect when it is loaded.

If *interactive* is non-`nil`, that says *function* can be called interactively. This lets completion in `M-x` work without loading *function*'s real definition. The complete interactive specification is not given here; it's not needed unless the user actually calls *function*, and when that happens, it's time to load the real definition.

If *interactive* is a list, it is interpreted as a list of modes this command is applicable for.

You can autoload macros and keymaps as well as ordinary functions. Specify *type* as `macro` if *function* is really a macro. Specify *type* as `keymap` if *function* is really a keymap. Various parts of Emacs need to know this information without loading the real definition.

An autoloaded keymap loads automatically during key lookup when a prefix key's binding is the symbol *function*. Autoloading does not occur for other kinds of access to the keymap. In particular, it does not happen when a Lisp program gets the keymap from the value of a variable and calls `keymap-set`; not even if the variable name is the same symbol *function*.

If *function* already has a non-void function definition that is not an autoload object, this function does nothing and returns `nil`. Otherwise, it constructs an autoload object (see Section 2.4.19 [Autoload Type], page 25), and stores it as the function definition for *function*. The autoload object has this form:

```
(autoload filename docstring interactive type)
```

For example,

```
(symbol-function 'run-prolog)
⇒ (autoload "prolog" 169681 t nil)
```

In this case, "prolog" is the name of the file to load, 169681 refers to the documentation string in the `emacs/etc/DOC` file (see Section 25.1 [Documentation Basics], page 595), `t` means the function is interactive, and `nil` that it is not a macro or a keymap.

autoloadp *object* [Function]

This function returns non-`nil` if *object* is an autoload object. For example, to check if `run-prolog` is defined as an autoloaded function, evaluate

```
(autoloadp (symbol-function 'run-prolog))
```

The autoloaded file usually contains other definitions and may require or provide one or more features. If the file is not completely loaded (due to an error in the evaluation of its contents), any function definitions or `provide` calls that occurred during the load are undone. This is to ensure that the next attempt to call any function autoloading from this file will try again to load the file. If not for this, then some of the functions in the file might be defined by the aborted load, but fail to work properly for the lack of certain subroutines not loaded successfully because they come later in the file.

If the autoloaded file fails to define the desired Lisp function or macro, then an error is signaled with data "Autoloading failed to define function *function-name*".

A magic autoload comment (often called an *autoload cookie*) consists of '`;; ;##autoload`', on a line by itself, just before the real definition of the function in its autoloadable source file. The function `loaddefs-generate` writes a corresponding `autoload` call into `loaddefs.el`. (The string that serves as the autoload cookie and the name of the file generated by

`loaddefs-generate` can be changed from the above defaults, see below.) Building Emacs loads `loaddefs.el` and thus calls `autoload`.

The same magic comment can copy any kind of form into `loaddefs.el`. The form following the magic comment is copied verbatim, *except* if it is one of the forms which the `autoload` facility handles specially (e.g., by conversion into an `autoload` call). The forms which are not copied verbatim are the following:

Definitions for function or function-like objects:

`defun` and `defmacro`; also `cl-defun` and `cl-defmacro` (see Section “Argument Lists” in *Common Lisp Extensions*), and `define-overloadable-function` (see the commentary in `mode-local.el`).

Definitions for major or minor modes:

`define-minor-mode`, `define-globalized-minor-mode`, `define-generic-mode`, `define-derived-mode`, `easy-mmode-define-minor-mode`, `easy-mmode-define-global-mode`, `define-compilation-mode`, and `define-global-minor-mode`.

Other definition types:

`defcustom`, `defgroup`, `deftheme`, `defclass` (see *EIEIO*), and `define-skeleton` (see *Autotyping*).

You can also use a magic comment to execute a form at build time *without* executing it when the file itself is loaded. To do this, write the form *on the same line* as the magic comment. Since it is in a comment, it does nothing when you load the source file; but `loaddefs-generate` copies it to `loaddefs.el`, where it is executed while building Emacs.

The following example shows how `doctor` is prepared for autoloading with a magic comment:

```
;;;###autoload
(defun doctor ()
  "Switch to *doctor* buffer and start giving psychotherapy."
  (interactive)
  (switch-to-buffer "*doctor*")
  (doctor-mode))
```

Here's what that produces in `loaddefs.el`:

```
(autoload 'doctor "doctor" "
Switch to *doctor* buffer and start giving psychotherapy.

\\(fn)" t nil)
```

While the `loaddefs.el` isn't for editing, we try to keep it somewhat readable for people. For instance, control characters in `defvar` values are escaped, and we insert a backslash and newline immediately following the double-quote of the doc string to keep the line length down. ‘`(fn)`’ in the usage part of the documentation string is replaced with the function's name when the various help functions (see Section 25.6 [Help Functions], page 602) display it.

If you write a function definition with an unusual macro that is not one of the known and recognized function definition methods, use of an ordinary magic `autoload` comment

would copy the whole definition into `loaddefs.el`. That is not desirable. You can put the desired autoload call into `loaddefs.el` instead by writing this:

```
; ;###autoload (autoload 'foo "myfile")
(mydefunmacro foo
...)
```

You can use a non-default string as the autoload cookie and have the corresponding autoload calls written into a file whose name is different from the default `loaddefs.el`. Emacs provides two variables to control this:

lisp-mode-autoload-regexp [Variable]

The value of this constant is a regexp that matches autoload cookies. `loaddefs-generate` copies the Lisp form that follows the cookie into the autoload file it generates. This will match comments like ‘`; ;###autoload`’ and ‘`; ;###calc-autoload`’.

generated-autoload-file [Variable]

The value of this variable names an Emacs Lisp file where the autoload calls should go. The default value is `loaddefs.el`, but you can override that, e.g., in the local variables section of a `.el` file (see Section 12.12 [File Local Variables], page 213). The autoload file is assumed to contain a trailer starting with a formfeed character.

The following function may be used to explicitly load the library specified by an autoload object:

autoload-do-load *autoload &optional name macro-only* [Function]

This function performs the loading specified by `autoload`, which should be an autoload object. The optional argument `name`, if non-`nil`, should be a symbol whose function value is `autoload`; in that case, the return value of this function is the symbol’s new function value. If the value of the optional argument `macro-only` is `macro`, this function avoids loading a function, only a macro.

16.5.1 Autoload by Prefix

During completion for the commands `describe-variable` and `describe-function`, Emacs will try to load files which may contain definitions matching the prefix being completed. The variable `definition-prefixes` holds a hashtable which maps a prefix to the corresponding list of files to load for it. Entries to this mapping are added by calls to `register-definition-prefixes` which are generated by `loaddefs-generate` (see Section 16.5 [Autoload], page 304). Files which don’t contain any definitions worth loading (test files, for example), should set `autoload-compute-prefixes` to `nil` as a file-local variable.

16.5.2 When to Use Autoload

Do not add an autoload comment unless it is really necessary. Autoloading code means it is always globally visible. Once an item is autoloaded, there is no compatible way to transition back to it not being autoloaded (after people become accustomed to being able to use it without an explicit load).

- The most common items to autoload are the interactive entry points to a library. For example, if `python.el` is a library defining a major-mode for editing Python code,

autoload the definition of the `python-mode` function, so that people can simply use `M-x python-mode` to load the library.

- Variables usually don't need to be autoloaded. An exception is if the variable on its own is generally useful without the whole defining library being loaded. (An example of this might be something like `find-exec-terminator`.)
- Don't autoload a user option just so that a user can set it.
- Never add an autoload *comment* to silence a compiler warning in another file. In the file that produces the warning, use `(defvar foo)` to silence an undefined variable warning, and `declare-function` (see Section 13.16 [Declaring Functions], page 265) to silence an undefined function warning; or require the relevant library; or use an explicit autoload *statement*.

16.6 Repeated Loading

You can load a given file more than once in an Emacs session. For example, after you have rewritten and reinstalled a function definition by editing it in a buffer, you may wish to return to the original version; you can do this by reloading the file it came from.

When you load or reload files, bear in mind that the `load` and `load-library` functions automatically load a byte-compiled file rather than a non-compiled file of similar name. If you rewrite a file that you intend to save and reinstall, you need to byte-compile the new version; otherwise Emacs will load the older, byte-compiled file instead of your newer, non-compiled file! If that happens, the message displayed when loading the file includes, '`(compiled; note, source is newer)`', to remind you to recompile it.

When writing the forms in a Lisp library file, keep in mind that the file might be loaded more than once. For example, think about whether each variable should be reinitialized when you reload the library; `defvar` does not change the value if the variable is already initialized. (See Section 12.5 [Defining Variables], page 194.)

The simplest way to add an element to an alist is like this:

```
(push '(leif-mode "Leif") minor-mode-alist)
```

But this would add multiple elements if the library is reloaded. To avoid the problem, use `add-to-list` (see Section 5.5 [List Variables], page 85):

```
(add-to-list 'minor-mode-alist '(leif-mode "Leif"))
```

Occasionally you will want to test explicitly whether a library has already been loaded. If the library uses `provide` to provide a named feature, you can use `featurep` earlier in the file to test whether the `provide` call has been executed before (see Section 16.7 [Named Features], page 309). Alternatively, you could use something like this:

```
(defvar foo-was-loaded nil)

(unless foo-was-loaded
  execute-first-time-only
  (setq foo-was-loaded t))
```

16.7 Features

`provide` and `require` are an alternative to `autoload` for loading files automatically. They work in terms of named *features*. Autoloading is triggered by calling a specific function, but a feature is loaded the first time another program asks for it by name.

A feature name is a symbol that stands for a collection of functions, variables, etc. The file that defines them should *provide* the feature. Another program that uses them may ensure they are defined by *requiring* the feature. This loads the file of definitions if it hasn't been loaded already.

To require the presence of a feature, call `require` with the feature name as argument. `require` looks in the global variable `features` to see whether the desired feature has been provided already. If not, it loads the feature from the appropriate file. This file should call `provide` at the top level to add the feature to `features`; if it fails to do so, `require` signals an error.

For example, in `idlwave.el`, the definition for `idlwave-complete-filename` includes the following code:

```
(defun idlwave-complete-filename ()
  "Use the comint stuff to complete a file name."
  (require 'comint)
  (let* ((comint-file-name-chars "^\~A-Za-z0-9+@:_.$#%={}\\\\"")
         (comint-completion-addsuffix nil)
         ...)
  (comint-dynamic-complete-filename)))
```

The expression `(require 'comint)` loads the file `comint.el` if it has not yet been loaded, ensuring that `comint-dynamic-complete-filename` is defined. Features are normally named after the files that provide them, so that `require` need not be given the file name. (Note that it is important that the `require` statement be outside the body of the `let`. Loading a library while its variables are let-bound can have unintended consequences, namely the variables becoming unbound after the `let` exits.)

The `comint.el` file contains the following top-level expression:

```
(provide 'comint)
```

This adds `comint` to the global `features` list, so that `(require 'comint)` will henceforth know that nothing needs to be done.

When `require` is used at top level in a file, it takes effect when you byte-compile that file (see Chapter 17 [Byte Compilation], page 316) as well as when you load it. This is in case the required package contains macros that the byte compiler must know about. It also avoids byte compiler warnings for functions and variables defined in the file loaded with `require`.

Although top-level calls to `require` are evaluated during byte compilation, `provide` calls are not. Therefore, you can ensure that a file of definitions is loaded before it is byte-compiled by including a `provide` followed by a `require` for the same feature, as in the following example.

```
(provide 'my-feature) ; Ignored by byte compiler,
                     ; evaluated by load.
(require 'my-feature) ; Evaluated by byte compiler.
```

The compiler ignores the `provide`, then processes the `require` by loading the file in question. Loading the file does execute the `provide` call, so the subsequent `require` call does nothing when the file is loaded.

provide feature &optional subfeatures [Function]

This function announces that *feature* is now loaded, or being loaded, into the current Emacs session. This means that the facilities associated with *feature* are or will be available for other Lisp programs.

The direct effect of calling `provide` is to add *feature* to the front of `features` if it is not already in that list and call any `eval-after-load` code waiting for it (see Section 16.10 [Hooks for Loading], page 313). The argument *feature* must be a symbol. `provide` returns *feature*.

If provided, *subfeatures* should be a list of symbols indicating a set of specific subfeatures provided by this version of *feature*. You can test the presence of a subfeature using `featurep`. The idea of subfeatures is that you use them when a package (which is one *feature*) is complex enough to make it useful to give names to various parts or functionalities of the package, which might or might not be loaded, or might or might not be present in a given version. See Section 40.17.3 [Network Feature Testing], page 1119, for an example.

```
features
⇒ (bar bish)

(provide 'foo)
⇒ foo
features
⇒ (foo bar bish)
```

When a file is loaded to satisfy an autoload, and it stops due to an error in the evaluation of its contents, any function definitions or `provide` calls that occurred during the load are undone. See Section 16.5 [Autoload], page 304.

require feature &optional filename noerror [Function]

This function checks whether *feature* is present in the current Emacs session (using (`featurep feature`); see below). The argument *feature* must be a symbol.

If the feature is not present, then `require` loads *filename* with `load`. If *filename* is not supplied, then the name of the symbol *feature* is used as the base file name to load. However, in this case, `require` insists on finding *feature* with an added ‘`.el`’ or ‘`.elc`’ suffix (possibly extended with a compression suffix); a file whose name is just *feature* won’t be used. (The variable `load-suffixes` specifies the exact required Lisp suffixes.)

If *noerror* is non-`nil`, that suppresses errors from actual loading of the file. In that case, `require` returns `nil` if loading the file fails. Normally, `require` returns *feature*.

If loading the file succeeds but does not provide *feature*, `require` signals an error about the missing feature.

featurep feature &optional subfeature [Function]

This function returns `t` if *feature* has been provided in the current Emacs session (i.e., if *feature* is a member of `features`.) If *subfeature* is non-`nil`, then the function

returns `t` only if that subfeature is provided as well (i.e., if `subfeature` is a member of the `subfeature` property of the `feature` symbol.)

features

[Variable]

The value of this variable is a list of symbols that are the features loaded in the current Emacs session. Each symbol was put in this list with a call to `provide`. The order of the elements in the `features` list is not significant.

The `use-package` macro provides a convenient way of loading a feature and configuring it for use. It provides a means to combine requiring a feature, like `require` does, with code to be run when the feature is actually loaded, similar to load-time hooks (see Section 16.10 [Hooks for Loading], page 313). The declarative syntax of `use-package` makes it exceptionally easy to use in user init files.

use-package *feature* &*rest args*

[Macro]

This macro specifies how to load the named *feature* and how to configure and customize it for use. The arguments *args* are keyword-value pairs. Some of the important keywords and their values are:

:init *forms*

Specifies *forms* to execute before *feature* is loaded.

:config *forms*

Specifies *forms* to execute after loading *feature*.

:defer *condition*

If *condition* is non-`nil`, it specifies to defer loading *feature* until any of the autoloaded commands or variables of *feature* are first used. If *condition* is a number *n*, it specifies that *feature* should be loaded after *n* seconds of idle time.

:commands *commands...*

Specifies commands of *feature* to be autoloaded.

:bind *keybindings...*

Specifies the *keybindings* for *features* commands. Each binding has the form

`(key-sequence . command)`

or

`(:map keymap (key-sequence . command))`

where *key-sequence* is in the form accepted by the `kbd` macro (see Section 23.1 [Key Sequences], page 480).

For more details about `use-package`, see *use-package User Manual*.

16.8 Which File Defined a Certain Symbol

symbol-file *symbol* &*optional type native-p*

[Function]

This function returns the name of the file that defined *symbol*. If *type* is `nil`, then any kind of definition is acceptable. If *type* is `defun`, `defvar`, or `defface`, that specifies function definition, variable definition, or face definition only.

The value is normally an absolute file name. It can also be `nil`, if the definition is not associated with any file. If *symbol* specifies an autoloaded function, the value can be a relative file name without extension.

If the optional third argument *native-p* is non-`nil`, and Emacs was built with native compilation support (see Chapter 18 [Native Compilation], page 327), this function will try to find the `.eln` file that defined *symbol*, instead of the `.elc` or `.el` file. If such a `.eln` file is found and is not outdated, the function will return its absolute file name; otherwise it will report the name of either the source or the byte-compiled file.

The basis for `symbol-file` is the data in the variable `load-history`.

load-history [Variable]

The value of this variable is an alist that associates the names of loaded library files with the names of the functions and variables they defined, as well as the features they provided or required.

Each element in this alist describes one loaded library (including libraries that are preloaded at startup). It is a list whose CAR is the absolute file name of the library (a string). The rest of the list elements have these forms:

- `var` The symbol *var* was defined as a variable.
- `(defun . fun)` The function *fun* was defined. `(defun . fun)`, which represents defining *fun* as a function.
- `(defface . face)` The face *face* was defined.
- `(require . feature)` The feature *feature* was required.
- `(provide . feature)` The feature *feature* was provided.
- `(cl-defmethod method specializers)` The named *method* was defined by using `cl-defmethod`, with *specializers* as its specializers.
- `(define-type . type)` The type *type* was defined.

The value of `load-history` may have one element whose CAR is `nil`. This element describes definitions made with `eval-buffer` on a buffer that is not visiting a file.

The command `eval-region` updates `load-history`, but does so by adding the symbols defined to the element for the file being visited, rather than replacing that element. See Section 10.4 [Eval], page 152.

In addition to `load-history`, every function keeps track of its own history in the symbol property `function-history`. The reason why functions are treated specially in this respect is that it is common for functions to be defined in two steps in two different files (typically, one of them is an autoload), so in order to be able to properly *unload* a file, we need to know more precisely what that file did to the function definition.

The symbol property **function-history** holds a list of the form (*file1 def2 file2 def3 ...*) ■ where *file1* is the last file that changed the definition and *def2* was the definition before *file1*, set by *file2*, etc. Logically this list should end with the name of the first file that defined this function, but to save space this last element is usually omitted.

16.9 Unloading

You can discard the functions and variables loaded by a library to reclaim memory for other Lisp objects. To do this, use the function **unload-feature**:

unload-feature *feature* &**optional** *force*

[Command]

This command unloads the library that provided feature *feature*. It undefines all functions, macros, and variables defined in that library with **defun**, **defalias**, **defsubst**, **defmacro**, **defconst**, **defvar**, and **defcustom**. It then restores any autoloads formerly associated with those symbols. (Loading saves these in the **function-history** property of the symbol.)

Before restoring the previous definitions, **unload-feature** runs **remove-hook** to remove functions defined by the library from certain hooks. These hooks include variables whose names end in ‘-hook’ (or the deprecated suffix ‘-hooks’), plus those listed in **unload-feature-special-hooks**, as well as **auto-mode-alist**. This is to prevent Emacs from ceasing to function because important hooks refer to functions that are no longer defined.

Standard unloading activities also undo ELP profiling of functions in that library, unprovides any features provided by the library, and cancels timers held in variables defined by the library.

If these measures are not sufficient to prevent malfunction, a library can define an explicit unloader named **feature-unload-function**. If that symbol is defined as a function, **unload-feature** calls it with no arguments before doing anything else. It can do whatever is appropriate to unload the library. If it returns **nil**, **unload-feature** proceeds to take the normal unload actions. Otherwise it considers the job to be done.

Ordinarily, **unload-feature** refuses to unload a library on which other loaded libraries depend. (A library *a* depends on library *b* if *a* contains a **require** for *b*.) If the optional argument *force* is non-**nil**, dependencies are ignored and you can unload any library.

The **unload-feature** function is written in Lisp; its actions are based on the variable **load-history**.

unload-feature-special-hooks

[Variable]

This variable holds a list of hooks to be scanned before unloading a library, to remove functions defined in the library.

16.10 Hooks for Loading

You can ask for code to be executed each time Emacs loads a library, by using the variable **after-load-functions**:

after-load-functions

[Variable]

This abnormal hook is run after loading a file. Each function in the hook is called with a single argument, the absolute filename of the file that was just loaded.

If you want code to be executed when a *particular* library is loaded, use the macro **with-eval-after-load**:

with-eval-after-load *library* *body* . . .

[Macro]

This macro arranges to evaluate *body* at the end of loading the file *library*, each time *library* is loaded. If *library* is already loaded, it evaluates *body* right away.

You don't need to give a directory or extension in the file name *library*. Normally, you just give a bare file name, like this:

```
(with-eval-after-load "js" (keymap-set js-mode-map "C-c C-c" 'js-eval))
```

To restrict which files can trigger the evaluation, include a directory or an extension or both in *library*. Only a file whose absolute true name (i.e., the name with all symbolic links chased out) matches all the given name components will match. In the following example, `my_inst.elc` or `my_inst.elc.gz` in some directory `..../foo/bar` will trigger the evaluation, but not `my_inst.el`:

```
(with-eval-after-load "foo/bar/my_inst.elc" ...)
```

library can also be a feature (i.e., a symbol), in which case *body* is evaluated at the end of any file where `(provide library)` is called.

An error in *body* does not undo the load, but does prevent execution of the rest of *body*.

Normally, well-designed Lisp programs should not use **with-eval-after-load**. If you need to examine and set the variables defined in another library (those meant for outside use), you can do it immediately—there is no need to wait until the library is loaded. If you need to call functions defined by that library, you should load the library, preferably with **require** (see Section 16.7 [Named Features], page 309).

16.11 Emacs Dynamic Modules

A *dynamic Emacs module* is a shared library that provides additional functionality for use in Emacs Lisp programs, just like a package written in Emacs Lisp would.

Functions that load Emacs Lisp packages can also load dynamic modules. They recognize dynamic modules by looking at their file-name extension, a.k.a. “suffix”. This suffix is platform-dependent.

module-file-suffix

[Variable]

This variable holds the system-dependent value of the file-name extension of the module files. Its value is `.so` on POSIX hosts, `.dylib` on macOS, and `.dll` on MS-Windows.

On macOS, dynamic modules can also have the suffix `.so` in addition to `.dylib`.

Every dynamic module should export a C-callable function named `emacs_module_init`, which Emacs will call as part of the call to `load` or `require` which loads the module. It should also export a symbol named `plugin_is_GPL_compatible` to indicate that its code is

released under the GPL or compatible license; Emacs will signal an error if your program tries to load modules that don't export such a symbol.

If a module needs to call Emacs functions, it should do so through the API (Application Programming Interface) defined and documented in the header file `emacs-module.h` that is part of the Emacs distribution. See Section E.8 [Writing Dynamic Modules], page 1361, for details of using that API when writing your own modules.

Modules can create `user-ptr` Lisp objects that embed pointers to C struct's defined by the module. This is useful for keeping around complex data structures created by a module, to be passed back to the module's functions. User-ptr objects can also have associated *finalizers* – functions to be run when the object is GC'ed; this is useful for freeing any resources allocated for the underlying data structure, such as memory, open file descriptors, etc. See Section E.8.3 [Module Values], page 1366.

`user-ptrp object` [Function]

This function returns `t` if its argument is a `user-ptr` object.

`module-load file` [Function]

Emacs calls this low-level primitive to load a module from the specified `file` and perform the necessary initialization of the module. This is the primitive which makes sure the module exports the `plugin_is_GPL_compatible` symbol, calls the module's `emacs_module_init` function, and signals an error if that function returns an error indication, or if the user typed `C-g` during the initialization. If the initialization succeeds, `module-load` returns `t`. Note that `file` must already have the proper file-name extension, as this function doesn't try looking for files with known extensions, unlike `load`.

Unlike `load`, `module-load` doesn't record the module in `load-history`, doesn't print any messages, and doesn't protect against recursive loads. Most users should therefore use `load`, `load-file`, `load-library`, or `require` instead of `module-load`.

Loadable modules in Emacs are enabled by using the `--with-modules` option at configure time.

17 Byte Compilation

Emacs Lisp has a *compiler* that translates functions written in Lisp into a special representation called *byte-code* that can be executed more efficiently. The compiler replaces Lisp function definitions with byte-code. When a byte-code function is called, its definition is evaluated by the *byte-code interpreter*.

Because the byte-compiled code is evaluated by the byte-code interpreter, instead of being executed directly by the machine's hardware (as true compiled code is), byte-code is completely transportable from machine to machine without recompilation. It is not, however, as fast as true compiled code.

In general, any version of Emacs can run byte-compiled code produced by recent earlier versions of Emacs, but the reverse is not true.

If you do not want a Lisp file to be compiled, ever, put a file-local variable binding for `no-byte-compile` into it, like this:

```
; -*-no-byte-compile: t; -*-
```

17.1 Performance of Byte-Compiled Code

A byte-compiled function is not as efficient as a primitive function written in C, but runs much faster than the version written in Lisp. Here is an example:

```
(defun silly-loop (n)
  "Return the time, in seconds, to run N iterations of a loop."
  (let ((t1 (float-time)))
    (while (> (setq n (1- n)) 0))
      (- (float-time) t1)))
⇒ silly-loop

(silly-loop 50000000)
⇒ 5.200886011123657

(byte-compile 'silly-loop)
⇒ [Compiled code not shown]

(silly-loop 50000000)
⇒ 0.6239290237426758
```

In this example, the interpreted code required more than 5 seconds to run, whereas the byte-compiled code required less than 1 second. These results are representative, but actual results may vary.

17.2 Byte-Compilation Functions

You can byte-compile an individual function or macro definition with the `byte-compile` function. You can compile a whole file with `byte-compile-file`, or several files with `byte-recompile-directory` or `batch-byte-compile`.

Sometimes, the byte compiler produces warning and/or error messages (see Section 17.6 [Compiler Errors], page 321, for details). These messages are normally recorded in a buffer

called ***Compile-Log***, which uses Compilation mode. See Section “Compilation Mode” in *The GNU Emacs Manual*. However, if the variable `byte-compile-debug` is non-`nil`, error messages will be signaled as Lisp errors instead (see Section 11.7.3 [Errors], page 179).

Be careful when writing macro calls in files that you intend to byte-compile. Since macro calls are expanded when they are compiled, the macros need to be loaded into Emacs or the byte compiler will not do the right thing. The usual way to handle this is with `require` forms which specify the files containing the needed macro definitions (see Section 16.7 [Named Features], page 309). Normally, the byte compiler does not evaluate the code that it is compiling, but it handles `require` forms specially, by loading the specified libraries. To avoid loading the macro definition files when someone *runs* the compiled program, write `eval-when-compile` around the `require` calls (see Section 17.5 [Eval During Compile], page 320). For more details, See Section 14.3 [Compiling Macros], page 270.

Inline (`defsubst`) functions are less troublesome; if you compile a call to such a function before its definition is known, the call will still work right, it will just run slower.

`byte-compile symbol` [Function]

This function byte-compiles the function definition of `symbol`, replacing the previous definition with the compiled one. The function definition of `symbol` must be the actual code for the function; `byte-compile` does not handle function indirection. The return value is the byte-code function object which is the compiled definition of `symbol` (see Section 17.7 [Byte-Code Objects], page 323).

```
(defun factorial (integer)
  "Compute factorial of INTEGER."
  (if (= 1 integer) 1
      (* integer (factorial (1- integer)))))
⇒ factorial

(byte-compile 'factorial)
⇒
#[257
  "\211\300U\203^H^@\300\207\211\301^BS!_\207"
  [1 factorial] 4
  "Compute factorial of INTEGER.\n\n(fn INTEGER)"]
```

If `symbol`’s definition is a byte-code function object, `byte-compile` does nothing and returns `nil`. It does not compile the symbol’s definition again, since the original (non-compiled) code has already been replaced in the symbol’s function cell by the byte-compiled code.

The argument to `byte-compile` can also be a `lambda` expression. In that case, the function returns the corresponding compiled code but does not store it anywhere.

`compile-defun &optional arg` [Command]

This command reads the defun containing point, compiles it, and evaluates the result. If you use this on a defun that is actually a function definition, the effect is to install a compiled version of that function.

`compile-defun` normally displays the result of evaluation in the echo area, but if `arg` is non-`nil`, it inserts the result in the current buffer after the form it has compiled.

byte-compile-file *filename* [Command]

This function compiles a file of Lisp code named *filename* into a file of byte-code. The output file's name is made by changing the '.el' suffix into '.elc'; if *filename* does not end in '.el', it adds '.elc' to the end of *filename*.

Compilation works by reading the input file one form at a time. If it is a definition of a function or macro, the compiled function or macro definition is written out. Other forms are batched together, then each batch is compiled, and written so that its compiled code will be executed when the file is read. All comments are discarded when the input file is read.

This command returns `t` if there were no errors and `nil` otherwise. When called interactively, it prompts for the file name.

```
$ ls -l push*
-rw-r--r-- 1 lewis lewis 791 Oct  5 20:31 push.el

(byte-compile-file "~/emacs/push.el")
⇒ t

$ ls -l push*
-rw-r--r-- 1 lewis lewis 791 Oct  5 20:31 push.el
-rw-rw-rw- 1 lewis lewis 638 Oct  8 20:25 push.elc
```

byte-recompile-directory *directory* &optional *flag force* [Command]
follow-symlinks

This command recompiles every '.el' file in *directory* (or its subdirectories) that needs recompilation. A file needs recompilation if a '.elc' file exists but is older than the '.el' file.

When a '.el' file has no corresponding '.elc' file, *flag* says what to do. If it is `nil`, this command ignores these files. If *flag* is 0, it compiles them. If it is neither `nil` nor 0, it asks the user whether to compile each such file, and asks about each subdirectory as well.

Interactively, `byte-recompile-directory` prompts for *directory* and *flag* is the prefix argument.

If *force* is non-`nil`, this command recompiles every '.el' file that has a '.elc' file.

This command will normally not compile '.el' files that are symlinked. If the optional *follow-symlink* parameter is non-`nil`, symlinked '.el' will also be compiled.

The returned value is unpredictable.

batch-byte-compile &optional *noforce* [Function]

This function runs `byte-compile-file` on files specified on the command line. This function must be used only in a batch execution of Emacs, as it kills Emacs on completion. An error in one file does not prevent processing of subsequent files, but no output file will be generated for it, and the Emacs process will terminate with a nonzero status code.

If *noforce* is non-`nil`, this function does not recompile files that have an up-to-date '.elc' file.

```
$ emacs -batch -f batch-byte-compile *.el
```

17.3 Documentation Strings and Compilation

When Emacs loads functions and variables from a byte-compiled file, it normally does not load their documentation strings into memory. Each documentation string is dynamically loaded from the byte-compiled file only when needed. This saves memory, and speeds up loading by skipping the processing of the documentation strings.

This feature has a drawback: if you delete, move, or alter the compiled file (such as by compiling a new version), Emacs may no longer be able to access the documentation string of previously-loaded functions or variables. Such a problem normally only occurs if you build Emacs yourself, and happen to edit and/or recompile the Lisp source files. To solve it, just reload each file after recompilation.

Dynamic loading of documentation strings from byte-compiled files is determined, at compile time, for each byte-compiled file. It can be disabled via the option `byte-compile-dynamic-docstrings`.

`byte-compile-dynamic-docstrings` [User Option]

If this is non-`nil`, the byte compiler generates compiled files that are set up for dynamic loading of documentation strings.

To disable the dynamic loading feature for a specific file, set this option to `nil` in its header line (see Section “Local Variables in Files” in *The GNU Emacs Manual*), like this:

```
--byte-compile-dynamic-docstrings: nil;--
```

This is useful mainly if you expect to change the file, and you want Emacs sessions that have already loaded it to keep working when the file changes.

Internally, the dynamic loading of documentation strings is accomplished by writing compiled files with a special Lisp reader construct, ‘`#@count`’. This construct skips the next `count` characters. It also uses the ‘`#$`’ construct, which stands for the name of this file, as a string. Do not use these constructs in Lisp source files; they are not designed to be clear to humans reading the file.

17.4 Dynamic Loading of Individual Functions

When you compile a file, you can optionally enable the *dynamic function loading* feature (also known as *lazy loading*). With dynamic function loading, loading the file doesn’t fully read the function definitions in the file. Instead, each function definition contains a place-holder which refers to the file. The first time each function is called, it reads the full definition from the file, to replace the place-holder.

The advantage of dynamic function loading is that loading the file should become faster. This is a good thing for a file which contains many separate user-callable functions, if using one of them does not imply you will probably also use the rest. A specialized mode which provides many keyboard commands often has that usage pattern: a user may invoke the mode, but use only a few of the commands it provides.

The dynamic loading feature has certain disadvantages:

- If you delete or move the compiled file after loading it, Emacs can no longer load the remaining function definitions not already loaded.

- If you alter the compiled file (such as by compiling a new version), then trying to load any function not already loaded will usually yield nonsense results.

These problems will never happen in normal circumstances with installed Emacs files. But they are quite likely to happen with Lisp files that you are changing. The easiest way to prevent these problems is to reload the new compiled file immediately after each recompilation.

Experience shows that using dynamic function loading provides benefits that are hardly measurable, so this feature is deprecated since Emacs 27.1.

The byte compiler uses the dynamic function loading feature if the variable `byte-compile-dynamic` is non-`nil` at compilation time. Do not set this variable globally, since dynamic loading is desirable only for certain files. Instead, enable the feature for specific source files with file-local variable bindings. For example, you could do it by writing this text in the source file's first line:

```
--*-byte-compile-dynamic: t;-*-
```

`byte-compile-dynamic`

[Variable]

If this is non-`nil`, the byte compiler generates compiled files that are set up for dynamic function loading.

`fetch-bytecode function`

[Function]

If `function` is a byte-code function object, this immediately finishes loading the byte code of `function` from its byte-compiled file, if it is not fully loaded already. Otherwise, it does nothing. It always returns `function`.

17.5 Evaluation During Compilation

These features permit you to write code to be evaluated during compilation of a program.

`eval-and-compile body...`

[Macro]

This form marks `body` to be evaluated both when you compile the containing code and when you run it (whether compiled or not).

You can get a similar result by putting `body` in a separate file and referring to that file with `require`. That method is preferable when `body` is large. Effectively `require` is automatically `eval-and-compile`, the package is loaded both when compiling and executing.

`autoload` is also effectively `eval-and-compile` too. It's recognized when compiling, so uses of such a function don't produce "not known to be defined" warnings.

Most uses of `eval-and-compile` are fairly sophisticated.

If a macro has a helper function to build its result, and that macro is used both locally and outside the package, then `eval-and-compile` should be used to get the helper both when compiling and then later when running.

If functions are defined programmatically (with `fset` say), then `eval-and-compile` can be used to have that done at compile-time as well as run-time, so calls to those functions are checked (and warnings about "not known to be defined" suppressed).

`eval-when-compile body...` [Macro]

This form marks *body* to be evaluated at compile time but not when the compiled program is loaded. The result of evaluation by the compiler becomes a constant which appears in the compiled program. If you load the source file, rather than compiling it, *body* is evaluated normally.

If you have a constant that needs some calculation to produce, `eval-when-compile` can do that at compile-time. For example,

```
(defvar my-regexp
  (eval-when-compile (regexp-opt '("aaa" "aba" "abb"))))
```

If you're using another package, but only need macros from it (the byte compiler will expand those), then `eval-when-compile` can be used to load it for compiling, but not executing. For example,

```
(eval-when-compile
  (require 'my-macro-package))
```

The same sort of thing goes for macros and `defsubst` functions defined locally and only for use within the file. They are needed for compiling the file, but in most cases they are not needed for execution of the compiled file. For example,

```
(eval-when-compile
  (unless (fboundp 'some-new-thing)
    (defmacro some-new-thing ()
      (compatibility code))))
```

This is often good for code that's only a fallback for compatibility with other versions of Emacs.

Common Lisp Note: At top level, `eval-when-compile` is analogous to the Common Lisp idiom `(eval-when (compile eval) ...)`. Elsewhere, the Common Lisp '#.' reader macro (but not when interpreting) is closer to what `eval-when-compile` does.

17.6 Compiler Errors

Error and warning messages from byte compilation are printed in a buffer named `*Compile-Log*`. These messages include file names and line numbers identifying the location of the problem. The usual Emacs commands for operating on compiler output can be used on these messages.

When an error is due to invalid syntax in the program, the byte compiler might get confused about the error's exact location. One way to investigate is to switch to the buffer `*Compiler Input*`. (This buffer name starts with a space, so it does not show up in the Buffer Menu.) This buffer contains the program being compiled, and point shows how far the byte compiler was able to read; the cause of the error might be nearby. See Section 19.3 [Syntax Errors], page 367, for some tips for locating syntax errors.

A common type of warning issued by the byte compiler is for functions and variables that were used but not defined. Such warnings report the line number for the end of the file, not the locations where the missing functions or variables were used; to find these, you must search the file manually.

If you are sure that a warning message about a missing function or variable is unjustified, there are several ways to suppress it:

- You can suppress the warning for a specific call to a function *func* by conditionalizing it on an `fboundp` test, like this:

```
(if (fboundp 'func) ... (func ...) ...)
```

The call to *func* must be in the *then-form* of the `if`, and *func* must appear quoted in the call to `fboundp`. (This feature operates for `cond` as well.)

- Likewise, you can suppress the warning for a specific use of a variable *variable* by conditionalizing it on a `boundp` test:

```
(if (boundp 'variable) ... variable ...)
```

The reference to *variable* must be in the *then-form* of the `if`, and *variable* must appear quoted in the call to `boundp`.

- You can tell the compiler that a function is defined using `declare-function`. See Section 13.16 [Declaring Functions], page 265.
- Likewise, you can tell the compiler that a variable is defined using `defvar` with no initial value. (Note that this marks the variable as special, i.e. dynamically bound, but only within the current lexical scope, or file if at top-level.) See Section 12.5 [Defining Variables], page 194.

You can also suppress compiler warnings within a certain expression using the `with-suppressed-warnings` macro:

with-suppressed-warnings *warnings body...* [Special Form]

In execution, this is equivalent to `(progn body...)`, but the compiler does not issue warnings for the specified conditions in *body*. *warnings* is an association list of warning symbols and function/variable symbols they apply to. For instance, if you wish to call an obsolete function called `foo`, but want to suppress the compilation warning, say:

```
(with-suppressed-warnings ((obsolete foo))
  (foo ...))
```

For more coarse-grained suppression of compiler warnings, you can use the `with-no-warnings` construct:

with-no-warnings *body...* [Special Form]

In execution, this is equivalent to `(progn body...)`, but the compiler does not issue warnings for anything that occurs inside *body*.

We recommend that you use `with-suppressed-warnings` instead, but if you do use this construct, that you use it around the smallest possible piece of code to avoid missing possible warnings other than one you intend to suppress.

Byte compiler warnings can be controlled more precisely by setting the variable `byte-compile-warnings`. See its documentation string for details.

Sometimes you may wish the byte-compiler warnings to be reported using `error`. If so, set `byte-compile-error-on-warn` to a non-`nil` value.

17.7 Byte-Code Function Objects

Byte-compiled functions have a special data type: they are *byte-code function objects*. Whenever such an object appears as a function to be called, Emacs uses the byte-code interpreter to execute the byte-code.

Internally, a byte-code function object is much like a vector; its elements can be accessed using `aref`. Its printed representation is like that for a vector, with an additional ‘#’ before the opening ‘[’. It must have at least four elements; there is no maximum number, but only the first six elements have any normal use. They are:

- `argdesc` The descriptor of the arguments. This can either be a list of arguments, as described in Section 13.2.3 [Argument List], page 234, or an integer encoding the required number of arguments. In the latter case, the value of the descriptor specifies the minimum number of arguments in the bits zero to 6, and the maximum number of arguments in bits 8 to 14. If the argument list uses `&rest`, then bit 7 is set; otherwise it’s cleared.
If `argdesc` is a list, the arguments will be dynamically bound before executing the byte code. If `argdesc` is an integer, the arguments will be instead pushed onto the stack of the byte-code interpreter, before executing the code.
- `byte-code` The string containing the byte-code instructions.
- `constants` The vector of Lisp objects referenced by the byte code. These include symbols used as function names and variable names.
- `stacksize` The maximum stack size this function needs.
- `docstring` The documentation string (if any); otherwise, `nil`. The value may be a number or a list, in case the documentation string is stored in a file. Use the function `documentation` to get the real documentation string (see Section 25.2 [Accessing Documentation], page 596).
- `interactive`
The interactive spec (if any). This can be a string or a Lisp expression. It is `nil` for a function that isn’t interactive.

Here’s an example of a byte-code function object, in printed representation. It is the definition of the command `backward-sexp`.

```
#[256
"\211\204^G@\300\262^A\301^A[!\207"
[1 forward-sexp]
3
1793299
"^\^p"]
```

The primitive way to create a byte-code object is with `make-byte-code`:

<code>make-byte-code &rest elements</code>	[Function]
This function constructs and returns a byte-code function object with <i>elements</i> as its elements.	

You should not try to come up with the elements for a byte-code function yourself, because if they are inconsistent, Emacs may crash when you call the function. Always leave it to the byte compiler to create these objects; it makes the elements consistent (we hope).

17.8 Disassembled Byte-Code

People do not write byte-code; that job is left to the byte compiler. But we provide a disassembler to satisfy a cat-like curiosity. The disassembler converts the byte-compiled code into human-readable form.

The byte-code interpreter is implemented as a simple stack machine. It pushes values onto a stack of its own, then pops them off to use them in calculations whose results are themselves pushed back on the stack. When a byte-code function returns, it pops a value off the stack and returns it as the value of the function.

In addition to the stack, byte-code functions can use, bind, and set ordinary Lisp variables, by transferring values between variables and the stack.

disassemble *object* &*optional buffer-or-name* [Command]

This command displays the disassembled code for *object*. In interactive use, or if *buffer-or-name* is `nil` or omitted, the output goes in a buffer named `*Disassemble*`. If *buffer-or-name* is non-`nil`, it must be a buffer or the name of an existing buffer. Then the output goes there, at point, and point is left before the output.

The argument *object* can be a function name, a lambda expression (see Section 13.2 [Lambda Expressions], page 232), or a byte-code object (see Section 17.7 [Byte-Code Objects], page 323). If it is a lambda expression, **disassemble** compiles it and disassembles the resulting compiled code.

Here are two examples of using the **disassemble** function. We have added explanatory comments to help you relate the byte-code to the Lisp source; these do not appear in the output of **disassemble**.

```
(defun factorial (integer)
  "Compute factorial of an integer."
  (if (= 1 integer) 1
      (* integer (factorial (1- integer))))
      ⇒ factorial

(factorial 4)
⇒ 24

(disassemble 'factorial)
  → byte-code for factorial:
doc: Compute factorial of an integer.
args: (arg1)

0  dup          ; Get the value of integer and
                  ; push it onto the stack.
1  constant 1   ; Push 1 onto stack.
2  eqlsign      ; Pop top two values off stack, compare
                  ; them, and push result onto stack.
```

```

3  goto-if-nil 1      ; Pop and test top of stack;
                      ; if nil, go to 1, else continue.
6  constant 1          ; Push 1 onto top of stack.
7  return               ; Return the top element of the stack.
8:1 dup                 ; Push value of integer onto stack.
9  constant factorial   ; Push factorial onto stack.
10 stack-ref 2           ; Push value of integer onto stack.
11 sub1                 ; Pop integer, decrement value,
                      ; push new value onto stack.
12 call     1           ; Call function factorial using first
                      ; (i.e., top) stack element as argument;
                      ; push returned value onto stack.
13 mult                  ; Pop top two values off stack, multiply
                      ; them, and push result onto stack.
14 return               ; Return the top element of the stack.

```

The `silly-loop` function is somewhat more complex:

```

(defun silly-loop (n)
  "Return time before and after N iterations of a loop."
  (let ((t1 (current-time-string)))
    (while (> (setq n (1- n))
                0))
    (list t1 (current-time-string))))
  ⇒ silly-loop

(disassemble 'silly-loop)
  ↓ byte-code for silly-loop:
doc: Return time before and after N iterations of a loop.
args: (arg1)

0  constant current-time-string ; Push current-time-string
                                 ; onto top of stack.
1  call     0                  ; Call current-time-string with no
                                 ; argument, push result onto stack as t1.
2:1 stack-ref 1               ; Get value of the argument n
                                 ; and push the value on the stack.
3  sub1                 ; Subtract 1 from top of stack.
4  dup                  ; Duplicate top of stack; i.e., copy the top
                                 ; of the stack and push copy onto stack.
5  stack-set 3              ; Pop the top of the stack,
                                 ; and set n to the value.

;; (In effect, the sequence dup stack-set copies the top of
;; the stack into the value of n without popping it.)

```

```
7  constant 0          ; Push 0 onto stack.  
8  gtr                ; Pop top two values off stack,  
                      ; test if n is greater than 0  
                      ; and push result onto stack.  
9  goto-if-not-nil 1  ; Goto 1 if n > 0  
                      ; (this continues the while loop)  
                      ; else continue.  
12 dup                ; Push value of t1 onto stack.  
13 constant current-time-string ; Push current-time-string  
                                ; onto the top of the stack.  
14 call    0           ; Call current-time-string again.  
15 list2              ; Pop top two elements off stack, create a  
                      ; list of them, and push it onto stack.  
16 return             ; Return value of the top of stack.
```

18 Compilation of Lisp to Native Code

In addition to the byte-compilation, described in Chapter 17 [Byte Compilation], page 316, Emacs can also optionally compile Lisp function definitions into a true compiled code, known as *native code*. This feature uses the `libgccjit` library, which is part of the GCC distribution, and requires that Emacs be built with support for using that library. It also requires to have GCC and Binutils (the assembler and linker) available on your system for you to be able to native-compile Lisp code.

To determine whether the current Emacs process can produce and load natively-compiled Lisp code, call `native-comp-available-p` (see Section 18.1 [Native-Compilation Functions], page 328).

Unlike byte-compiled code, natively-compiled Lisp code is executed directly by the machine’s hardware, and therefore runs at full speed that the host CPU can provide. The resulting speedup generally depends on what the Lisp code does, but is usually 2.5 to 5 times faster than the corresponding byte-compiled code.

Since native code is generally incompatible between different systems, the natively-compiled code is *not* transportable from one machine to another, it can only be used on the same machine where it was produced or on very similar ones (having the same CPU and run-time libraries). The transportability of natively-compiled code is the same as that of shared libraries (`.so` or `.dll` files).

Libraries of natively-compiled code include crucial dependencies on Emacs Lisp primitives (see Section 13.1 [What Is a Function], page 230) and their calling conventions, and thus Emacs usually won’t load natively-compiled code produced by earlier or later Emacs versions; native compilation of the same Lisp code by a different Emacs version will usually produce a natively-compiled library under a unique file name that only that version of Emacs will be able to load. However, the use of unique file names allows to have in the same directory several versions of the same Lisp library natively-compiled by several different versions of Emacs.

A non-`nil` file-local variable binding of `no-byte-compile` (see Chapter 17 [Byte Compilation], page 316) also disables the native compilation of that file. In addition, a similar variable `no-native-compile` disables just the native compilation of the file. If both `no-byte-compile` and `no-native-compile` are specified, the former takes precedence.

Sometimes there could be a need to prevent the native compilation from writing its results, the `*.eln` files, into a subdirectory of `user-emacs-directory` (see Section 42.1.2 [Init File], page 1258). You can do that by either changing the value of `native-comp-eln-load-path` (see Section 18.2 [Native-Compilation Variables], page 330) or by temporarily pointing the `HOME` environment variable to a non-existing directory. Note that the latter technique might still produce a small number of `*.eln` files if Emacs needs to generate *trampolines*, which are used if Lisp primitives are advised or redefined in your Lisp code that is being natively compiled. See Section 18.2 [Native-Compilation Variables], page 330. Alternatively, you can specify that the `*.eln` files are written to a non-default directory using the `startup-redirect-eln-cache` function; see Section 18.1 [Native-Compilation Functions], page 328.

18.1 Native-Compilation Functions

Native-Compilation is implemented as a side effect of byte-compilation (see Chapter 17 [Byte Compilation], page 316). Thus, compiling Lisp code natively always produces its byte code as well, and therefore all the rules and caveats of preparing Lisp code for byte compilation (see Section 17.2 [Compilation Functions], page 316) are valid for native-compilation as well.

You can natively-compile either a single function or macro definition, or a whole file of Lisp code, with the `native-compile` function. Natively-compiling a file will produce the `.eln` file with native code.

Native compilation might produce warning or error messages; these are normally recorded in the buffer called `*Native-compile-Log*`. In interactive sessions, it uses the special LIMPLE mode (`native-comp-limple-mode`), which sets up `font-lock` as appropriate for this log, and is otherwise the same as Fundamental mode. Logging of messages resulting from native-compilation can be controlled by the `native-comp-verbose` variable (see Section 18.2 [Native-Compilation Variables], page 330).

When Emacs is run non-interactively, messages produced by native-compilation are reported by calling `message` (see Section 41.4.1 [Displaying Messages], page 1131), and are usually displayed on the standard error stream of the terminal from which Emacs was invoked.

`native-compile` *function-or-file* &`optional` *output*

[Function]

This function compiles *function-or-file* into native code. The argument *function-or-file* can be a function symbol, a Lisp form, or a name (a string) of the file which contains the Emacs Lisp source code to compile. If the optional argument *output* is provided, it must be a string specifying the name of the file to write the compiled code into. Otherwise, if *function-or-file* is a function or a Lisp form, this function returns the compiled object, and if *function-or-file* is a file name, the function returns the full absolute name of the file it created for the compiled code. The output file is by default given the `.eln` extension.

This function runs the final phase of the native compilation, which invokes GCC via `libgccjit`, in a separate subprocess, which invokes the same Emacs executable as the process that called this function.

`batch-native-compile` &`optional` *for-tarball*

[Function]

This function runs native-compilation on files specified on the Emacs command line in batch mode. It must be used only in a batch execution of Emacs, as it kills Emacs upon completion of the compilation. If one or more of the files fail to compile, the Emacs process will attempt to compile all the other files, and will terminate with a non-zero status code. The optional argument *for-tarball*, if non-`nil`, tells the function to place the resulting `.eln` files in the last directory mentioned in `native-comp-eln-load-path` (see Section 16.3 [Library Search], page 301); this is meant to be used as part of building an Emacs source tarball for the first time, when the natively-compiled files, which are absent from the source tarball, should be generated in the build tree instead of the user's cache directory.

Native compilation can be run entirely asynchronously, in a subprocess of the main Emacs process. This leaves the main Emacs process free to use while the compilation

runs in the background. This is the method used by Emacs to natively-compile any Lisp file or byte-compiled Lisp file that is loaded into Emacs, when no natively-compiled file for it is available. Note that because of this use of a subprocess, native compilation may produce warning and errors which byte-compilation does not, and Lisp code may thus need to be modified to work correctly. See `native-comp-async-report-warnings-errors` in see Section 18.2 [Native-Compilation Variables], page 330, for more details.

`native-compile-async files &optional recursively load selector` [Function]

This function compiles the named *files* asynchronously. The argument *files* should be a single file name (a string) or a list of one or more file and/or directory names. If directories are present in the list, the optional argument *recursively* should be non-`nil` to cause the compilation to recurse into those directories. If *load* is non-`nil`, Emacs will load each file that it succeeded to compile. The optional argument *selector* allows control of which of *files* will be compiled; it can have one of the following values:

`nil` or omitted

Select all the files and directories in *files*.

a regular expression string

Select the files and directories whose names match the regexp.

a function A predicate function, which will be called with each file and directory in *files*, and should return non-`nil` if the file or the directory should be selected for compilation.

On systems with multiple CPU execution units, when *files* names more than one file, this function will normally start several compilation subprocesses in parallel, under the control of `native-comp-async-jobs-number` (see Section 18.2 [Native-Compilation Variables], page 330).

`emacs-lisp-native-compile` [Command]

This command compiles the file visited by the current buffer into native code, if the file was changed since the last time it was natively-compiled.

`emacs-lisp-native-compile-and-load` [Command]

This command compiles the file visited by the current buffer into native code, like `emacs-lisp-native-compile`, but it also loads the native code when the compilation finishes.

The following function allows Lisp programs to test whether native-compilation is available at runtime.

`native-comp-available-p` [Function]

This function returns non-`nil` if the running Emacs process has the native-compilation support compiled into it. On systems that load `libgccjit` dynamically, it also makes sure that library is available and can be loaded. Lisp programs that need to know up front whether native-compilation is available should use this predicate.

By default, asynchronous native compilation writes the `*.eln` files it produces to a subdirectory of the first writable directory specified by the `native-comp-eln-load-path` variable (see Section 18.2 [Native-Compilation Variables], page 330). You can change this by using the following function in your startup files:

startup-redirect-eln-cache cache-directory [Function]

This function arranges for the asynchronous native compilation to write the produced `*.eln` files to `cache-directory`, which must be a single directory, a string. It also destructively modifies `native-comp-eln-load-path` such that its first element is `cache-directory`. If `cache-directory` is not an absolute file name, it is interpreted relative to `user-emacs-directory` (see Section 42.1.2 [Init File], page 1258).

18.2 Native-Compilation Variables

This section documents the variables that control native-compilation.

native-comp-speed [User Option]

This variable specifies the optimization level for native compilation. Its value should be a number between `-1` and `3`. Values between `0` and `3` specify the optimization levels equivalent to the corresponding compiler `-O0`, `-O1`, etc. command-line options of the compiler. The value `-1` means disable native-compilation: functions and files will be only byte-compiled; however, the `*.eln` files will still be produced, they will just contain the compiled code in bytecode form. (This can be achieved at function granularity by using the `(declare (speed -1))` form, see Section 13.15 [Declare Form], page 263.) The default value is `2`.

native-comp-debug [User Option]

This variable specifies the level of debugging information produced by native-compilation. Its value should be a number between zero and `3`, with the following meaning:

- `0` No debugging output. This is the default.
- `1` Emit debugging symbols with the native code. This allows easier debugging of the native code with debuggers such as `gdb`.
- `2` Like `1`, and in addition dump pseudo-C code.
- `3` Like `2`, and in addition dump the GCC intermediate passes and `libgccjit` log file.

native-comp-verbose [User Option]

This variable controls the verbosity of native-compilation by suppressing some or all of the log messages emitted by it. If its value is zero, the default, all of the log messages are suppressed. Setting it to a value between `1` and `3` will allow logging of the messages whose level is above the value. The values have the following interpretations:

- `0` No logging. This is the default.
- `1` Log the final LIMPLE representation of the code.
- `2` Log the LAP, the final LIMPLE, and some additional pass info.
- `3` Maximum verbosity: log everything.

native-comp-async-jobs-number [User Option]

This variable determines the maximum number of native-compilation subprocesses that will be started simultaneously. It should be a non-negative number. The default value is zero, which means use half the number of the CPU execution units, or `1` if the CPU has only one execution unit.

native-comp-async-report-warnings-errors [User Option]

If this variable's value is non-`nil`, warnings and errors from asynchronous native-compilation subprocesses are reported in the main Emacs session in a buffer named `*Warnings*`. The default value `t` means display the resulting buffer. To log warnings without popping up the `*Warnings*` buffer, set this variable to `silent`.

A common cause for asynchronous native-compilation to produce warnings is compiling a file that is missing some `require` of a necessary feature. The feature may be loaded into the main emacs, but because native compilation always starts from a subprocess with a pristine environment, that may not be true for the subprocess.

native-comp-async-query-on-exit [User Option]

If this variable's value is non-`nil`, Emacs will query upon exiting whether to exit and kill any asynchronous native-compilation subprocesses that are still running, thus preventing the corresponding `.eln` files from being written. If the value is `nil`, the default, Emacs will kill these subprocesses without querying.

The variable `native-comp-eln-load-path` holds the list of directories where Emacs looks for the `*.eln` files (see Section 16.3 [Library Search], page 301); in that role it is the equivalent of `load-path` used to look for `*.el` and `*.elc` files. The directories in this list are also used for writing the `*.eln` files produced by asynchronous native-compilation; specifically, Emacs will write these files into the first writable directory in the list. Thus, you can control where native-compilation stores the results by changing the value of this variable.

native-comp-jit-compilation [Variable]

This variable, if non-`nil`, enables asynchronous (a.k.a. *just-in-time*, or JIT) native compilation of the `*.elc` files loaded by Emacs for which the corresponding `*.eln` files do not already exist. This JIT compilation uses separate Emacs sub-processes running in batch mode, according to the value of `native-comp-async-jobs-number`. When the JIT compilation of a Lisp file finishes successfully, the resulting `.eln` file is loaded and its code replaces the definition of functions provided by the `.elc` file.

Setting the value of `native-comp-jit-compilation` to `nil` disables JIT native compilation. However, even when JIT native compilation is disabled, Emacs might still need to start asynchronous native compilation subprocesses to produce *trampolines*. To control this, use a separate variable, described below.

native-comp-enable-subr-trampolines [Variable]

This variable controls generation of trampolines. A trampoline is a small piece of native code required to allow calling Lisp primitives, which were advised or redefined, from Lisp code that was natively-compiled with `native-comp-speed` set to 2 or greater. Emacs stores the generated trampolines on separate `*.eln` files. By default, this variable's value is `t`, which enables the generation of trampoline files; setting it to `nil` disables the generation of trampolines. Note that if a trampoline needed for advising or redefining a primitive is not available and cannot be generated, calls to that primitive from natively-compiled Lisp will ignore redefinitions and advices, and will behave as if the primitive was called directly from C. Therefore, we don't recommend disabling the trampoline generation, unless you know that all the trampolines needed by your Lisp programs are already compiled and accessible to Emacs.

The value of this variable can also be a string, in which case it specifies the name of a directory in which to store the generated trampoline `*.eln` files, overriding the directories in `native-comp-eln-load-path`. This is useful if you want the trampolines to be generated as needed, but don't want to store them under the user's `HOME` directory or in the other public directories where `*.eln` files are kept. However, unlike with directories in `native-comp-eln-load-path`, the trampolines will be stored in the directory given by the value of this variable, not in its version-specific subdirectory. If the name of this directory is not absolute, it is interpreted relative to `invocation-directory` (see Section 42.3 [System Environment], page 1265).

If this variable is non-`nil`, and Emacs needs to produce a trampoline, but it cannot find any writable directory to store the trampoline, it will store it inside `temporary-file-directory` (see Section 26.9.5 [Unique File Names], page 641).

Trampolines produced when no writable directory is found to store them, or when this variable is a string, will only be available for the duration of the current Emacs session, because Emacs doesn't look for trampolines in either of these places.

19 Debugging Lisp Programs

There are several ways to find and investigate problems in an Emacs Lisp program.

- If a problem occurs when you run the program, you can use the built-in Emacs Lisp debugger (see Section 19.1 [Debugger], page 333) to suspend the Lisp evaluator, and examine and/or alter its internal state.
- You can use Edebug, a source-level debugger for Emacs Lisp. See Section 19.2 [Edebug], page 344.
- You can trace the execution of functions involved in the problem using the tracing facilities provided by the `trace.el` package. This package provides the functions `trace-function-foreground` and `trace-function-background` for tracing function calls, and `trace-values` for adding values of select variables to the trace. For the details, see the documentation of these facilities in `trace.el`.
- If a syntactic problem is preventing Lisp from even reading the program, you can locate it using Lisp editing commands.
- You can look at the error and warning messages produced by the byte compiler when it compiles the program. See Section 17.6 [Compiler Errors], page 321.
- You can use the Testcover package to perform coverage testing on the program.
- You can use the ERT package to write regression tests for the program. See *ERT: Emacs Lisp Regression Testing*.
- You can profile the program to get hints about how to make it more efficient. See Section 19.5 [Profiling], page 369.

Other useful tools for debugging input and output problems are the `dribble` file (see Section 42.13 [Terminal Input], page 1285) and the `open-terminalscript` function (see Section 42.14 [Terminal Output], page 1287).

19.1 The Lisp Debugger

The ordinary *Lisp debugger* provides the ability to suspend evaluation of a form. While evaluation is suspended (a state that is commonly known as a *break*), you may examine the run time stack, examine the values of local or global variables, or change those values. Since a break is a recursive edit, all the usual editing facilities of Emacs are available; you can even run programs that will enter the debugger recursively. See Section 22.13 [Recursive Editing], page 475.

19.1.1 Entering the Debugger on an Error

The most important time to enter the debugger is when a Lisp error happens. This allows you to investigate the immediate causes of the error.

However, entry to the debugger is not a normal consequence of an error. Many commands signal Lisp errors when invoked inappropriately, and during ordinary editing it would be very inconvenient to enter the debugger each time this happens. So if you want errors to enter the debugger, set the variable `debug-on-error` to `non-nil`. (The command `toggle-debug-on-error` provides an easy way to do this.)

Note that, for technical reasons, you cannot use the facilities defined in this subsection to debug errors in Lisp that the redisplay code has invoked. See Section 19.1.2 [Debugging Redisplay], page 335, for help with these.

debug-on-error

[User Option]

This variable determines whether the debugger is called when an error is signaled and not handled. If `debug-on-error` is `t`, all kinds of errors call the debugger, except those listed in `debug-ignored-errors` (see below). If it is `nil`, none call the debugger.

The value can also be a list of error conditions (see Section 11.7.3.1 [Signaling Errors], page 180). Then the debugger is called only for error conditions in this list (except those also listed in `debug-ignored-errors`). For example, if you set `debug-on-error` to the list (`void-variable`), the debugger is only called for errors about a variable that has no value.

Note that `eval-expression-debug-on-error` overrides this variable in some cases; see below.

When this variable is `non-nil`, Emacs does not create an error handler around process filter functions and sentinels. Therefore, errors in these functions also invoke the debugger. See Chapter 40 [Processes], page 1078.

debug-ignored-errors

[User Option]

This variable specifies errors which should not enter the debugger, regardless of the value of `debug-on-error`. Its value is a list of error condition symbols and/or regular expressions. If the error has any of those condition symbols, or if the error message matches any of the regular expressions, then that error does not enter the debugger.

The normal value of this variable includes `user-error`, as well as several errors that happen often during editing but rarely result from bugs in Lisp programs. However, “rarely” is not “never”; if your program fails with an error that matches this list, you may try changing this list to debug the error. The easiest way is usually to set `debug-ignored-errors` to `nil`.

eval-expression-debug-on-error

[User Option]

If this variable has a non-`nil` value (the default), running the command `eval-expression` causes `debug-on-error` to be temporarily bound to `t`. See Section “Evaluating Emacs Lisp Expressions” in *The GNU Emacs Manual*.

If `eval-expression-debug-on-error` is `nil`, then the value of `debug-on-error` is not changed during `eval-expression`.

debug-on-signal

[User Option]

Normally, errors caught by `condition-case` never invoke the debugger. The `condition-case` gets a chance to handle the error before the debugger gets a chance.

If you change `debug-on-signal` to a non-`nil` value, the debugger gets the first chance at every error, regardless of the presence of `condition-case`. (To invoke the debugger, the error must still fulfill the criteria specified by `debug-on-error` and `debug-ignored-errors`.)

For example, setting this variable is useful to get a backtrace from code evaluated by `emacsclient`’s `--eval` option. If Lisp code evaluated by `emacsclient` signals an error while this variable is non-`nil`, the backtrace will popup in the running Emacs.

Warning: Setting this variable to non-`nil` may have annoying effects. Various parts of Emacs catch errors in the normal course of affairs, and you may not even realize that errors happen there. If you need to debug code wrapped in `condition-case`, consider using `condition-case-unless-debug` (see Section 11.7.3.3 [Handling Errors], page 182).

`debug-on-event` [User Option]

If you set `debug-on-event` to a special event (see Section 22.9 [Special Events], page 470), Emacs will try to enter the debugger as soon as it receives this event, bypassing `special-event-map`. At present, the only supported values correspond to the signals `SIGUSR1` and `SIGUSR2` (this is the default). This can be helpful when `inhibit-quit` is set and Emacs is not otherwise responding.

`debug-on-message` [Variable]

If you set `debug-on-message` to a regular expression, Emacs will enter the debugger if it displays a matching message in the echo area. For example, this can be useful when trying to find the cause of a particular message.

`debug-allow-recursive-debug` [Variable]

You can evaluate forms in the current stack frame in the ‘*Backtrace*’ buffer with the `e` command, and while edebugging you can use the `e` and `C-x C-e` commands to do something similar. By default, the debugger is inhibited by these commands (because (re-)entering the debugger at this point will usually take you out of the debugging context you’re in). Set `debug-allow-recursive-debug` to a non-`nil` value to allow these commands to enter the debugger recursively.

To debug an error that happens during loading of the init file, use the option ‘`--debug-init`’. This binds `debug-on-error` to `t` while loading the init file, and bypasses the `condition-case` which normally catches errors in the init file.

19.1.2 Debugging Redisplay Errors

When an error occurs in Lisp code which redisplay has invoked, Emacs’s usual debugging mechanisms are unusable, for technical reasons. This subsection describes how to get a backtrace from such an error, which should be helpful in debugging it.

These directions apply to Lisp forms used, for example, in `:eval` mode line constructs (see Section 24.4.2 [Mode Line Data], page 551), and in all hooks invoked from redisplay, such as:

- `fontification-functions` (see Section 41.12.7 [Auto Faces], page 1178).
- `window-scroll-functions` (see Section 29.28 [Window Hooks], page 779).

Note that if you have had an error in a hook function called from redisplay, the error handling might have removed this function from the hook. You will thus need to reinitialize that hook somehow, perhaps with `add-hook`, to be able to replay the bug.

To generate a backtrace in these circumstances, set the variable `backtrace-on-redisplay-error` to non-`nil`. When the error occurs, Emacs will dump the backtrace to the buffer `*Redisplay-trace*`, but won’t automatically display it in a window. This is to avoid needlessly corrupting the redisplay you are debugging. You will thus need to display the buffer yourself, with a command such as `switch-to-buffer-other-frame C-x 5 b`.

backtrace-on-redisplay-error [Variable]

Set this variable to non-*nil* to enable the generation of a backtrace when an error occurs in any Lisp called from redisplay.

19.1.3 Debugging Infinite Loops

When a program loops infinitely and fails to return, your first problem is to stop the loop. On most operating systems, you can do this with *C-g*, which causes a *quit*. See Section 22.11 [Quitting], page 471.

Ordinary quitting gives no information about why the program was looping. To get more information, you can set the variable `debug-on-quit` to non-*nil*. Once you have the debugger running in the middle of the infinite loop, you can proceed from the debugger using the stepping commands. If you step through the entire loop, you may get enough information to solve the problem.

Quitting with *C-g* is not considered an error, and `debug-on-error` has no effect on the handling of *C-g*. Likewise, `debug-on-quit` has no effect on errors.

debug-on-quit [User Option]

This variable determines whether the debugger is called when *quit* is signaled and not handled. If `debug-on-quit` is non-*nil*, then the debugger is called whenever you quit (that is, type *C-g*). If `debug-on-quit` is *nil* (the default), then the debugger is not called when you quit.

19.1.4 Entering the Debugger on a Function Call

To investigate a problem that happens in the middle of a program, one useful technique is to enter the debugger whenever a certain function is called. You can do this to the function in which the problem occurs, and then step through the function, or you can do this to a function called shortly before the problem, step quickly over the call to that function, and then step through its caller.

debug-on-entry function-name [Command]

This function requests *function-name* to invoke the debugger each time it is called.

Any function or macro defined as Lisp code may be set to break on entry, regardless of whether it is interpreted code or compiled code. If the function is a command, it will enter the debugger when called from Lisp and when called interactively (after the reading of the arguments). You can also set `debug-on-entry` for primitive functions (i.e., those written in C) this way, but it only takes effect when the primitive is called from Lisp code. Debug-on-entry is not allowed for special forms.

When `debug-on-entry` is called interactively, it prompts for *function-name* in the minibuffer. If the function is already set up to invoke the debugger on entry, `debug-on-entry` does nothing. `debug-on-entry` always returns *function-name*.

Here's an example to illustrate use of this function:

```
(defun fact (n)
  (if (zerop n) 1
      (* n (fact (1- n))))
  ⇒ fact
  (debug-on-entry 'fact)
  ⇒ fact
```

```
(fact 3)

----- Buffer: *Backtrace*
Debugger entered--entering a function:
* fact(3)
  eval((fact 3))
  eval-last-sexp-1(nil)
  eval-last-sexp(nil)
  call-interactively(eval-last-sexp)
----- Buffer: *Backtrace*
```

cancel-debug-on-entry &optional function-name [Command]

This function undoes the effect of `debug-on-entry` on *function-name*. When called interactively, it prompts for *function-name* in the minibuffer. If *function-name* is omitted or `nil`, it cancels break-on-entry for all functions. Calling `cancel-debug-on-entry` does nothing to a function which is not currently set up to break on entry.

19.1.5 Entering the debugger when a variable is modified

Sometimes a problem with a function is due to a wrong setting of a variable. Setting up the debugger to trigger whenever the variable is changed is a quick way to find the origin of the setting.

debug-on-variable-change variable [Command]

This function arranges for the debugger to be called whenever *variable* is modified.

It is implemented using the watchpoint mechanism, so it inherits the same characteristics and limitations: all aliases of *variable* will be watched together, only dynamic variables can be watched, and changes to the objects referenced by variables are not detected. For details, see Section 12.9 [Watching Variables], page 200.

cancel-debug-on-variable-change &optional variable [Command]

This function undoes the effect of `debug-on-variable-change` on *variable*. When called interactively, it prompts for *variable* in the minibuffer. If *variable* is omitted or `nil`, it cancels break-on-change for all variables. Calling `cancel-debug-on-variable-change` does nothing to a variable which is not currently set up to break on change.

19.1.6 Explicit Entry to the Debugger

You can cause the debugger to be called at a certain point in your program by writing the expression `(debug)` at that point. To do this, visit the source file, insert the text ‘`(debug)`’ at the proper place, and type *C-M-x (eval-defun*, a Lisp mode key binding). **Warning:** if you do this for temporary debugging purposes, be sure to undo this insertion before you save the file!

The place where you insert ‘`(debug)`’ must be a place where an additional form can be evaluated and its value ignored. (If the value of `(debug)` isn’t ignored, it will alter the execution of the program!) The most common suitable places are inside a `progn` or an implicit `progn` (see Section 11.1 [Sequencing], page 158).

If you don't know exactly where in the source code you want to put the debug statement, but you want to display a backtrace when a certain message is displayed, you can set `debug-on-message` to a regular expression matching the desired message.

19.1.7 Using the Debugger

When the debugger is entered, it displays the previously selected buffer in one window and a buffer named `*Backtrace*` in another window. The backtrace buffer contains one line for each level of Lisp function execution currently going on. At the beginning of this buffer is a message describing the reason that the debugger was invoked (such as the error message and associated data, if it was invoked due to an error).

The backtrace buffer is read-only and uses a special major mode, Debugger mode, in which letters are defined as debugger commands. The usual Emacs editing commands are available; thus, you can switch windows to examine the buffer that was being edited at the time of the error, switch buffers, visit files, or do any other sort of editing. However, the debugger is a recursive editing level (see Section 22.13 [Recursive Editing], page 475) and it is wise to go back to the backtrace buffer and exit the debugger (with the `q` command) when you are finished with it. Exiting the debugger gets out of the recursive edit and buries the backtrace buffer. (You can customize what the `q` command does with the backtrace buffer by setting the variable `debugger-bury-or-kill`. For example, set it to `kill` if you prefer to kill the buffer rather than bury it. Consult the variable's documentation for more possibilities.)

When the debugger has been entered, the `debug-on-error` variable is temporarily set according to `eval-expression-debug-on-error`. If the latter variable is non-`nil`, `debug-on-error` will temporarily be set to `t`. However, further errors that occur while debugging won't (by default) trigger another debugger, because `inhibit-debugger` will also be bound to `non-nil`.

The debugger itself must be run byte-compiled, since it makes assumptions about the state of the Lisp interpreter. These assumptions are false if the debugger is running interpreted.

19.1.8 Backtraces

Debugger mode is derived from Backtrace mode, which is also used to show backtraces by Edebug and ERT. (see Section 19.2 [Edebug], page 344, and *ERT: Emacs Lisp Regression Testing*.)

The backtrace buffer shows you the functions that are executing and their argument values. When a backtrace buffer is created, it shows each stack frame on one, possibly very long, line. (A stack frame is the place where the Lisp interpreter records information about a particular invocation of a function.) The most recently called function will be at the top.

In a backtrace you can specify a stack frame by moving point to a line describing that frame. The frame whose line point is on is considered the *current frame*.

If a function name is underlined, that means Emacs knows where its source code is located. You can click with the mouse on that name, or move to it and type RET, to visit the source code. You can also type RET while point is on any name of a function or variable which is not underlined, to see help information for that symbol in a help buffer, if any exists. The `xref-find-definitions` command, bound to `M-.`, can also be used on any identifier in a backtrace (see Section "Looking Up Identifiers" in *The GNU Emacs Manual*).

In backtraces, the tails of long lists and the ends of long strings, vectors or structures, as well as objects which are deeply nested, will be printed as underlined “...”. You can click with the mouse on a “...”, or type RET while point is on it, to show the part of the object that was hidden. To control how much abbreviation is done, customize `backtrace-line-length`.

Here is a list of commands for navigating and viewing backtraces:

- `v` Toggle the display of local variables of the current stack frame.
- `p` Move to the beginning of the frame, or to the beginning of the previous frame.
- `n` Move to the beginning of the next frame.
- `+` Add line breaks and indentation to the top-level Lisp form at point to make it more readable.
- `-` Collapse the top-level Lisp form at point back to a single line.
- `#` Toggle `print-circle` for the frame at point.
- `:` Toggle `print-gensym` for the frame at point.
- `.` Expand all the forms abbreviated with “...” in the frame at point.

19.1.9 Debugger Commands

The debugger buffer (in Debugger mode) provides special commands in addition to the usual Emacs commands and to the Backtrace mode commands described in the previous section. The most important use of debugger commands is for stepping through code, so that you can see how control flows. The debugger can step through the control structures of an interpreted function, but cannot do so in a byte-compiled function. If you would like to step through a byte-compiled function, replace it with an interpreted definition of the same function. (To do this, visit the source for the function and type `C-M-x` on its definition.) You cannot use the Lisp debugger to step through a primitive function.

Some of the debugger commands operate on the current frame. If a frame starts with a star, that means that exiting that frame will call the debugger again. This is useful for examining the return value of a function.

Here is a list of Debugger mode commands:

- `c` Exit the debugger and continue execution. This resumes execution of the program as if the debugger had never been entered (aside from any side-effects that you caused by changing variable values or data structures while inside the debugger).
- `d` Continue execution, but enter the debugger the next time any Lisp function is called. This allows you to step through the subexpressions of an expression, seeing what values the subexpressions compute, and what else they do.
The stack frame made for the function call which enters the debugger in this way will be flagged automatically so that the debugger will be called again when the frame is exited. You can use the `u` command to cancel this flag.
- `b` Flag the current frame so that the debugger will be entered when the frame is exited. Frames flagged in this way are marked with stars in the backtrace buffer.

- u** Don't enter the debugger when the current frame is exited. This cancels a **b** command on that frame. The visible effect is to remove the star from the line in the backtrace buffer.
- j** Flag the current frame like **b**. Then continue execution like **c**, but temporarily disable break-on-entry for all functions that are set up to do so by `debug-on-entry`.
- e** Read a Lisp expression in the minibuffer, evaluate it (with the relevant lexical environment, if applicable), and print the value in the echo area. The debugger alters certain important variables, and the current buffer, as part of its operation; **e** temporarily restores their values from outside the debugger, so you can examine and change them. This makes the debugger more transparent. By contrast, **M-:** does nothing special in the debugger; it shows you the variable values within the debugger. By default, this command suppresses the debugger during evaluation, so that an error in the evaluated expression won't add a new error on top of the existing one. Set the `debug-allow-recursive-debug` user option to a non-nil value to override this.
- R** Like **e**, but also save the result of evaluation in the buffer ***Debugger-record***.
- q** Terminate the program being debugged; return to top-level Emacs command execution.
If the debugger was entered due to a **C-g** but you really want to quit, and not debug, use the **q** command.
- r** Return a value from the debugger. The value is computed by reading an expression with the minibuffer and evaluating it.
The **r** command is useful when the debugger was invoked due to exit from a Lisp call frame (as requested with **b** or by entering the frame with **d**); then the value specified in the **r** command is used as the value of that frame. It is also useful if you call `debug` and use its return value. Otherwise, **r** has the same effect as **c**, and the specified return value does not matter.
You can't use **r** when the debugger was entered due to an error.
- l** Display a list of functions that will invoke the debugger when called. This is a list of functions that are set to break on entry by means of `debug-on-entry`.

19.1.10 Invoking the Debugger

Here we describe in full detail the function `debug` that is used to invoke the debugger.

debug &rest debugger-args [Command]

This function enters the debugger. In interactive sessions, it switches to a buffer named ***Backtrace*** (or ***Backtrace*<2>** if it is the second recursive entry to the debugger, etc.), and fills it with information about the stack of Lisp function calls. It then enters a recursive edit, showing the backtrace buffer in Debugger mode. In batch mode (more generally, when `noninteractive` is non-nil, see Section 42.17 [Batch Mode], page 1289), this function shows the Lisp backtrace on the standard error stream, and then kills Emacs, causing it to exit with a non-zero exit code (see Section 42.2.1).

[Killing Emacs], page 1262). Binding `backtrace-on-error-noninteractive` to `nil` suppresses the backtrace in batch mode, see below.

The Debugger mode `c`, `d`, `j`, and `r` commands exit the recursive edit; then `debug` switches back to the previous buffer and returns to whatever called `debug`. This is the only way the function `debug` can return to its caller.

The use of the `debugger-args` is that `debug` displays the rest of its arguments at the top of the `*Backtrace*` buffer, so that the user can see them. Except as described below, this is the *only* way these arguments are used.

However, certain values for first argument to `debug` have a special significance. (Normally, these values are used only by the internals of Emacs, and not by programmers calling `debug`.) Here is a table of these special values:

<code>lambda</code>	A first argument of <code>lambda</code> means <code>debug</code> was called because of entry to a function when <code>debug-on-next-call</code> was non- <code>nil</code> . The debugger displays ‘Debugger entered--entering a function:’ as a line of text at the top of the buffer.
<code>debug</code>	<code>debug</code> as first argument means <code>debug</code> was called because of entry to a function that was set to debug on entry. The debugger displays the string ‘Debugger entered--entering a function:’, just as in the <code>lambda</code> case. It also marks the stack frame for that function so that it will invoke the debugger when exited.
<code>t</code>	When the first argument is <code>t</code> , this indicates a call to <code>debug</code> due to evaluation of a function call form when <code>debug-on-next-call</code> is non- <code>nil</code> . The debugger displays ‘Debugger entered--beginning evaluation of function call form:’ as the top line in the buffer.
<code>exit</code>	When the first argument is <code>exit</code> , it indicates the exit of a stack frame previously marked to invoke the debugger on exit. The second argument given to <code>debug</code> in this case is the value being returned from the frame. The debugger displays ‘Debugger entered--returning value:’ in the top line of the buffer, followed by the value being returned.
<code>error</code>	When the first argument is <code>error</code> , the debugger indicates that it is being entered because an error or <code>quit</code> was signaled and not handled, by displaying ‘Debugger entered--Lisp error:’ followed by the error signaled and any arguments to <code>signal</code> . For example,

```
(let ((debug-on-error t))
  (/ 1 0))

----- Buffer: *Backtrace* -----
Debugger entered--Lisp error: (arith-error)
  /(1 0)
...
----- Buffer: *Backtrace* -----
```

If an error was signaled, presumably the variable `debug-on-error` is non-`nil`. If `quit` was signaled, then presumably the variable `debug-on-quit` is non-`nil`.

nil Use `nil` as the first of the `debugger-args` when you want to enter the debugger explicitly. The rest of the `debugger-args` are printed on the top line of the buffer. You can use this feature to display messages—for example, to remind yourself of the conditions under which `debug` is called.

backtrace-on-error-noninteractive [Variable]

If this variable is non-`nil`, the default, entering the debugger in batch mode shows the backtrace of Lisp functions calls. Binding the variable to the `nil` value suppresses the backtrace and shows only the error message.

19.1.11 Internals of the Debugger

This section describes functions and variables used internally by the debugger.

debugger [Variable]

The value of this variable is the function to call to invoke the debugger. Its value must be a function of any number of arguments, or, more typically, the name of a function. This function should invoke some kind of debugger. The default value of the variable is `debug`.

The first argument that Lisp hands to the function indicates why it was called. The convention for arguments is detailed in the description of `debug` (see Section 19.1.10 [Invoking the Debugger], page 340).

backtrace [Function]

This function prints a trace of Lisp function calls currently active. The trace is identical to the one that `debug` would show in the `*Backtrace*` buffer. The return value is always `nil`.

In the following example, a Lisp expression calls `backtrace` explicitly. This prints the backtrace to the stream `standard-output`, which, in this case, is the buffer ‘`backtrace-output`’.

Each line of the backtrace represents one function call. The line shows the function followed by a list of the values of the function’s arguments if they are all known; if they are still being computed, the line consists of a list containing the function and its unevaluated arguments. Long lists or deeply nested structures may be elided.

```
(with-output-to-temp-buffer "backtrace-output"
  (let ((var 1))
    (save-excursion
      (setq var (eval '(progn
                           (1+ var)
                           (list 'testing (backtrace)))))))
  ⇒ (testing nil)

----- Buffer: backtrace-output -----
backtrace()
(list 'testing (backtrace))
(progn ...)
eval((progn (1+ var) (list 'testing (backtrace))))
(setq ...)
(save-excursion ...)
(let ...)
```

```
(with-output-to-temp-buffer ...)
eval((with-output-to-temp-buffer ...))
eval-last-sexp-1(nil)
eval-last-sexp(nil)
call-interactively(eval-last-sexp)
----- Buffer: backtrace-output -----
```

debugger-stack-frame-as-list

[User Option]

If this variable is non-nil, every stack frame of the backtrace is displayed as a list. This aims at improving the backtrace readability at the cost of special forms no longer being visually different from regular function calls.

With `debugger-stack-frame-as-list` non-nil, the above example would look as follows:

```
----- Buffer: backtrace-output -----
(backtrace)
(list 'testing (backtrace))
(progn ...)
(eval (progn (1+ var) (list 'testing (backtrace))))
(setq ...)
(save-excursion ...)
(let ...)
(with-output-to-temp-buffer ...)
(eval (with-output-to-temp-buffer ...))
(eval-last-sexp-1 nil)
(eval-last-sexp nil)
(call-interactively eval-last-sexp)
----- Buffer: backtrace-output -----
```

debug-on-next-call

[Variable]

If this variable is non-nil, it says to call the debugger before the next `eval`, `apply` or `funcall`. Entering the debugger sets `debug-on-next-call` to nil.

The `d` command in the debugger works by setting this variable.

backtrace-debug level flag

[Function]

This function sets the debug-on-exit flag of the stack frame *level* levels down the stack, giving it the value *flag*. If *flag* is non-nil, this will cause the debugger to be entered when that frame later exits. Even a nonlocal exit through that frame will enter the debugger.

This function is used only by the debugger.

command-debug-status

[Variable]

This variable records the debugging status of the current interactive command. Each time a command is called interactively, this variable is bound to nil. The debugger can set this variable to leave information for future debugger invocations during the same command invocation.

The advantage of using this variable rather than an ordinary global variable is that the data will never carry over to a subsequent command invocation.

This variable is obsolete and will be removed in future versions.

backtrace-frame frame-number &optional base [Function]

The function `backtrace-frame` is intended for use in Lisp debuggers. It returns information about what computation is happening in the stack frame *frame-number* levels down.

If that frame has not evaluated the arguments yet, or is a special form, the value is `(nil function arg-forms...)`.

If that frame has evaluated its arguments and called its function already, the return value is `(t function arg-values...)`.

In the return value, *function* is whatever was supplied as the CAR of the evaluated list, or a `lambda` expression in the case of a macro call. If the function has a `&rest` argument, that is represented as the tail of the list *arg-values*.

If *base* is specified, *frame-number* counts relative to the topmost frame whose *function* is *base*.

If *frame-number* is out of range, `backtrace-frame` returns `nil`.

mapbacktrace function &optional base [Function]

The function `mapbacktrace` calls *function* once for each frame in the backtrace, starting at the first frame whose function is *base* (or from the top if *base* is omitted or `nil`).

function is called with four arguments: *evald*, *func*, *args*, and *flags*.

If a frame has not evaluated its arguments yet or is a special form, *evald* is `nil` and *args* is a list of forms.

If a frame has evaluated its arguments and called its function already, *evald* is `t` and *args* is a list of values. *flags* is a plist of properties of the current frame: currently, the only supported property is `:debug-on-exit`, which is `t` if the stack frame's `debug-on-exit` flag is set.

19.2 Edebug

Edebug is a source-level debugger for Emacs Lisp programs, with which you can:

- Step through evaluation, stopping before and after each expression.
- Set conditional or unconditional breakpoints.
- Stop when a specified condition is true (the global break event).
- Trace slow or fast, stopping briefly at each stop point, or at each breakpoint.
- Display expression results and evaluate expressions as if outside of Edebug.
- Automatically re-evaluate a list of expressions and display their results each time Edebug updates the display.
- Output trace information on function calls and returns.
- Stop when an error occurs.
- Display a backtrace, omitting Edebug's own frames.
- Specify argument evaluation for macros and defining forms.
- Obtain rudimentary coverage testing and frequency counts.

The first three sections below should tell you enough about Edebug to start using it.

19.2.1 Using Edebug

To debug a Lisp program with Edebug, you must first *instrument* the Lisp code that you want to debug. A simple way to do this is to first move point into the definition of a function or macro and then do **C-u C-M-x** (`eval-defun` with a prefix argument). See Section 19.2.2 [Instrumenting], page 346, for alternative ways to instrument code.

Once a function is instrumented, any call to the function activates Edebug. Depending on which Edebug execution mode you have selected, activating Edebug may stop execution and let you step through the function, or it may update the display and continue execution while checking for debugging commands. The default execution mode is step, which stops execution. See Section 19.2.3 [Edebug Execution Modes], page 347.

Within Edebug, you normally view an Emacs buffer showing the source of the Lisp code you are debugging. This is referred to as the *source code buffer*, and it is temporarily read-only.

An arrow in the left fringe indicates the line where the function is executing. Point initially shows where within the line the function is executing, but this ceases to be true if you move point yourself.

If you instrument the definition of `fac` (shown below) and then execute `(fac 3)`, here is what you would normally see. Point is at the open-parenthesis before `if`.

```
(defun fac (n)
=>*(if (< 0 n)
        (* n (fac (1- n)))
        1))
```

The places within a function where Edebug can stop execution are called *stop points*. These occur both before and after each subexpression that is a list, and also after each variable reference. Here we use periods to show the stop points in the function `fac`:

```
(defun fac (n)
.(if .(< 0 n)..
    .(* n. .(fac .(1- n.)..).
    1)..)
```

The special commands of Edebug are available in the source code buffer in addition to the commands of Emacs Lisp mode. For example, you can type the Edebug command `SPC` to execute until the next stop point. If you type `SPC` once after entry to `fac`, here is the display you will see:

```
(defun fac (n)
=>(if *(< 0 n)
        (* n (fac (1- n)))
        1))
```

When Edebug stops execution after an expression, it displays the expression's value in the echo area.

Other frequently used commands are `b` to set a breakpoint at a stop point, `g` to execute until a breakpoint is reached, and `q` to exit Edebug and return to the top-level command loop. Type `?` to display a list of all Edebug commands.

19.2.2 Instrumenting for Edebug

In order to use Edebug to debug Lisp code, you must first *instrument* the code. Instrumenting code inserts additional code into it, to invoke Edebug at the proper places.

When you invoke command `C-M-x (eval-defun)` with a prefix argument on a function definition, it instruments the definition before evaluating it. (This does not modify the source code itself.) If the variable `edebug-all-defs` is non-`nil`, that inverts the meaning of the prefix argument: in this case, `C-M-x` instruments the definition *unless* it has a prefix argument. The default value of `edebug-all-defs` is `nil`. The command `M-x edebug-all-defs` toggles the value of the variable `edebug-all-defs`.

If `edebug-all-defs` is non-`nil`, then the commands `eval-region`, and `eval-buffer` also instrument any definitions they evaluate. Similarly, `edebug-all-forms` controls whether `eval-region` should instrument *any* form, even non-defining forms. This doesn't apply to loading or evaluations in the minibuffer. The command `M-x edebug-all-forms` toggles this option.

Another command, `M-x edebug-eval-top-level-form`, is available to instrument any top-level form regardless of the values of `edebug-all-defs` and `edebug-all-forms`. `edebug-defun` is an alias for `edebug-eval-top-level-form`.

While Edebug is active, the command `I (edebug-instrument-callee)` instruments the definition of the function or macro called by the list form after point, if it is not already instrumented. This is possible only if Edebug knows where to find the source for that function; for this reason, after loading Edebug, `eval-region` records the position of every definition it evaluates, even if not instrumenting it. See also the `i` command (see Section 19.2.4 [Jumping], page 348), which steps into the call after instrumenting the function.

Edebug knows how to instrument all the standard special forms, `interactive` forms with an expression argument, anonymous lambda expressions, and other defining forms. However, Edebug cannot determine on its own what a user-defined macro will do with the arguments of a macro call, so you must provide that information using Edebug specifications; for details, see Section 19.2.15 [Edebug and Macros], page 358.

When Edebug is about to instrument code for the first time in a session, it runs the hook `edebug-setup-hook`, then sets it to `nil`. You can use this to load Edebug specifications associated with a package you are using, but only when you use Edebug.

If Edebug detects a syntax error while instrumenting, it leaves point at the erroneous code and signals an `invalid-read-syntax` error. Example:

```
error Invalid read syntax: "Expected lambda expression"
```

One potential reason for such a failure to instrument is that some macro definitions are not yet known to Emacs. To work around this, load the file which defines the function you are about to instrument.

To remove instrumentation from a definition, simply re-evaluate its definition in a way that does not instrument. There are two ways of evaluating forms that never instrument them: from a file with `load`, and from the minibuffer with `eval-expression (M-:)`.

A different way to remove the instrumentation from a definition is to use the `edebug-remove-instrumentation` command. It also allows removing the instrumentation from everything that has been instrumented.

See Section 19.2.9 [Edebug Eval], page 352, for other evaluation functions available inside of Edebug.

19.2.3 Edebug Execution Modes

Edebug supports several execution modes for running the program you are debugging. We call these alternatives *Edebug execution modes*; do not confuse them with major or minor modes. The current Edebug execution mode determines how far Edebug continues execution before stopping—whether it stops at each stop point, or continues to the next breakpoint, for example—and how much Edebug displays the progress of the evaluation before it stops.

Normally, you specify the Edebug execution mode by typing a command to continue the program in a certain mode. Here is a table of these commands; all except for *S* resume execution of the program, at least for a certain distance.

<i>S</i>	Stop: don't execute any more of the program, but wait for more Edebug commands (<code>edebug-stop</code>).
<i>SPC</i>	Step: stop at the next stop point encountered (<code>edebug-step-mode</code>).
<i>n</i>	Next: stop at the next stop point encountered after an expression (<code>edebug-next-mode</code>). Also see <code>edebug-forward-sexp</code> in Section 19.2.4 [Jumping], page 348.
<i>t</i>	Trace: pause (normally one second) at each Edebug stop point (<code>edebug-trace-mode</code>).
<i>T</i>	Rapid trace: update the display at each stop point, but don't actually pause (<code>edebug-Trace-fast-mode</code>).
<i>g</i>	Go: run until the next breakpoint (<code>edebug-go-mode</code>). See Section 19.2.6.1 [Breakpoints], page 350.
<i>c</i>	Continue: pause one second at each breakpoint, and then continue (<code>edebug-continue-mode</code>).
<i>C</i>	Rapid continue: move point to each breakpoint, but don't pause (<code>edebug-Continue-fast-mode</code>).
<i>G</i>	Go non-stop: ignore breakpoints (<code>edebug-Go-nonstop-mode</code>). You can still stop the program by typing <i>S</i> , or any editing command.

In general, the execution modes earlier in the above list run the program more slowly or stop sooner than the modes later in the list.

When you enter a new Edebug level, Edebug will normally stop at the first instrumented function it encounters. If you prefer to stop only at a break point, or not at all (for example, when gathering coverage data), change the value of `edebug-initial-mode` from its default `step` to `go`, or `Go-nonstop`, or one of its other values (see Section 19.2.16 [Edebug Options], page 364). You can do this readily with *C-x C-a C-m* (`edebug-set-initial-mode`):

`edebug-set-initial-mode` [Command]

This command, bound to *C-x C-a C-m*, sets `edebug-initial-mode`. It prompts you for a key to indicate the mode. You should enter one of the eight keys listed above, which sets the corresponding mode.

Note that you may reenter the same Edebug level several times if, for example, an instrumented function is called several times from one command.

While executing or tracing, you can interrupt the execution by typing any Edebug command. Edebug stops the program at the next stop point and then executes the command you typed. For example, typing `t` during execution switches to trace mode at the next stop point. You can use `S` to stop execution without doing anything else.

If your function happens to read input, a character you type intending to interrupt execution may be read by the function instead. You can avoid such unintended results by paying attention to when your program wants input.

Keyboard macros containing the commands in this section do not completely work: exiting from Edebug, to resume the program, loses track of the keyboard macro. This is not easy to fix. Also, defining or executing a keyboard macro outside of Edebug does not affect commands inside Edebug. This is usually an advantage. See also the `edebug-continue-kbd-macro` option in Section 19.2.16 [Edebug Options], page 364.

`edebug-sit-for-seconds`

[User Option]

This option specifies how many seconds to wait between execution steps in trace mode or continue mode. The default is 1 second.

19.2.4 Jumping

The commands described in this section execute until they reach a specified location. All except `i` make a temporary breakpoint to establish the place to stop, then switch to go mode. Any other breakpoint reached before the intended stop point will also stop execution. See Section 19.2.6.1 [Breakpoints], page 350, for the details on breakpoints.

These commands may fail to work as expected in case of nonlocal exit, as that can bypass the temporary breakpoint where you expected the program to stop.

- `h` Proceed to the stop point near where point is (`edebug-goto-here`).
- `f` Run the program for one expression (`edebug-forward-sexp`).
- `o` Run the program until the end of the containing sexp (`edebug-step-out`).
- `i` Step into the function or macro called by the form after point (`edebug-step-in`).

The `h` command proceeds to the stop point at or after the current location of point, using a temporary breakpoint.

The `f` command runs the program forward over one expression. More precisely, it sets a temporary breakpoint at the position that `forward-sexp` would reach, then executes in go mode so that the program will stop at breakpoints.

With a prefix argument `n`, the temporary breakpoint is placed `n` sexps beyond point. If the containing list ends before `n` more elements, then the place to stop is after the containing expression.

You must check that the position `forward-sexp` finds is a place that the program will really get to. In `cond`, for example, this may not be true.

For flexibility, the `f` command does `forward-sexp` starting at point, rather than at the stop point. If you want to execute one expression *from the current stop point*, first type `w` (`edebug-where`) to move point there, and then type `f`.

The `o` command continues out of an expression. It places a temporary breakpoint at the end of the sexp containing point. If the containing sexp is a function definition itself, `o` continues until just before the last sexp in the definition. If that is where you are now, it returns from the function and then stops. In other words, this command does not exit the currently executing function unless you are positioned after the last sexp.

Normally, the `h`, `f`, and `o` commands display “Break” and pause for `edebg-sit-for-seconds` before showing the result of the form just evaluated. You can avoid this pause by setting `edebg-sit-on-break` to `nil`. See Section 19.2.16 [Edebug Options], page 364.

The `i` command steps into the function or macro called by the list form after point, and stops at its first stop point. Note that the form need not be the one about to be evaluated. But if the form is a function call about to be evaluated, remember to use this command before any of the arguments are evaluated, since otherwise it will be too late.

The `i` command instruments the function or macro it’s supposed to step into, if it isn’t instrumented already. This is convenient, but keep in mind that the function or macro remains instrumented unless you explicitly arrange to deinstrument it.

19.2.5 Miscellaneous Edebug Commands

Some miscellaneous Edebug commands are described here.

- `?` Display the help message for Edebug (`edebg-help`).
- `a`
- `C-]` Abort one level back to the previous command level (`abort-recursive-edit`).
- `q` Return to the top level editor command loop (`top-level`). This exits all recursive editing levels, including all levels of Edebug activity. However, instrumented code protected with `unwind-protect` or `condition-case` forms may resume debugging.
- `Q` Like `q`, but don’t stop even for protected code (`edebg-top-level-nonstop`).
- `r` Redisplay the most recently known expression result in the echo area (`edebg-previous-result`).
- `d` Display a backtrace, excluding Edebug’s own functions for clarity (`edebg-pop-to-backtrace`).

See Section 19.1.8 [Backtraces], page 338, for a description of backtraces and the commands which work on them.

If you would like to see Edebug’s functions in the backtrace, use `M-x edebg-backtrace-show-instrumentation`. To hide them again use `M-x edebg-backtrace-hide-instrumentation`.

If a backtrace frame starts with ‘`>`’ that means that Edebug knows where the source code for the frame is located. Use `s` to jump to the source code for the current frame.

The backtrace buffer is killed automatically when you continue execution.

You can invoke commands from Edebug that activate Edebug again recursively. Whenever Edebug is active, you can quit to the top level with `q` or abort one recursive edit level with `C-]`. You can display a backtrace of all the pending evaluations with `d`.

19.2.6 Breaks

Edebug's step mode stops execution when the next stop point is reached. There are three other ways to stop Edebug execution once it has started: breakpoints, the global break condition, and source breakpoints.

19.2.6.1 Edebug Breakpoints

While using Edebug, you can specify *breakpoints* in the program you are testing: these are places where execution should stop. You can set a breakpoint at any stop point, as defined in Section 19.2.1 [Using Edebug], page 345. For setting and unsetting breakpoints, the stop point that is affected is the first one at or after point in the source code buffer. Here are the Edebug commands for breakpoints:

- b** Set a breakpoint at the stop point at or after point (`edebug-set-breakpoint`). If you use a prefix argument, the breakpoint is temporary—it turns off the first time it stops the program. An overlay with the `edebug-enabled-breakpoint` or `edebug-disabled-breakpoint` faces is put at the breakpoint.
- u** Unset the breakpoint (if any) at the stop point at or after point (`edebug-unset-breakpoint`).
- U** Unset any breakpoints in the current form (`edebug-unset-breakpoints`).
- D** Toggle whether to disable the breakpoint near point (`edebug-toggle-disable-breakpoint`). This command is mostly useful if the breakpoint is conditional and it would take some work to recreate the condition.
- x condition RET** Set a conditional breakpoint which stops the program only if evaluating *condition* produces a non-`nil` value (`edebug-set-conditional-breakpoint`). With a prefix argument, the breakpoint is temporary.
- B** Move point to the next breakpoint in the current definition (`edebug-next-breakpoint`).

While in Edebug, you can set a breakpoint with **b** and unset one with **u**. First move point to the Edebug stop point of your choice, then type **b** or **u** to set or unset a breakpoint there. Unsetting a breakpoint where none has been set has no effect.

Re-evaluating or reinstrumenting a definition removes all of its previous breakpoints.

A *conditional breakpoint* tests a condition each time the program gets there. Any errors that occur as a result of evaluating the condition are ignored, as if the result were `nil`. To set a conditional breakpoint, use **x**, and specify the condition expression in the minibuffer. Setting a conditional breakpoint at a stop point that has a previously established conditional breakpoint puts the previous condition expression in the minibuffer so you can edit it.

You can make a conditional or unconditional breakpoint *temporary* by using a prefix argument with the command to set the breakpoint. When a temporary breakpoint stops the program, it is automatically unset.

Edebug always stops or pauses at a breakpoint, except when the Edebug mode is Go-nonstop. In that mode, it ignores breakpoints entirely.

To find out where your breakpoints are, use the **B** command, which moves point to the next breakpoint following point, within the same function, or to the first breakpoint if there

are no following breakpoints. This command does not continue execution—it just moves point in the buffer.

19.2.6.2 Global Break Condition

A *global break condition* stops execution when a specified condition is satisfied, no matter where that may occur. Edebug evaluates the global break condition at every stop point; if it evaluates to a non-`nil` value, then execution stops or pauses depending on the execution mode, as if a breakpoint had been hit. If evaluating the condition gets an error, execution does not stop.

The condition expression is stored in `edebug-global-break-condition`. You can specify a new expression using the `X` command from the source code buffer while Edebug is active, or using `C-x X X` from any buffer at any time, as long as Edebug is loaded (`edebug-set-global-break-condition`).

The global break condition is the simplest way to find where in your code some event occurs, but it makes code run much more slowly. So you should reset the condition to `nil` when not using it.

19.2.6.3 Source Breakpoints

All breakpoints in a definition are forgotten each time you reinstrument it. If you wish to make a breakpoint that won't be forgotten, you can write a *source breakpoint*, which is simply a call to the function `edebug` in your source code. You can, of course, make such a call conditional. For example, in the `fac` function, you can insert the first line as shown below, to stop when the argument reaches zero:

```
(defun fac (n)
  (if (= n 0) (edebug))
  (if (< 0 n)
      (* n (fac (1- n)))
      1))
```

When the `fac` definition is instrumented and the function is called, the call to `edebug` acts as a breakpoint. Depending on the execution mode, Edebug stops or pauses there.

If no instrumented code is being executed when `edebug` is called, that function calls `debug`.

19.2.7 Trapping Errors

Emacs normally displays an error message when an error is signaled and not handled with `condition-case`. While Edebug is active and executing instrumented code, it normally responds to all unhandled errors. You can customize this with the options `edebug-on-error` and `edebug-on-quit`; see Section 19.2.16 [Edebug Options], page 364.

When Edebug responds to an error, it shows the last stop point encountered before the error. This may be the location of a call to a function which was not instrumented, and within which the error actually occurred. For an unbound variable error, the last known stop point might be quite distant from the offending variable reference. In that case, you might want to display a full backtrace (see Section 19.2.5 [Edebug Misc], page 349).

If you change `debug-on-error` or `debug-on-quit` while Edebug is active, these changes will be forgotten when Edebug becomes inactive. Furthermore, during Edebug's recursive edit, these variables are bound to the values they had outside of Edebug.

19.2.8 Edebug Views

These Edebug commands let you view aspects of the buffer and window status as they were before entry to Edebug. The outside window configuration is the collection of windows and contents that were in effect outside of Edebug.

- P*
- v* Switch to viewing the outside window configuration (`edebug-view-outside`). Type `C-x X w` to return to Edebug.
- p* Temporarily display the outside current buffer with point at its outside position (`edebug-bounce-point`), pausing for one second before returning to Edebug. With a prefix argument *n*, pause for *n* seconds instead.
- w* Move point back to the current stop point in the source code buffer (`edebug-where`).
If you use this command in a different window displaying the same buffer, that window will be used instead to display the current definition in the future.
- W* Toggle whether Edebug saves and restores the outside window configuration (`edebug-toggle-save-windows`).
With a prefix argument, *W* only toggles saving and restoring of the selected window. To specify a window that is not displaying the source code buffer, you must use `C-x X W` from the global keymap.

You can view the outside window configuration with *v* or just bounce to the point in the current buffer with *p*, even if it is not normally displayed.

After moving point, you may wish to jump back to the stop point. You can do that with *w* from a source code buffer. You can jump back to the stop point in the source code buffer from any buffer using `C-x X w`.

Each time you use *W* to turn saving *off*, Edebug forgets the saved outside window configuration—so that even if you turn saving back *on*, the current window configuration remains unchanged when you next exit Edebug (by continuing the program). However, the automatic redisplay of `*edebug*` and `*edebug-trace*` may conflict with the buffers you wish to see unless you have enough windows open.

19.2.9 Evaluation

While within Edebug, you can evaluate expressions as if Edebug were not running. Edebug tries to be invisible to the expression's evaluation and printing. Evaluation of expressions that cause side effects will work as expected, except for changes to data that Edebug explicitly saves and restores. See Section 19.2.14 [The Outside Context], page 357, for details on this process.

- `e exp RET` Evaluate expression *exp* in the context outside of Edebug (`edebug-eval-expression`). That is, Edebug tries to minimize its interference with the

evaluation. The result is shown in the echo area, or, if this command is given a prefix, pop up a new buffer and pretty-print the result there.

By default, this command suppresses the debugger during evaluation, so that an error in the evaluated expression won't add a new error on top of the existing one. Set the `debug-allow-recursive-debug` user option to a non-`nil` value to override this.

M-: exp RET

Evaluate expression *exp* in the context of Edebug itself (`eval-expression`).

C-x C-e Evaluate the expression before point, in the context outside of Edebug (`edebug-eval-last-sexp`). With the prefix argument of zero (*C-u 0 C-x C-e*), don't shorten long items (like strings and lists). Any other prefix will result in the value being pretty-printed in a separate buffer.

Edebug supports evaluation of expressions containing references to lexically bound symbols created by the following constructs in `cl.el`: `lexical-let`, `macrolet`, and `symbol-macrolet`.

19.2.10 Evaluation List Buffer

You can use the *evaluation list buffer*, called `*edebug*`, to evaluate expressions interactively. You can also set up the *evaluation list* of expressions to be evaluated automatically each time Edebug updates the display.

E Switch to the evaluation list buffer `*edebug*` (`edebug-visit-eval-list`).

In the `*edebug*` buffer you can use the commands of Lisp Interaction mode (see Section “Lisp Interaction” in *The GNU Emacs Manual*) as well as these special commands:

C-j Evaluate the expression before point, in the outside context, and insert the value in the buffer (`edebug-eval-print-last-sexp`). With prefix argument of zero (*C-u 0 C-j*), don't shorten long items (like strings and lists).

C-x C-e Evaluate the expression before point, in the context outside of Edebug (`edebug-eval-last-sexp`).

C-c C-u Build a new evaluation list from the contents of the buffer (`edebug-update-eval-list`).

C-c C-d Delete the evaluation list group that point is in (`edebug-delete-eval-item`).

C-c C-w Switch back to the source code buffer at the current stop point (`edebug-where`).

You can evaluate expressions in the evaluation list window with *C-j* or *C-x C-e*, just as you would in `*scratch*`; but they are evaluated in the context outside of Edebug.

The expressions you enter interactively (and their results) are lost when you continue execution; but you can set up an *evaluation list* consisting of expressions to be evaluated each time execution stops.

To do this, write one or more *evaluation list groups* in the evaluation list buffer. An evaluation list group consists of one or more Lisp expressions. Groups are separated by comment lines.

The command **C-c C-u (edebug-update-eval-list)** rebuilds the evaluation list, scanning the buffer and using the first expression of each group. (The idea is that the second expression of the group is the value previously computed and displayed.)

Each entry to Edebug redisplays the evaluation list by inserting each expression in the buffer, followed by its current value. It also inserts comment lines so that each expression becomes its own group. Thus, if you type **C-c C-u** again without changing the buffer text, the evaluation list is effectively unchanged.

If an error occurs during an evaluation from the evaluation list, the error message is displayed in a string as if it were the result. Therefore, expressions using variables that are not currently valid do not interrupt your debugging.

Here is an example of what the evaluation list window looks like after several expressions have been added to it:

```
(current-buffer)
#<buffer *scratch*>
;-----
(selected-window)
#<window 16 on *scratch*>
;-----
(point)
196
;-----
bad-var
"Symbol's value as variable is void: bad-var"
;-----
(recursion-depth)
0
;-----
(this-command
eval-last-sexp
;-----
```

To delete a group, move point into it and type **C-c C-d**, or simply delete the text for the group and update the evaluation list with **C-c C-u**. To add a new expression to the evaluation list, insert the expression at a suitable place, insert a new comment line, then type **C-c C-u**. You need not insert dashes in the comment line—its contents don't matter.

After selecting ***edebug***, you can return to the source code buffer with **C-c C-w**. The ***edebug*** buffer is killed when you continue execution, and recreated next time it is needed.

19.2.11 Printing in Edebug

If an expression in your program produces a value containing circular list structure, you may get an error when Edebug attempts to print it.

One way to cope with circular structure is to set `print-length` or `print-level` to truncate the printing. Edebug does this for you; it binds `print-length` and `print-level` to the values of the variables `edebug-print-length` and `edebug-print-level` (so long as they have non-`nil` values). See Section 20.6 [Output Variables], page 380.

edebug-print-length [User Option]

If non-`nil`, Edebug binds `print-length` to this value while printing results. The default value is 50.

edebug-print-level [User Option]

If non-nil, Edebug binds `print-level` to this value while printing results. The default value is 50.

You can also print circular structures and structures that share elements more informatively by binding `print-circle` to a non-nil value.

Here is an example of code that creates a circular structure:

```
(setq a (list 'x 'y))
      (setcar a a)
```

If `print-circle` is non-nil, printing functions (e.g., `prin1`) will print `a` as ‘#1=(#1# y)’. The ‘#1=’ notation labels the structure that follows it with the label ‘1’, and the ‘#1#’ notation references the previously labeled structure. This notation is used for any shared elements of lists or vectors.

edebug-print-circle [User Option]

If non-nil, Edebug binds `print-circle` to this value while printing results. The default value is t.

For further details about how printing can be customized, see Section 20.5 [Output Functions], page 377.

19.2.12 Trace Buffer

Edebug can record an execution trace, storing it in a buffer named `*edebug-trace*`. This is a log of function calls and returns, showing the function names and their arguments and values. To enable trace recording, set `edebug-trace` to a non-nil value.

Making a trace buffer is not the same thing as using trace execution mode (see Section 19.2.3 [Edebug Execution Modes], page 347).

When trace recording is enabled, each function entry and exit adds lines to the trace buffer. A function entry record consists of ‘:::::{’, followed by the function name and argument values. A function exit record consists of ‘:::}:’, followed by the function name and result of the function.

The number of ‘::’s in an entry shows its recursion depth. You can use the braces in the trace buffer to find the matching beginning or end of function calls.

You can customize trace recording for function entry and exit by redefining the functions `edebug-print-trace-before` and `edebug-print-trace-after`.

edebug-tracing *string* *body*... [Macro]

This macro requests additional trace information around the execution of the *body* forms. The argument *string* specifies text to put in the trace buffer, after the ‘{’ or ‘}’. All the arguments are evaluated, and `edebug-tracing` returns the value of the last form in *body*.

edebug-trace *format-string* &rest *format-args* [Function]

This function inserts text in the trace buffer. It computes the text with (`apply 'format format-string format-args`). It also appends a newline to separate entries.

`edebug-tracing` and `edebug-trace` insert lines in the trace buffer whenever they are called, even if Edebug is not active. Adding text to the trace buffer also scrolls its window to show the last lines inserted.

19.2.13 Coverage Testing

Edebug provides rudimentary coverage testing and display of execution frequency.

Coverage testing works by comparing the result of each expression with the previous result; each form in the program is considered covered if it has returned two different values since you began testing coverage in the current Emacs session. Thus, to do coverage testing on your program, execute it under various conditions and note whether it behaves correctly; Edebug will tell you when you have tried enough different conditions that each form has returned two different values.

Coverage testing makes execution slower, so it is only done if `edebug-test-coverage` is non-`nil`. Frequency counting is performed for all executions of an instrumented function, even if the execution mode is Go-nonstop, and regardless of whether coverage testing is enabled.

Use `C-x X = (edebug-display-freq-count)` to display both the coverage information and the frequency counts for a definition. Just `= (edebug-temp-display-freq-count)` displays the same information temporarily, only until you type another key.

`edebug-display-freq-count`

[Command]

This command displays the frequency count data for each line of the current definition.

It inserts frequency counts as comment lines after each line of code. You can undo all insertions with one `undo` command. The counts appear under the ‘(’ before an expression or the ‘)’ after an expression, or on the last character of a variable. To simplify the display, a count is not shown if it is equal to the count of an earlier expression on the same line.

The character ‘=’ following the count for an expression says that the expression has returned the same value each time it was evaluated. In other words, it is not yet covered for coverage testing purposes.

To clear the frequency count and coverage data for a definition, simply reinstrument it with `eval-defun`.

For example, after evaluating `(fac 5)` with a source breakpoint, and setting `edebug-test-coverage` to `t`, when the breakpoint is reached, the frequency data looks like this:

```
(defun fac (n)
  (if (= n 0) (edebug))
;#6           1      =  =5
  (if (< 0 n)
;#5           =
    (* n (fac (1- n)))
;#   5           0
  1))
;#   0
```

The comment lines show that `fac` was called 6 times. The first `if` statement returned 5 times with the same result each time; the same is true of the condition on the second `if`. The recursive call of `fac` did not return at all.

19.2.14 The Outside Context

Edebug tries to be transparent to the program you are debugging, but it does not succeed completely. Edebug also tries to be transparent when you evaluate expressions with `e` or with the evaluation list buffer, by temporarily restoring the outside context. This section explains precisely what context Edebug restores, and how Edebug fails to be completely transparent.

19.2.14.1 Checking Whether to Stop

Whenever Edebug is entered, it needs to save and restore certain data before even deciding whether to make trace information or stop the program.

- `max-lisp-eval-depth` (see Section 10.4 [Eval], page 152) is increased to reduce Edebug’s impact on the stack. You could, however, still run out of stack space when using Edebug. You can also enlarge the value of `edebug-max-depth` if Edebug reaches the limit of recursion depth instrumenting code that contains very large quoted lists.
- The state of keyboard macro execution is saved and restored. While Edebug is active, `executing-kbd-macro` is bound to `nil` unless `edebug-continue-kbd-macro` is non-`nil`.

19.2.14.2 Edebug Display Update

When Edebug needs to display something (e.g., in trace mode), it saves the current window configuration from outside Edebug (see Section 29.26 [Window Configurations], page 774). When you exit Edebug, it restores the previous window configuration.

Emacs redisplay only when it pauses. Usually, when you continue execution, the program re-enters Edebug at a breakpoint or after stepping, without pausing or reading input in between. In such cases, Emacs never gets a chance to redisplay the outside configuration. Consequently, what you see is the same window configuration as the last time Edebug was active, with no interruption.

Entry to Edebug for displaying something also saves and restores the following data (though some of them are deliberately not restored if an error or quit signal occurs).

- Which buffer is current, and the positions of point and the mark in the current buffer, are saved and restored.
- The outside window configuration is saved and restored if `edebug-save-windows` is non-`nil` (see Section 19.2.16 [Edebug Options], page 364). If the value of `edebug-save-windows` is a list, only the listed windows are saved and restored.

The window configuration is not restored on error or quit, but the outside selected window *is* reselected even on error or quit in case a `save-excursion` is active.

The window start and horizontal scrolling of the source code buffer are not restored, however, so that the display remains coherent within Edebug.

Saving and restoring the outside window configuration can sometimes change the positions of point in the buffers on which the Lisp program you are debugging operates, especially if your program moves point. If this happens and interferes with your debugging, we recommend to set `edebug-save-windows` to `nil` (see Section 19.2.16 [Edebug Options], page 364).

- The value of point in each displayed buffer is saved and restored if `edebug-save-displayed-buffer-points` is non-`nil`.

- The variables `overlay-arrow-position` and `overlay-arrow-string` are saved and restored, so you can safely invoke Edebug from the recursive edit elsewhere in the same buffer.
- `cursor-in-echo-area` is locally bound to `nil` so that the cursor shows up in the window.

19.2.14.3 Edebug Recursive Edit

When Edebug is entered and actually reads commands from the user, it saves (and later restores) these additional data:

- The current match data. See Section 35.6 [Match Data], page 1011.
- The variables `last-command`, `this-command`, `last-command-event`, `last-input-event`, `last-event-frame`, `last-nonmenu-event`, and `track-mouse`. Commands in Edebug do not affect these variables outside of Edebug.

Executing commands within Edebug can change the key sequence that would be returned by `this-command-keys`, and there is no way to reset the key sequence from Lisp.

Edebug cannot save and restore the value of `unread-command-events`. Entering Edebug while this variable has a nontrivial value can interfere with execution of the program you are debugging.

- Complex commands executed while in Edebug are added to the variable `command-history`. In rare cases this can alter execution.
- Within Edebug, the recursion depth appears one deeper than the recursion depth outside Edebug. This is not true of the automatically updated evaluation list window.
- `standard-output` and `standard-input` are bound to `nil` by the `recursive-edit`, but Edebug temporarily restores them during evaluations.
- The state of keyboard macro definition is saved and restored. While Edebug is active, `defining-kbd-macro` is bound to `edbug-continue-kbd-macro`.

19.2.15 Edebug and Macros

To make Edebug properly instrument expressions that call macros, some extra care is needed. This subsection explains the details.

19.2.15.1 Instrumenting Macro Calls

When Edebug instruments an expression that calls a Lisp macro, it needs additional information about the macro to do the job properly. This is because there is no a-priori way to tell which subexpressions of the macro call are forms to be evaluated. (Evaluation may occur explicitly in the macro body, or when the resulting expansion is evaluated, or any time later.)

Therefore, you must define an Edebug specification for each macro that Edebug will encounter, to explain the format of calls to that macro. To do this, add a `debug` declaration to the macro definition. Here is a simple example that shows the specification for the `for` example macro (see Section 14.5.2 [Argument Evaluation], page 271).

```
(defmacro for (var from init to final do &rest body)
  "Execute a simple \"for\" loop.
  For example, (for i from 1 to 10 do (print i))."
  (declare (debug (symbolp "from" form "to" form "do" &rest form)))
```

...)

The Edebug specification says which parts of a call to the macro are forms to be evaluated. For simple macros, the specification often looks very similar to the formal argument list of the macro definition, but specifications are much more general than macro arguments. See Section 14.4 [Defining Macros], page 270, for more explanation of the `declare` form.

Take care to ensure that the specifications are known to Edebug when you instrument code. If you are instrumenting a function which uses a macro defined in another file, you may first need to either evaluate the `require` forms in the file containing your function, or explicitly load the file containing the macro. If the definition of a macro is wrapped by `eval-when-compile`, you may need to evaluate it.

You can also define an edebug specification for a macro separately from the macro definition with `def-edebug-spec`. Adding `debug` declarations is preferred, and more convenient, for macro definitions in Lisp, but `def-edebug-spec` makes it possible to define Edebug specifications for special forms implemented in C.

def-edebug-spec *macro specification* [Macro]

Specify which expressions of a call to macro *macro* are forms to be evaluated. *specification* should be the Edebug specification. Neither argument is evaluated.

The *macro* argument can actually be any symbol, not just a macro name.

Here is a table of the possibilities for *specification* and how each directs processing of arguments.

<i>t</i>	All arguments are instrumented for evaluation. This is short for <code>(body)</code> .
a symbol	The symbol must have an Edebug specification, which is used instead. This indirection is repeated until another kind of specification is found. This allows you to inherit the specification from another macro.
a list	The elements of the list describe the types of the arguments of a calling form. The possible elements of a specification list are described in the following sections.

If a macro has no Edebug specification, neither through a `debug` declaration nor through a `def-edebug-spec` call, the variable `edebug-eval-macro-args` comes into play.

edebug-eval-macro-args [User Option]

This controls the way Edebug treats macro arguments with no explicit Edebug specification. If it is `nil` (the default), none of the arguments is instrumented for evaluation. Otherwise, all arguments are instrumented.

19.2.15.2 Specification List

A *specification list* is required for an Edebug specification if some arguments of a macro call are evaluated while others are not. Some elements in a specification list match one or more arguments, but others modify the processing of all following elements. The latter, called *specification keywords*, are symbols beginning with ‘&’ (such as `&optional`).

A specification list may contain sublists, which match arguments that are themselves lists, or it may contain vectors used for grouping. Sublists and groups thus subdivide the specification list into a hierarchy of levels. Specification keywords apply only to the remainder of the sublist or group they are contained in.

When a specification list involves alternatives or repetition, matching it against an actual macro call may require backtracking. For more details, see Section 19.2.15.3 [Backtracking], page 363.

Edebug specifications provide the power of regular expression matching, plus some context-free grammar constructs: the matching of sublists with balanced parentheses, recursive processing of forms, and recursion via indirect specifications.

Here's a table of the possible elements of a specification list, with their meanings (see Section 19.2.15.4 [Specification Examples], page 363, for the referenced examples):

sexp	A single unevaluated Lisp object, which is not instrumented.
form	A single evaluated expression, which is instrumented. If your macro wraps the expression with <code>lambda</code> before it is evaluated, use <code>def-form</code> instead. See <code>def-form</code> below.
place	A generalized variable. See Section 12.17 [Generalized Variables], page 224.
body	Short for <code>&rest form</code> . See <code>&rest</code> below. If your macro wraps its body of code with <code>lambda</code> before it is evaluated, use <code>def-body</code> instead. See <code>def-body</code> below.
lambda-expr	A lambda expression with no quoting.
&optional	All following elements in the specification list are optional; as soon as one does not match, Edebug stops matching at this level. To make just a few elements optional, followed by non-optional elements, use <code>[&optional specs...]</code> . To specify that several elements must all match or none, use <code>&optional [specs...]</code> . See the <code>defun</code> example.
&rest	All following elements in the specification list are repeated zero or more times. In the last repetition, however, it is not a problem if the expression runs out before matching all of the elements of the specification list. To repeat only a few elements, use <code>[&rest specs...]</code> . To specify several elements that must all match on every repetition, use <code>&rest [specs...]</code> .
&or	Each of the following elements in the specification list is an alternative. One of the alternatives must match, or the <code>&or</code> specification fails. Each list element following <code>&or</code> is a single alternative. To group two or more list elements as a single alternative, enclose them in <code>[...]</code> .
&not	Each of the following elements is matched as alternatives as if by using <code>&or</code> , but if any of them match, the specification fails. If none of them match, nothing is matched, but the <code>&not</code> specification succeeds.
&define	Indicates that the specification is for a defining form. Edebug's definition of a defining form is a form containing one or more code forms which are saved and executed later, after the execution of the defining form. The defining form itself is not instrumented (that is, Edebug does not stop before and after the defining form), but forms inside it typically will be instrumented. The <code>&define</code> keyword should be the first element in a list specification.

nil This is successful when there are no more arguments to match at the current argument list level; otherwise it fails. See sublist specifications and the backquote example.

gate No argument is matched but backtracking through the gate is disabled while matching the remainder of the specifications at this level. This is primarily used to generate more specific syntax error messages. See Section 19.2.15.3 [Backtracking], page 363, for more details. Also see the `let` example.

&error `&error` should be followed by a string, an error message, in the edebug-spec; it aborts the instrumentation, displaying the message in the minibuffer.

&interpose

Lets a function control the parsing of the remaining code. It takes the form `&interpose spec fun args...` and means that Edebug will first match `spec` against the code and then call `fun` with the code that matched `spec`, a parsing function `pf`, and finally `args....`. The parsing function expects a single argument indicating the specification list to use to parse the remaining code. It should be called exactly once and returns the instrumented code that `fun` is expected to return. For example `(&interpose symbolp pcase--match-pat-args)` matches sexps whose first element is a symbol and then lets `pcase--match-pat-args` lookup the specs associated with that head symbol according to `pcase--match-pat-args` and pass them to the `pf` it received as argument.

other-symbol

Any other symbol in a specification list may be a predicate or an indirect specification.

If the symbol has an Edebug specification, this *indirect specification* should be either a list specification that is used in place of the symbol, or a function that is called to process the arguments. The specification may be defined with `def-edebug-elem-spec`:

def-edebug-elem-spec *element specification* [Function]

Define the *specification* to use in place of the symbol *element*. *specification* has to be a list.

Otherwise, the symbol should be a predicate. The predicate is called with the argument, and if the predicate returns `nil`, the specification fails and the argument is not instrumented.

Some suitable predicates include `symbolp`, `integerp`, `stringp`, `vectorp`, and `atom`.

[elements...]

A vector of elements groups the elements into a single *group specification*. Its meaning has nothing to do with vectors.

"string" The argument should be a symbol named `string`. This specification is equivalent to the quoted symbol, '`symbol`', where the name of `symbol` is the `string`, but the string form is preferred.

(vector elements...)

The argument should be a vector whose elements must match the *elements* in the specification. See the backquote example.

(elements...)

Any other list is a *sublist specification* and the argument must be a list whose elements match the specification *elements*.

A sublist specification may be a dotted list and the corresponding list argument may then be a dotted list. Alternatively, the last CDR of a dotted list specification may be another sublist specification (via a grouping or an indirect specification, e.g., `(spec . [(more specs...)])`) whose elements match the non-dotted list arguments. This is useful in recursive specifications such as in the backquote example. Also see the description of a `nil` specification above for terminating such recursion.

Note that a sublist specification written as `(specs . nil)` is equivalent to `(specs)`, and `(specs . (sublist-elements...))` is equivalent to `(specs sublist-elements...)`.

Here is a list of additional specifications that may appear only after `&define`. See the `defun` example.

&name Extracts the name of the current defining form from the code. It takes the form `&name [prestring] spec [poststring] fun args...` and means that Edebug will match `spec` against the code and then call `fun` with the concatenation of the current name, `args...`, `prestring`, the code that matched `spec`, and `poststring`. If `fun` is absent, it defaults to a function that concatenates the arguments (with an `@` between the previous name and the new).

name The argument, a symbol, is the name of the defining form. Shorthand for `[&name symbolp]`.

A defining form is not required to have a name field; and it may have multiple name fields.

arg The argument, a symbol, is the name of an argument of the defining form. However, lambda-list keywords (symbols starting with ‘`&`’) are not allowed.

lambda-list

This matches a lambda list—the argument list of a lambda expression.

def-body The argument is the body of code in a definition. This is like `body`, described above, but a definition body must be instrumented with a different Edebug call that looks up information associated with the definition. Use `def-body` for the highest level list of forms within the definition.

def-form The argument is a single, highest-level form in a definition. This is like `def-body`, except it is used to match a single form rather than a list of forms. As a special case, `def-form` also means that tracing information is not output when the form is executed. See the `interactive` example.

19.2.15.3 Backtracking in Specifications

If a specification fails to match at some point, this does not necessarily mean a syntax error will be signaled; instead, *backtracking* will take place until all alternatives have been exhausted. Eventually every element of the argument list must be matched by some element in the specification, and every required element in the specification must match some argument.

When a syntax error is detected, it might not be reported until much later, after higher-level alternatives have been exhausted, and with the point positioned further from the real error. But if backtracking is disabled when an error occurs, it can be reported immediately. Note that backtracking is also reenabled automatically in several situations; when a new alternative is established by `&optional`, `&rest`, or `&or`, or at the start of processing a sublist, group, or indirect specification. The effect of enabling or disabling backtracking is limited to the remainder of the level currently being processed and lower levels.

Backtracking is disabled while matching any of the form specifications (that is, `form`, `body`, `def-form`, and `def-body`). These specifications will match any form so any error must be in the form itself rather than at a higher level.

Backtracking is also disabled after successfully matching a quoted symbol, string specification, or `&define` keyword, since this usually indicates a recognized construct. But if you have a set of alternative constructs that all begin with the same symbol, you can usually work around this constraint by factoring the symbol out of the alternatives, e.g., `["foo" &or [first case] [second case] ...]`.

Most needs are satisfied by these two ways that backtracking is automatically disabled, but occasionally it is useful to explicitly disable backtracking by using the `gate` specification. This is useful when you know that no higher alternatives could apply. See the example of the `let` specification.

19.2.15.4 Specification Examples

It may be easier to understand Edebug specifications by studying the examples provided here.

Consider a hypothetical macro `my-test-generator` that runs tests on supplied lists of data. Although it is Edebug’s default behavior to not instrument arguments as code, as controlled by `edebug-eval-macro-args` (see Section 19.2.15.1 [Instrumenting Macro Calls], page 358), it can be useful to explicitly document that the arguments are data:

```
(def-edebug-spec my-test-generator (&rest sexp))
```

A `let` special form has a sequence of bindings and a body. Each of the bindings is either a symbol or a sublist with a symbol and optional expression. In the specification below, notice the `gate` inside of the sublist to prevent backtracking once a sublist is found.

```
(def-edebug-spec let
  ((&rest
    &or symbolp (gate symbolp &optional form))
   body))
```

Edebug uses the following specifications for `defun` and the associated argument list and `interactive` specifications. It is necessary to handle interactive forms specially since an

expression argument is actually evaluated outside of the function body. (The specification for `defmacro` is very similar to that for `defun`, but allows for the `declare` statement.)

```
(def-edebug-spec defun
  (&define name lambda-list
    [&optional stringp] ; Match the doc string, if present.
    [&optional ("interactive" interactive)]
    def-body))

(def-edebug-elem-spec 'lambda-list
  '(([&rest arg]
     [&optional [&optional arg &rest arg]]
     &optional [&rest arg]
     )))

(def-edebug-elem-spec 'interactive
  '(&optional &or stringp def-form)) ; Notice: def-form
```

The specification for backquote below illustrates how to match dotted lists and use `nil` to terminate recursion. It also illustrates how components of a vector may be matched. (The actual specification defined by Edebug is a little different, and does not support dotted lists because doing so causes very deep recursion that could fail.)

```
(def-edebug-spec ` (backquote-form)) ; Alias just for clarity.

(def-edebug-elem-spec 'backquote-form
  '(&or ([&or ", ", @] &or ("quote" backquote-form) form)
        (backquote-form . [&or nil backquote-form])
        (vector &rest backquote-form)
        sexp))
```

19.2.16 Edebug Options

These options affect the behavior of Edebug:

`edebug-setup-hook` [User Option]

Functions to call before Edebug is used. Each time it is set to a new value, Edebug will call those functions once and then reset `edebug-setup-hook` to `nil`. You could use this to load up Edebug specifications associated with a package you are using, but only when you also use Edebug. See Section 19.2.2 [Instrumenting], page 346.

`edebug-all-defs` [User Option]

If this is non-`nil`, normal evaluation of defining forms such as `defun` and `defmacro` instruments them for Edebug. This applies to `eval-defun`, `eval-region` and `eval-buffer`.

Use the command `M-x edebug-all-defs` to toggle the value of this option. See Section 19.2.2 [Instrumenting], page 346.

`edebug-all-forms` [User Option]

If this is non-`nil`, the commands `eval-defun`, `eval-region` and `eval-buffer` instrument all forms, even those that don't define anything. This doesn't apply to loading or evaluations in the minibuffer.

Use the command `M-x edebug-all-forms` to toggle the value of this option. See Section 19.2.2 [Instrumenting], page 346.

edebug-eval-macro-args

[User Option]

When this is non-*nil*, all macro arguments will be instrumented in the generated code. For any macro, the `debug` declaration overrides this option. So to specify exceptions for macros that have some arguments evaluated and some not, use the `debug` declaration specify an Edebug form specification.

edebug-save-windows

[User Option]

If this is non-*nil*, Edebug saves and restores the window configuration. That takes some time, so if your program does not care what happens to the window configurations, it is better to set this variable to *nil*. We also recommend to set this to *nil* if the default value causes Edebug to overwrite the positions of point in buffers that are involved in the program you are debugging, as result of saving and restoring the window configuration; this could happen if your program moves point in one or more of those buffers. Another option to try to customize in this case is `edebug-save-displayed-buffer-points`, described below.

If the value of `edebug-save-windows` is a list, only the listed windows are saved and restored.

You can use the `W` command in Edebug to change this variable interactively. See Section 19.2.14.2 [Edebug Display Update], page 357.

edebug-save-displayed-buffer-points

[User Option]

If this is non-*nil*, Edebug saves and restores point in all displayed buffers.

Saving and restoring point in other buffers is necessary if you are debugging code that changes the point of a buffer that is displayed in a non-selected window. If Edebug or the user then selects the window, point in that buffer will move to the window's value of point.

Saving and restoring point in all buffers is expensive, since it requires selecting each window twice, so enable this only if you need it. See Section 19.2.14.2 [Edebug Display Update], page 357.

edebug-initial-mode

[User Option]

If this variable is non-*nil*, it specifies the initial execution mode for Edebug when it is first activated. Possible values are `step`, `next`, `go`, `Go-nonstop`, `trace`, `Trace-fast`, `continue`, and `Continue-fast`.

The default value is `step`. This variable can be set interactively with `C-x C-a C-m` (`edebug-set-initial-mode`). See Section 19.2.3 [Edebug Execution Modes], page 347.

edebug-trace

[User Option]

If this is non-*nil*, trace each function entry and exit. Tracing output is displayed in a buffer named `*edebug-trace*`, one function entry or exit per line, indented by the recursion level.

Also see `edebug-tracing`, in Section 19.2.12 [Trace Buffer], page 355.

edebug-test-coverage

[User Option]

If non-*nil*, Edebug tests coverage of all expressions debugged. See Section 19.2.13 [Coverage Testing], page 356.

edebug-continue-kbd-macro [User Option]

If non-*nil*, continue defining or executing any keyboard macro that is executing outside of Edebug. Use this with caution since it is not debugged. See Section 19.2.3 [Edebug Execution Modes], page 347.

edebug-print-length [User Option]

If non-*nil*, the default value of `print-length` for printing results in Edebug. See Section 20.6 [Output Variables], page 380.

edebug-print-level [User Option]

If non-*nil*, the default value of `print-level` for printing results in Edebug. See Section 20.6 [Output Variables], page 380.

edebug-print-circle [User Option]

If non-*nil*, the default value of `print-circle` for printing results in Edebug. See Section 20.6 [Output Variables], page 380.

edebug-unwrap-results [User Option]

If non-*nil*, Edebug tries to remove any of its own instrumentation when showing the results of expressions. This is relevant when debugging macros where the results of expressions are themselves instrumented expressions. As a very artificial example, suppose that the example function `fac` has been instrumented, and consider a macro of the form:

```
(defmacro test () "Edebug example."
  (if (symbol-function 'fac)
    ...))
```

If you instrument the `test` macro and step through it, then by default the result of the `symbol-function` call has numerous `edebug-after` and `edebug-before` forms, which can make it difficult to see the actual result. If `edebug-unwrap-results` is non-*nil*, Edebug tries to remove these forms from the result.

edebug-on-error [User Option]

Edebug binds `debug-on-error` to this value, if `debug-on-error` was previously *nil*. See Section 19.2.7 [Trapping Errors], page 351.

edebug-on-quit [User Option]

Edebug binds `debug-on-quit` to this value, if `debug-on-quit` was previously *nil*. See Section 19.2.7 [Trapping Errors], page 351.

If you change the values of `edebug-on-error` or `edebug-on-quit` while Edebug is active, their values won't be used until the *next* time Edebug is invoked via a new command.

edebug-global-break-condition [User Option]

If non-*nil*, an expression to test for at every stop point. If the result is non-*nil*, then break. Errors are ignored. See Section 19.2.6.2 [Global Break Condition], page 351.

edebug-sit-for-seconds [User Option]

Number of seconds to pause when a breakpoint is reached and the execution mode is trace or continue. See Section 19.2.3 [Edebug Execution Modes], page 347.

edebug-sit-on-break [User Option]

Whether or not to pause for `edebug-sit-for-seconds` on reaching a breakpoint. Set to `nil` to prevent the pause, non-`nil` to allow it.

edebug-behavior-alist [User Option]

By default, this alist contains one entry with the key `edebug` and a list of three functions, which are the default implementations of the functions inserted in instrumented code: `edebug-enter`, `edebug-before` and `edebug-after`. To change Edebug's behavior globally, modify the default entry.

Edebug's behavior may also be changed on a per-definition basis by adding an entry to this alist, with a key of your choice and three functions. Then set the `edebug-behavior` symbol property of an instrumented definition to the key of the new entry, and Edebug will call the new functions in place of its own for that definition.

edebug-new-definition-function [User Option]

A function run by Edebug after it wraps the body of a definition or closure. After Edebug has initialized its own data, this function is called with one argument, the symbol associated with the definition, which may be the actual symbol defined or one generated by Edebug. This function may be used to set the `edebug-behavior` symbol property of each definition instrumented by Edebug.

edebug-after-instrumentation-function [User Option]

To inspect or modify Edebug's instrumentation before it is used, set this variable to a function which takes one argument, an instrumented top-level form, and returns either the same or a replacement form, which Edebug will then use as the final result of instrumentation.

19.3 Debugging Invalid Lisp Syntax

The Lisp reader reports invalid syntax, but cannot say where the real problem is. For example, the error ‘End of file during parsing’ in evaluating an expression indicates an excess of open parentheses (or square brackets). The reader detects this imbalance at the end of the file, but it cannot figure out where the close parenthesis should have been. Likewise, ‘Invalid read syntax: “)”’ indicates an excess close parenthesis or missing open parenthesis, but does not say where the missing parenthesis belongs. How, then, to find what to change?

If the problem is not simply an imbalance of parentheses, a useful technique is to try `C-M-e` (`end-of-defun`, see Section “Moving by Defuns” in *The GNU Emacs Manual*) at the beginning of each defun, and see if it goes to the place where that defun appears to end. If it does not, there is a problem in that defun.

However, unmatched parentheses are the most common syntax errors in Lisp, and we can give further advice for those cases. (In addition, just moving point through the code with Show Paren mode enabled might find the mismatch.)

19.3.1 Excess Open Parentheses

The first step is to find the defun that is unbalanced. If there is an excess open parenthesis, the way to do this is to go to the end of the file and type `C-u C-M-u` (`backward-up-list`,

see Section “Moving by Parens” in *The GNU Emacs Manual*). This will move you to the beginning of the first defun that is unbalanced.

The next step is to determine precisely what is wrong. There is no way to be sure of this except by studying the program, but often the existing indentation is a clue to where the parentheses should have been. The easiest way to use this clue is to reindent with *C-M-q* (*indent-pp-sexp*, see Section “Multi-line Indent” in *The GNU Emacs Manual*) and see what moves. **But don’t do this yet!** Keep reading, first.

Before you do this, make sure the defun has enough close parentheses. Otherwise, *C-M-q* will get an error, or will reindent all the rest of the file until the end. So move to the end of the defun and insert a close parenthesis there. Don’t use *C-M-e* (*end-of-defun*) to move there, since that too will fail to work until the defun is balanced.

Now you can go to the beginning of the defun and type *C-M-q*. Usually all the lines from a certain point to the end of the function will shift to the right. There is probably a missing close parenthesis, or a superfluous open parenthesis, near that point. (However, don’t assume this is true; study the code to make sure.) Once you have found the discrepancy, undo the *C-M-q* with *C-_* (*undo*), since the old indentation is probably appropriate to the intended parentheses.

After you think you have fixed the problem, use *C-M-q* again. If the old indentation actually fit the intended nesting of parentheses, and you have put back those parentheses, *C-M-q* should not change anything.

19.3.2 Excess Close Parentheses

To deal with an excess close parenthesis, first go to the beginning of the file, then type *C-u -1 C-M-u* (*backward-up-list* with an argument of -1) to find the end of the first unbalanced defun.

Then find the actual matching close parenthesis by typing *C-M-f* (*forward-sexp*, see Section “Expressions” in *The GNU Emacs Manual*) at the beginning of that defun. This will leave you somewhere short of the place where the defun ought to end. It is possible that you will find a spurious close parenthesis in that vicinity.

If you don’t see a problem at that point, the next thing to do is to type *C-M-q* (*indent-pp-sexp*) at the beginning of the defun. A range of lines will probably shift left; if so, the missing open parenthesis or spurious close parenthesis is probably near the first of those lines. (However, don’t assume this is true; study the code to make sure.) Once you have found the discrepancy, undo the *C-M-q* with *C-_* (*undo*), since the old indentation is probably appropriate to the intended parentheses.

After you think you have fixed the problem, use *C-M-q* again. If the old indentation actually fits the intended nesting of parentheses, and you have put back those parentheses, *C-M-q* should not change anything.

19.4 Test Coverage

You can do coverage testing for a file of Lisp code by loading the `testcover` library and using the command *M-x testcover-start RET file RET* to instrument the code. Then test your code by calling it one or more times. Then use the command *M-x testcover-mark-all* to display colored highlights on the code to show where coverage is insufficient. The command *M-x testcover-next-mark* will move point forward to the next highlighted spot.

Normally, a red highlight indicates the form was never completely evaluated; a brown highlight means it always evaluated to the same value (meaning there has been little testing of what is done with the result). However, the red highlight is skipped for forms that can't possibly complete their evaluation, such as `error`. The brown highlight is skipped for forms that are expected to always evaluate to the same value, such as `(setq x 14)`.

For difficult cases, you can add do-nothing macros to your code to give advice to the test coverage tool.

`1value form` [Macro]

Evaluate *form* and return its value, but inform coverage testing that *form*'s value should always be the same.

`noreturn form` [Macro]

Evaluate *form*, informing coverage testing that *form* should never return. If it ever does return, you get a run-time error.

Edebug also has a coverage testing feature (see Section 19.2.13 [Coverage Testing], page 356). These features partly duplicate each other, and it would be cleaner to combine them.

19.5 Profiling

If your program is working correctly, but not fast enough, and you want to make it run more quickly or efficiently, the first thing to do is *profile* your code so that you know where it spends most of the execution time. If you find that one particular function is responsible for a significant portion of the execution time, you can start looking for ways to optimize that piece.

Emacs has built-in support for this. To begin profiling, type `M-x profiler-start`. You can choose to sample CPU usage periodically (`cpu`), when memory is allocated (`memory`), or both. Then run the code you'd like to speed up. After that, type `M-x profiler-report` to display a summary buffer for CPU usage sampled by each type (`cpu` and `memory`) that you chose to profile. The names of the report buffers include the times at which the reports were generated, so you can generate another report later on without erasing previous results. When you have finished profiling, type `M-x profiler-stop` (there is a small overhead associated with profiling, so we don't recommend leaving it active except when you are actually running the code you want to examine).

The profiler report buffer shows, on each line, a function that was called, preceded by how much CPU resources it used in absolute and percentage terms since profiling started. If a given line has a '+' symbol to the left of the function name, you can expand that line by typing `RET`, in order to see the function(s) called by the higher-level function. Use a prefix argument (`C-u RET`) to see the whole call tree below a function. Pressing `RET` again will collapse back to the original state.

Press `j` (`profiler-report-find-entry`) or `mouse-2` to jump to the definition of a function at point. Press `d` (`profiler-report-describe-entry`) to view a function's documentation. You can save a profile to a file using `C-x C-w` (`profiler-report-write-profile`) and read a saved profile with `M-x profiler-find-profile` or `M-x profiler-find-profile-other-window`. You can compare two profiles using `=` (`profiler-report-compare-profile`).

The `elp` library offers an alternative approach, which is useful when you know in advance which Lisp function(s) you want to profile. Using that library, you begin by setting `elp-function-list` to the list of function symbols—those are the functions you want to profile. Then type `M-x elp-instrument-list RET nil RET` to arrange for profiling those functions. After running the code you want to profile, invoke `M-x elp-results` to display the current results. See the file `elp.el` for more detailed instructions. This approach is limited to profiling functions written in Lisp, it cannot profile Emacs primitives.

You can measure the time it takes to evaluate individual Emacs Lisp forms using the `benchmark` library. See the function `benchmark-call` as well as the macros `benchmark-run`, `benchmark-run-compiled`, and `benchmark-progn` in `benchmark.el`. You can also use the `benchmark` command for timing forms interactively.

20 Reading and Printing Lisp Objects

Printing and *reading* are the operations of converting Lisp objects to textual form and vice versa. They use the printed representations and read syntax described in Chapter 2 [Lisp Data Types], page 8.

This chapter describes the Lisp functions for reading and printing. It also describes *streams*, which specify where to get the text (if reading) or where to put it (if printing).

20.1 Introduction to Reading and Printing

Reading a Lisp object means parsing a Lisp expression in textual form and producing a corresponding Lisp object. This is how Lisp programs get into Lisp from files of Lisp code. We call the text the *read syntax* of the object. For example, the text ‘(a . 5)’ is the read syntax for a cons cell whose CAR is **a** and whose CDR is the number 5.

Printing a Lisp object means producing text that represents that object—converting the object to its *printed representation* (see Section 2.1 [Printed Representation], page 8). Printing the cons cell described above produces the text ‘(a . 5)’.

Reading and printing are more or less inverse operations: printing the object that results from reading a given piece of text often produces the same text, and reading the text that results from printing an object usually produces a similar-looking object. For example, printing the symbol **foo** produces the text ‘**foo**’, and reading that text returns the symbol **foo**. Printing a list whose elements are **a** and **b** produces the text ‘(a b)’, and reading that text produces a list (but not the same list) with elements **a** and **b**.

However, these two operations are not precisely inverse to each other. There are three kinds of exceptions:

- Printing can produce text that cannot be read. For example, buffers, windows, frames, subprocesses and markers print as text that starts with ‘#’; if you try to read this text, you get an error. There is no way to read those data types.
- One object can have multiple textual representations. For example, ‘1’ and ‘01’ represent the same integer, and ‘(a b)’ and ‘(a . (b))’ represent the same list. Reading will accept any of the alternatives, but printing must choose one of them.
- Comments can appear at certain points in the middle of an object’s read sequence without affecting the result of reading it.

20.2 Input Streams

Most of the Lisp functions for reading text take an *input stream* as an argument. The input stream specifies where or how to get the characters of the text to be read. Here are the possible types of input stream:

buffer The input characters are read from *buffer*, starting with the character directly after point. Point advances as characters are read.

marker The input characters are read from the buffer that *marker* is in, starting with the character directly after the marker. The marker position advances as characters are read. The value of point in the buffer has no effect when the stream is a marker.

<i>string</i>	The input characters are taken from <i>string</i> , starting at the first character in the string and using as many characters as required.
<i>function</i>	The input characters are generated by <i>function</i> , which must support two kinds of calls: <ul style="list-style-type: none"> • When it is called with no arguments, it should return the next character. • When it is called with one argument (always a character), <i>function</i> should save the argument and arrange to return it on the next call. This is called <i>unreadable</i> the character; it happens when the Lisp reader reads one character too many and wants to put it back where it came from. In this case, it makes no difference what value <i>function</i> returns.
<i>t</i>	<i>t</i> used as a stream means that the input is read from the minibuffer. In fact, the minibuffer is invoked once and the text given by the user is made into a string that is then used as the input stream. If Emacs is running in batch mode (see Section 42.17 [Batch Mode], page 1289), standard input is used instead of the minibuffer. For example,
	(message "%s" (read t))
	will in batch mode read a Lisp expression from standard input and print the result to standard output.
<i>nil</i>	<i>nil</i> supplied as an input stream means to use the value of standard-input instead; that value is the <i>default input stream</i> , and must be a non- <i>nil</i> input stream.
<i>symbol</i>	A symbol as input stream is equivalent to the symbol's function definition (if any).

Here is an example of reading from a stream that is a buffer, showing where point is located before and after:

```
----- Buffer: foo -----
This* is the contents of foo.
----- Buffer: foo -----  
  

(read (get-buffer "foo"))
  ⇒ is
(read (get-buffer "foo"))
  ⇒ the  
  

----- Buffer: foo -----
This is the* contents of foo.
----- Buffer: foo -----
```

Note that the first read skips a space. Reading skips any amount of whitespace preceding the significant text.

Here is an example of reading from a stream that is a marker, initially positioned at the beginning of the buffer shown. The value read is the symbol **This**.

```

----- Buffer: foo -----
This is the contents of foo.
----- Buffer: foo -----  

(setq m (set-marker (make-marker) 1 (get-buffer "foo")))
  ⇒ #<marker at 1 in foo>
(read m)
  ⇒ This
m
  ⇒ #<marker at 5 in foo>    ;; Before the first space.

```

Here we read from the contents of a string:

```

(read "(When in) the course")
  ⇒ (When in)

```

The following example reads from the minibuffer. The prompt is: ‘Lisp expression:’. (That is always the prompt used when you read from the stream t.) The user’s input is shown following the prompt.

```

(read t)
  ⇒ 23
----- Buffer: Minibuffer -----
Lisp expression: 23 RET
----- Buffer: Minibuffer -----

```

Finally, here is an example of a stream that is a function, named `useless-stream`. Before we use the stream, we initialize the variable `useless-list` to a list of characters. Then each call to the function `useless-stream` obtains the next character in the list or unread a character by adding it to the front of the list.

```

(setq useless-list (append "XY()" nil))
  ⇒ (88 89 40 41)  

(defun useless-stream (&optional unread)
  (if unread
      (setq useless-list (cons unread useless-list))
      (prog1 (car useless-list)
        (setq useless-list (cdr useless-list)))))
  ⇒ useless-stream

```

Now we read using the stream thus constructed:

```

(read 'useless-stream)
  ⇒ XY  

useless-list
  ⇒ (40 41)

```

Note that the open and close parentheses remain in the list. The Lisp reader encountered the open parenthesis, decided that it ended the input, and unread it. Another attempt to read from the stream at this point would read ‘()’ and return `nil`.

20.3 Input Functions

This section describes the Lisp functions and variables that pertain to reading.

In the functions below, *stream* stands for an input stream (see the previous section). If *stream* is `nil` or omitted, it defaults to the value of `standard-input`.

An `end-of-file` error is signaled if reading encounters an unterminated list, vector, or string.

read &optional stream [Function]

This function reads one textual Lisp expression from *stream*, returning it as a Lisp object. This is the basic Lisp input function.

read-from-string string &optional start end [Function]

This function reads the first textual Lisp expression from the text in *string*. It returns a cons cell whose CAR is that expression, and whose CDR is an integer giving the position of the next remaining character in the string (i.e., the first one not read).

If *start* is supplied, then reading begins at index *start* in the string (where the first character is at index 0). If you specify *end*, then reading is forced to stop just before that index, as if the rest of the string were not there.

For example:

```
(read-from-string "(setq x 55) (setq y 5)")
  ⇒ ((setq x 55) . 11)
(read-from-string "\"A short string\"")
  ⇒ ("A short string" . 16)

;; Read starting at the first character.
(read-from-string "(list 112)" 0)
  ⇒ ((list 112) . 10)
;; Read starting at the second character.
(read-from-string "(list 112)" 1)
  ⇒ (list . 5)
;; Read starting at the seventh character,
;; and stopping at the ninth.
(read-from-string "(list 112)" 6 8)
  ⇒ (11 . 8)
```

read-positioning-symbols &optional stream [Function]

This function reads one textual expression from *stream*, like `read` does, but additionally positions the read symbols to the positions in *stream* where they occurred. Only the symbol `nil` is not positioned, this for efficiency reasons. See Section 9.6 [Symbols with Position], page 143. This function is used by the byte compiler.

standard-input [Variable]

This variable holds the default input stream—the stream that `read` uses when the *stream* argument is `nil`. The default is `t`, meaning use the minibuffer.

read-circle [Variable]

If non-`nil`, this variable enables the reading of circular and shared structures. See Section 2.6 [Circular Objects], page 30. Its default value is `t`.

When reading or writing from the standard input/output streams of the Emacs process in batch mode, it is sometimes required to make sure any arbitrary binary data will be read/written verbatim, and/or that no translation of newlines to or from CR-LF pairs is performed. This issue does not exist on POSIX hosts, only on MS-Windows and MS-DOS. The following function allows you to control the I/O mode of any standard stream of the Emacs process.

set-binary-mode *stream mode*

[Function]

Switch *stream* into binary or text I/O mode. If *mode* is non-*nil*, switch to binary mode, otherwise switch to text mode. The value of *stream* can be one of **stdin**, **stdout**, or **stderr**. This function flushes any pending output data of *stream* as a side effect, and returns the previous value of I/O mode for *stream*. On POSIX hosts, it always returns a non-*nil* value and does nothing except flushing pending output.

readablep *object*

[Function]

This predicate says whether *object* has *readable syntax*, i.e., it can be written out and then read back by the Emacs Lisp reader. If it can't, this function returns **nil**; if it can, this function returns a printed representation (via **prin1**, see Section 20.5 [Output Functions], page 377) of *object*.

20.4 Output Streams

An output stream specifies what to do with the characters produced by printing. Most print functions accept an output stream as an optional argument. Here are the possible types of output stream:

<i>buffer</i>	The output characters are inserted into <i>buffer</i> at point. Point advances as characters are inserted.
<i>marker</i>	The output characters are inserted into the buffer that <i>marker</i> points into, at the marker position. The marker position advances as characters are inserted. The value of point in the buffer has no effect on printing when the stream is a marker, and this kind of printing does not move point (except that if the marker points at or before the position of point, point advances with the surrounding text, as usual).
<i>function</i>	The output characters are passed to <i>function</i> , which is responsible for storing them away. It is called with a single character as argument, as many times as there are characters to be output, and is responsible for storing the characters wherever you want to put them.
t	The output characters are displayed in the echo area. If Emacs is running in batch mode (see Section 42.17 [Batch Mode], page 1289), the output is written to the standard output descriptor instead.
nil	nil specified as an output stream means to use the value of the standard-output variable instead; that value is the <i>default output stream</i> , and must not be nil .
<i>symbol</i>	A symbol as output stream is equivalent to the symbol's function definition (if any).

Many of the valid output streams are also valid as input streams. The difference between input and output streams is therefore more a matter of how you use a Lisp object, than of different types of object.

Here is an example of a buffer used as an output stream. Point is initially located as shown immediately before the ‘h’ in ‘the’. At the end, point is located directly before that same ‘h’.

```
----- Buffer: foo -----
This is t*he contents of foo.
----- Buffer: foo -----
```

```
(print "This is the output" (get-buffer "foo"))
⇒ "This is the output"
```

```
----- Buffer: foo -----
This is t
"This is the output"
*he contents of foo.
----- Buffer: foo -----
```

Now we show a use of a marker as an output stream. Initially, the marker is in buffer `foo`, between the ‘t’ and the ‘h’ in the word ‘`the`’. At the end, the marker has advanced over the inserted text so that it remains positioned before the same ‘h’. Note that the location of point, shown in the usual fashion, has no effect.

```
----- Buffer: foo -----
This is the *output
----- Buffer: foo -----
```

```
(setq m (copy-marker 10))
⇒ #<marker at 10 in foo>
```

```
(print "More output for foo." m)
⇒ "More output for foo."
```

```
----- Buffer: foo -----
This is t
"More output for foo."
he *output
----- Buffer: foo -----
```

```
m
⇒ #<marker at 34 in foo>
```

The following example shows output to the echo area:

```
(print "Echo Area output" t)
⇒ "Echo Area output"
----- Echo Area -----
"Echo Area output"
----- Echo Area -----
```

Finally, we show the use of a function as an output stream. The function `eat-output` takes each character that it is given and conses it onto the front of the list `last-output` (see Section 5.4 [Building Lists], page 82). At the end, the list contains all the characters output, but in reverse order.

```
(setq last-output nil)
⇒ nil

(defun eat-output (c)
  (setq last-output (cons c last-output)))
⇒ eat-output

(print "This is the output" #'eat-output)
⇒ "This is the output"

last-output
⇒ (10 34 116 117 112 116 117 111 32 101 104
     116 32 115 105 32 115 105 104 84 34 10)
```

Now we can put the output in the proper order by reversing the list:

```
(concat (nreverse last-output))
⇒ "
\"This is the output\""
"
```

Calling `concat` converts the list to a string so you can see its contents more clearly.

`external-debugging-output character` [Function]

This function can be useful as an output stream when debugging. It writes `character` to the standard error stream.

For example

```
(print "This is the output" #'external-debugging-output)
+ This is the output
⇒ "This is the output"
```

20.5 Output Functions

This section describes the Lisp functions for printing Lisp objects—converting objects into their printed representation.

Some of the Emacs printing functions add quoting characters to the output when necessary so that it can be read properly. The quoting characters used are “`”` and ‘`\`; they distinguish strings from symbols, and prevent punctuation characters in strings and symbols from being taken as delimiters when reading. See Section 2.1 [Printed Representation], page 8, for full details. You specify quoting or no quoting by the choice of printing function.

If the text is to be read back into Lisp, then you should print with quoting characters to avoid ambiguity. Likewise, if the purpose is to describe a Lisp object clearly for a Lisp programmer. However, if the purpose of the output is to look nice for humans, then it is usually better to print without quoting.

Lisp objects can refer to themselves. Printing a self-referential object in the normal way would require an infinite amount of text, and the attempt could cause infinite recursion. Emacs detects such recursion and prints ‘#*level*’ instead of recursively printing an object already being printed. For example, here ‘#0’ indicates a recursive reference to the object at level 0 of the current print operation:

```
(setq foo (list nil))
  ⇒ (nil)
(setcar foo foo)
  ⇒ (#0)
```

In the functions below, *stream* stands for an output stream. (See the previous section for a description of output streams. Also See [external-debugging-output], page 377, a useful stream value for debugging.) If *stream* is `nil` or omitted, it defaults to the value of `standard-output`.

print *object* &**optional** *stream*

[Function]

The `print` function is a convenient way of printing. It outputs the printed representation of *object* to *stream*, printing in addition one newline before *object* and another after it. Quoting characters are used. `print` returns *object*. For example:

```
(progn (print 'The\ cat\ in)
        (print "the hat")
        (print " came back"))
  ↘
  ↘ The\ cat\ in
  ↘
  ↘ "the hat"
  ↘
  ↘ " came back"
  ⇒ " came back"
```

prin1 *object* &**optional** *stream* *overrides*

[Function]

This function outputs the printed representation of *object* to *stream*. It does not print newlines to separate output as `print` does, but it does use quoting characters just like `print`. It returns *object*.

```
(progn (prin1 'The\ cat\ in)
        (prin1 "the hat")
        (prin1 " came back"))
  ↘ The\ cat\ in"the hat"" came back"
  ⇒ " came back"
```

If *overrides* is non-`nil`, it should either be `t` (which tells `prin1` to use the defaults for all printer related variables), or a list of settings. See Section 20.7 [Output Overrides], page 383, for details.

princ *object* &**optional** *stream*

[Function]

This function outputs the printed representation of *object* to *stream*. It returns *object*.

This function is intended to produce output that is readable by people, not by `read`, so it doesn’t insert quoting characters and doesn’t put double-quotes around the contents of strings. It does not add any spacing between calls.

```
(progn
  (princ 'The\ cat)
  (princ " in the \"hat\"")
  ⇒ The cat in the "hat"
  ⇒ " in the \"hat\""
```

terpri &**optional** *stream ensure* [Function]

This function outputs a newline to *stream*. The name stands for “terminate print”. If *ensure* is non-*nil* no newline is printed if *stream* is already at the beginning of a line. Note in this case *stream* can not be a function and an error is signaled if it is. This function returns *t* if a newline is printed.

write-char *character* &**optional** *stream* [Function]

This function outputs *character* to *stream*. It returns *character*.

flush-standard-output [Function]

If you have Emacs-based batch scripts that send output to the terminal, Emacs will automatically display the output whenever you write a newline characters to **standard-output**. This function allows you to flush to **standard-output** without sending a newline character first, which enables you to display incomplete lines.

prin1-to-string *object* &**optional** *noescape overrides* [Function]

This function returns a string containing the text that **prin1** would have printed for the same argument.

```
(prin1-to-string 'foo)
  ⇒ "foo"
(prin1-to-string (mark-marker))
  ⇒ "#<marker at 2773 in strings.texi>"
```

If *overrides* is non-*nil*, it should either be *t* (which tells **prin1** to use the defaults for all printer related variables), or a list of settings. See Section 20.7 [Output Overrides], page 383, for details.

If *noescape* is non-*nil*, that inhibits use of quoting characters in the output. (This argument is supported in Emacs versions 19 and later.)

```
(prin1-to-string "foo")
  ⇒ "\"foo\""
(prin1-to-string "foo" t)
  ⇒ "foo"
```

See **format**, in Section 4.7 [Formatting Strings], page 66, for other ways to obtain the printed representation of a Lisp object as a string.

with-output-to-string *body...* [Macro]

This macro executes the *body* forms with **standard-output** set up to feed output into a string. Then it returns that string.

For example, if the current buffer name is ‘*foo*’,

```
(with-output-to-string
```

```
(princ "The buffer is ")
(princ (buffer-name)))
returns "The buffer is foo".
```

pp object &optional stream [Function]

This function outputs *object* to *stream*, just like `prin1`, but does it in a prettier way. That is, it'll indent and fill the object to make it more readable for humans.

If you need to use binary I/O in batch mode, e.g., use the functions described in this section to write out arbitrary binary data or avoid conversion of newlines on non-POSIX hosts, see Section 20.3 [Input Functions], page 374.

20.6 Variables Affecting Output

standard-output [Variable]

The value of this variable is the default output stream—the stream that print functions use when the *stream* argument is `nil`. The default is `t`, meaning display in the echo area.

print-quoted [Variable]

If this is non-`nil`, that means to print quoted forms using abbreviated reader syntax, e.g., `(quote foo)` prints as `'foo`, and `(function foo)` as `#'foo`. The default is `t`.

print-escape-newlines [Variable]

If this variable is non-`nil`, then newline characters in strings are printed as `\n` and formfeeds are printed as `\f`. Normally these characters are printed as actual newlines and formfeeds.

This variable affects the print functions `prin1` and `print` that print with quoting. It does not affect `princ`. Here is an example using `prin1`:

```
(prin1 "a\nb")
  ↗ "a
  ↗ b"
  ⇒ "a
      b"
```

```
(let ((print-escape-newlines t))
  (prin1 "a\nb"))
  ↗ "a\nb"
  ⇒ "a
      b"
```

In the second expression, the local binding of `print-escape-newlines` is in effect during the call to `prin1`, but not during the printing of the result.

print-escape-control-characters [Variable]

If this variable is non-`nil`, control characters in strings are printed as backslash sequences by the print functions `prin1` and `print` that print with quoting. If this variable and `print-escape-newlines` are both non-`nil`, the latter takes precedences for newlines and formfeeds.

print-escape-nonascii

[Variable]

If this variable is non-`nil`, then unibyte non-ASCII characters in strings are unconditionally printed as backslash sequences by the print functions `prin1` and `print` that print with quoting.

Those functions also use backslash sequences for unibyte non-ASCII characters, regardless of the value of this variable, when the output stream is a multibyte buffer or a marker pointing into one.

print-escape-multibyte

[Variable]

If this variable is non-`nil`, then multibyte non-ASCII characters in strings are unconditionally printed as backslash sequences by the print functions `prin1` and `print` that print with quoting.

Those functions also use backslash sequences for multibyte non-ASCII characters, regardless of the value of this variable, when the output stream is a unibyte buffer or a marker pointing into one.

print-charset-text-property

[Variable]

This variable controls printing of ‘charset’ text property on printing a string. The value should be `nil`, `t`, or `default`.

If the value is `nil`, `charset` text properties are never printed. If `t`, they are always printed.

If the value is `default`, only print `charset` text properties if there is an “unexpected” `charset` property. For ascii characters, all charsets are considered “expected”. Otherwise, the expected `charset` property of a character is given by `char-charset`.

print-length

[Variable]

The value of this variable is the maximum number of elements to print in any list, vector or bool-vector. If an object being printed has more than this many elements, it is abbreviated with an ellipsis.

If the value is `nil` (the default), then there is no limit.

```
(setq print-length 2)
⇒ 2
(print '(1 2 3 4 5))
⇒ (1 2 ...)
⇒ (1 2 ...)
```

print-level

[Variable]

The value of this variable is the maximum depth of nesting of parentheses and brackets when printed. Any list or vector at a depth exceeding this limit is abbreviated with an ellipsis. A value of `nil` (which is the default) means no limit.

eval-expression-print-length

[User Option]

eval-expression-print-level

[User Option]

These are the values for `print-length` and `print-level` used by `eval-expression`, and thus, indirectly, by many interactive evaluation commands (see Section “Evaluating Emacs Lisp Expressions” in *The GNU Emacs Manual*).

These variables are used for detecting and reporting circular and shared structure:

print-circle [Variable]

If non-`nil`, this variable enables detection of circular and shared structure in printing. See Section 2.6 [Circular Objects], page 30.

print-unreadable-function [Variable]

By default, Emacs prints unreadable objects as ‘#<...>’. For instance:

```
(prin1-to-string (make-marker))
⇒ "#<marker in no buffer>"
```

If this variable is non-`nil`, it should be a function that will be called to handle printing of these objects. The function will be called with two arguments: the object and the `noescape` flag used by the printing functions (see Section 20.5 [Output Functions], page 377).

The function should return either `nil` (print the object as usual), or a string (which will be printed), or any other object (don’t print the object). For instance:

```
(let ((print-unreadable-function
      (lambda (object escape) "hello")))
  (prin1-to-string (make-marker)))
⇒ "hello"
```

print-gensym [Variable]

If non-`nil`, this variable enables detection of uninterned symbols (see Section 9.3 [Creating Symbols], page 135) in printing. When this is enabled, uninterned symbols print with the prefix ‘#:’, which tells the Lisp reader to produce an uninterned symbol.

print-continuous-numbering [Variable]

If non-`nil`, that means number continuously across print calls. This affects the numbers printed for ‘#n=’ labels and ‘#m#’ references. Don’t set this variable with `setq`; you should only bind it temporarily to `t` with `let`. When you do that, you should also bind `print-number-table` to `nil`.

print-number-table [Variable]

This variable holds a vector used internally by printing to implement the `print-circle` feature. You should not use it except to bind it to `nil` when you bind `print-continuous-numbering`.

float-output-format [Variable]

This variable specifies how to print floating-point numbers. The default is `nil`, meaning use the shortest output that represents the number without losing information.

To control output format more precisely, you can put a string in this variable. The string should hold a ‘%’-specification to be used in the C function `sprintf`. For further restrictions on what you can use, see the variable’s documentation string.

print-integers-as-characters [Variable]

When this variable is non-`nil`, integers that represent graphic base characters will be printed using Lisp character syntax (see Section 2.4.3.1 [Basic Char Syntax], page 11). Other numbers are printed the usual way. For example, the list `(4 65 -1 10)` would be printed as ‘(4 ?A -1 ?\n)’.

More precisely, values printed in character syntax are those representing characters belonging to the Unicode general categories Letter, Number, Punctuation, Symbol and Private-use (see Section 34.6 [Character Properties], page 968), as well as the control characters having their own escape syntax such as newline.

20.7 Overriding Output Variables

The previous section (see Section 20.6 [Output Variables], page 380) lists the numerous variables that control how the Emacs Lisp printer formats data for outputs. These are generally available for users to change, but sometimes you want to output data in the default format, or override the user settings in some other way. For instance, if you’re storing Emacs Lisp data in a file, you don’t want that data to be shortened by a `print-length` setting.

The `prin1` and `prin1-to-string` functions therefore have an optional `overrides` argument. This argument can either be `t` (which means that all printing variables should be reset to the default values), or a list of settings for some of the variables. Each element in the list can be either `t` (which means “reset to defaults”, and will usually be the first element of the list), or a pair whose `car` is a symbol that stands for an output variable and whose `cdr` is the value for that variable.

For instance, this prints using nothing but defaults:

```
(prin1 object nil t)
```

This prints `object` using the current printing settings, but overrides the value of `print-length` to be 5:

```
(prin1 object nil '((length . 5)))
```

And finally, this prints `object` using only default settings, but with `print-length` bound to 5:

```
(prin1 object nil '(t (length . 5)))
```

Below is a list of symbols that can be used, and which variables they map to:

<code>length</code>	This overrides <code>print-length</code> .
<code>level</code>	This overrides <code>print-level</code> .
<code>circle</code>	This overrides <code>print-circle</code> .
<code>quoted</code>	This overrides <code>print-quoted</code> .
<code>escape-newlines</code>	This overrides <code>print-escape-newlines</code> .
<code>escape-control-characters</code>	This overrides <code>print-escape-control-characters</code> .
<code>escape-nonascii</code>	This overrides <code>print-escape-nonascii</code> .
<code>escape-multibyte</code>	This overrides <code>print-escape-multibyte</code> .
<code>charset-text-property</code>	This overrides <code>print-charset-text-property</code> .

unreadable-function

This overrides `print-unreadable-function`.

gensym This overrides `print-gensym`.**continuous-numbering**

This overrides `print-continuous-numbering`.

number-table

This overrides `print-number-table`.

float-format

This overrides `float-output-format`.

integers-as-characters

This overrides `print-integers-as-characters`.

In the future, more overrides may be offered that do not map directly to a variable, but can only be used via this parameter.

21 Minibuffers

A *minibuffer* is a special buffer that Emacs commands use to read arguments more complicated than the single numeric prefix argument. These arguments include file names, buffer names, and command names (as in `M-x`). The minibuffer is displayed on the bottom line of the frame, in the same place as the echo area (see Section 41.4 [The Echo Area], page 1131), but only while it is in use for reading an argument.

21.1 Introduction to Minibuffers

In most ways, a minibuffer is a normal Emacs buffer. Most operations *within* a buffer, such as editing commands, work normally in a minibuffer. However, many operations for managing buffers do not apply to minibuffers. The name of a minibuffer always has the form ‘`*Minibuf-number*`’, and it cannot be changed. Minibuffers are displayed only in special windows used only for minibuffers; these windows always appear at the bottom of a frame. (Sometimes frames have no minibuffer window, and sometimes a special kind of frame contains nothing but a minibuffer window; see Section 30.9 [Minibuffers and Frames], page 824.)

The text in the minibuffer always starts with the *prompt string*, the text that was specified by the program that is using the minibuffer to tell the user what sort of input to type. This text is marked read-only so you won’t accidentally delete or change it. It is also marked as a field (see Section 33.19.9 [Fields], page 936), so that certain motion functions, including `beginning-of-line`, `forward-word`, `forward-sentence`, and `forward-paragraph`, stop at the boundary between the prompt and the actual text.

The minibuffer’s window is normally a single line; it grows automatically if the contents require more space. Whilst the minibuffer is active, you can explicitly resize its window temporarily with the window sizing commands; the window reverts to its normal size when the minibuffer is exited. When the minibuffer is not active, you can resize its window permanently by using the window sizing commands in the frame’s other window, or dragging the mode line with the mouse. (Due to details of the current implementation, for this to work `resize-mini-windows` must be `nil`.) If the frame contains just a minibuffer window, you can change its size by changing the frame’s size.

Use of the minibuffer reads input events, and that alters the values of variables such as `this-command` and `last-command` (see Section 22.5 [Command Loop Info], page 436). Your program should bind them around the code that uses the minibuffer, if you do not want that to change them.

Under some circumstances, a command can use a minibuffer even if there is an active minibuffer; such a minibuffer is called a *recursive minibuffer*. The first minibuffer is named ‘`*Minibuf-1*`’. Recursive minibuffers are named by incrementing the number at the end of the name. (The names begin with a space so that they won’t show up in normal buffer lists.) Of several recursive minibuffers, the innermost (or most recently entered) is the *active minibuffer*—it is the one you can terminate by typing `RET` (`exit-minibuffer`) in. We usually call this *the* minibuffer. You can permit or forbid recursive minibuffers by setting the variable `enable-recursive-minibuffers`, or by putting properties of that name on command symbols (See Section 21.13 [Recursive Mini], page 420.)

Like other buffers, a minibuffer uses a local keymap (see Chapter 23 [Keymaps], page 480) to specify special key bindings. The function that invokes the minibuffer also sets up its local map according to the job to be done. See Section 21.2 [Text from Minibuffer], page 386, for the non-completion minibuffer local maps. See Section 21.6.3 [Completion Commands], page 400, for the minibuffer local maps for completion.

An active minibuffer usually has major mode `minibuffer-mode`. This is an Emacs internal mode without any special features. To customize the setup of minibuffers, we suggest you use `minibuffer-setup-hook` (see Section 21.15 [Minibuffer Misc], page 421) rather than `minibuffer-mode-hook`, since the former is run later, after the minibuffer has been fully initialized.

When a minibuffer is inactive, its major mode is `minibuffer-inactive-mode`, with keymap `minibuffer-inactive-mode-map`. This is only really useful if the minibuffer is in a separate frame. See Section 30.9 [Minibuffers and Frames], page 824.

When Emacs is running in batch mode, any request to read from the minibuffer actually reads a line from the standard input descriptor that was supplied when Emacs was started. This supports only basic input: none of the special minibuffer features (history, completion, etc.) are available in batch mode.

21.2 Reading Text Strings with the Minibuffer

The most basic primitive for minibuffer input is `read-from-minibuffer`, which can be used to read either a string or a Lisp object in textual form. The function `read-regexp` is used for reading regular expressions (see Section 35.3 [Regular Expressions], page 995), which are a special kind of string. There are also specialized functions for reading commands, variables, file names, etc. (see Section 21.6 [Completion], page 395).

In most cases, you should not call minibuffer input functions in the middle of a Lisp function. Instead, do all minibuffer input as part of reading the arguments for a command, in the `interactive` specification. See Section 22.2 [Defining Commands], page 424.

`read-from-minibuffer` *prompt &optional initial keymap read* [Function]
history default inherit-input-method

This function is the most general way to get input from the minibuffer. By default, it accepts arbitrary text and returns it as a string; however, if `read` is non-`nil`, then it uses `read` to convert the text into a Lisp object (see Section 20.3 [Input Functions], page 374).

The first thing this function does is to activate a minibuffer and display it with `prompt` (which must be a string) as the prompt. Then the user can edit text in the minibuffer.

When the user types a command to exit the minibuffer, `read-from-minibuffer` constructs the return value from the text in the minibuffer. Normally it returns a string containing that text. However, if `read` is non-`nil`, `read-from-minibuffer` reads the text and returns the resulting Lisp object, unevaluated. (See Section 20.3 [Input Functions], page 374, for information about reading.)

The argument `default` specifies default values to make available through the history commands. It should be a string, a list of strings, or `nil`. The string or strings become the minibuffer’s “future history”, available to the user with `M-n`. In addition, if the call provides completion (e.g., via the `keymap` argument), the completion candidates

are added to the “future history” when the values in *default* are exhausted by *M-n*; see Section 21.4 [minibuffer-default-add-function], page 392.

If *read* is non-*nil*, then *default* is also used as the input to *read*, if the user enters empty input. If *default* is a list of strings, the first string is used as the input. If *default* is *nil*, empty input results in an **end-of-file** error. However, in the usual case (where *read* is *nil*), **read-from-minibuffer** ignores *default* when the user enters empty input and returns an empty string, “”. In this respect, it differs from all the other minibuffer input functions in this chapter.

If *keymap* is non-*nil*, that keymap is the local keymap to use in the minibuffer. If *keymap* is omitted or *nil*, the value of **minibuffer-local-map** is used as the keymap. Specifying a keymap is the most important way to customize the minibuffer for various applications such as completion.

The argument *history* specifies a history list variable to use for saving the input and for history commands used in the minibuffer. It defaults to **minibuffer-history**. If *history* is the symbol *t*, history is not recorded. You can optionally specify a starting position in the history list as well. See Section 21.4 [Minibuffer History], page 392.

If the variable **minibuffer-allow-text-properties** is non-*nil*, then the string that is returned includes whatever text properties were present in the minibuffer. Otherwise all the text properties are stripped when the value is returned. (By default this variable is *nil*.)

The text properties in **minibuffer-prompt-properties** are applied to the prompt. By default, this property list defines a face to use for the prompt. This face, if present, is applied to the end of the face list and merged before display.

If the user wants to completely control the look of the prompt, the most convenient way to do that is to specify the *default* face at the end of all face lists. For instance:

```
(read-from-minibuffer
  (concat
    (propertize "Bold" 'face '(bold default))
    (propertize " and normal: " 'face '(default))))
```

If the argument *inherit-input-method* is non-*nil*, then the minibuffer inherits the current input method (see Section 34.11 [Input Methods], page 990) and the setting of **enable-multibyte-characters** (see Section 34.1 [Text Representations], page 963) from whichever buffer was current before entering the minibuffer.

Use of *initial* is mostly deprecated; we recommend using a non-*nil* value only in conjunction with specifying a cons cell for *history*. See Section 21.5 [Initial Input], page 394.

read-string <i>prompt</i> & optional <i>initial history default</i>	[Function]
<i>inherit-input-method</i>	

This function reads a string from the minibuffer and returns it. The arguments *prompt*, *initial*, *history* and *inherit-input-method* are used as in **read-from-minibuffer**. The keymap used is **minibuffer-local-map**.

The optional argument *default* is used as in **read-from-minibuffer**, except that, if non-*nil*, it also specifies a default value to return if the user enters null input. As in **read-from-minibuffer** it should be a string, a list of strings, or *nil*, which is

equivalent to an empty string. When *default* is a string, that string is the default value. When it is a list of strings, the first string is the default value. (All these strings are available to the user in the “future minibuffer history”.)

This function works by calling the `read-from-minibuffer` function:

```
(read-string prompt initial history default inherit)
≡
(let ((value
       (read-from-minibuffer prompt initial nil nil
                             history default inherit)))
  (if (and (equal value "") default)
      (if (consp default) (car default) default)
      value))
```

If you have a long string (for instance, one that is several lines long) that you wish to edit, using `read-string` may not be ideal. In that case, popping to a new, normal buffer where the user can edit the string may be more convenient, and you can use the `read-string-from-buffer` function to do that.

`read-regexp` *prompt &optional defaults history*

[Function]

This function reads a regular expression as a string from the minibuffer and returns it. If the minibuffer prompt string *prompt* does not end in ‘:’ (followed by optional whitespace), the function adds ‘:’ to the end, preceded by the default return value (see below), if that is non-empty.

The optional argument *defaults* controls the default value to return if the user enters null input, and should be one of: a string; `nil`, which is equivalent to an empty string; a list of strings; or a symbol.

If *defaults* is a symbol, `read-regexp` consults the value of the variable `read-regexp-defaults-function` (see below), and if that is non-`nil` uses it in preference to *defaults*. The value in this case should be either:

- `regexp-history-last`, which means to use the first element of the appropriate minibuffer history list (see below).
- A function of no arguments, whose return value (which should be `nil`, a string, or a list of strings) becomes the value of *defaults*.

`read-regexp` now ensures that the result of processing *defaults* is a list (i.e., if the value is `nil` or a string, it converts it to a list of one element). To this list, `read-regexp` then appends a few potentially useful candidates for input. These are:

- The word or symbol at point.
- The last regexp used in an incremental search.
- The last string used in an incremental search.
- The last string or pattern used in query-replace commands.

The function now has a list of regular expressions that it passes to `read-from-minibuffer` to obtain the user’s input. The first element of the list is the default result in case of empty input. All elements of the list are available to the user as the “future minibuffer history” list (see Section “Minibuffer History” in *The GNU Emacs Manual*).

The optional argument *history*, if non-*nil*, is a symbol specifying a minibuffer history list to use (see Section 21.4 [Minibuffer History], page 392). If it is omitted or *nil*, the history list defaults to `regexp-history`.

The user can use the *M-s c* command to indicate whether case folding should be on or off. If the user has used this command, the returned string will have the text property `case-fold` set to either `fold` or `inhibit-fold`. It is up to the caller of `read-regexp` to actually use this value, and the convenience function `read-regexp-case-fold-search` is provided for that. A typical usage pattern here might look like:

```
(let* ((regexp (read-regexp "Search for: "))
      (case-fold-search (read-regexp-case-fold-search regexp)))
  (re-search-forward regexp))
```

read-regexp-defaults-function

[User Option]

The function `read-regexp` may use the value of this variable to determine its list of default regular expressions. If non-*nil*, the value of this variable should be either:

- The symbol `regexp-history-last`.
- A function of no arguments that returns either *nil*, a string, or a list of strings.

See `read-regexp` above for details of how these values are used.

minibuffer-allow-text-properties

[Variable]

If this variable is *nil*, the default, then `read-from-minibuffer` and `read-string` strip all text properties from the minibuffer input before returning it. However, `read-no-blanks-input` (see below), as well as `read-minibuffer` and related functions (see Section 21.3 [Reading Lisp Objects With the Minibuffer], page 391), and all functions that do minibuffer input with completion, remove the `face` property unconditionally, regardless of the value of this variable.

If this variable is non-*nil*, most text properties on strings from the completion table are preserved—but only on the part of the strings that were completed.

```
(let ((minibuffer-allow-text-properties t))
  (completing-read "String: " (list (propertize "foobar" 'data 'zot))))■
=> #("foobar" 3 6 (data zot))
```

In this example, the user typed ‘foo’ and then hit the *TAB* key, so the text properties are only preserved on the last three characters.

minibuffer-local-map

[Variable]

This is the default local keymap for reading from the minibuffer. By default, it makes the following bindings:

<i>C-j</i>	<code>exit-minibuffer</code>
<i>RET</i>	<code>exit-minibuffer</code>
<i>M-<</i>	<code>minibuffer-beginning-of-buffer</code>
<i>C-g</i>	<code>abort-recursive-edit</code>
<i>M-n</i>	
<i>DOWN</i>	<code>next-history-element</code>

```

M-p           previous-history-element
UP            previous-history-element
M-s           next-matching-history-element
M-r           previous-matching-history-element

```

The variable `minibuffer-mode-map` is an alias for this variable.

`read-no-blanks-input prompt &optional initial` [Function]
`inherit-input-method`

This function reads a string from the minibuffer, but does not allow whitespace characters as part of the input: instead, those characters terminate the input. The arguments `prompt`, `initial`, and `inherit-input-method` are used as in `read-from-minibuffer`.

This is a simplified interface to the `read-from-minibuffer` function, and passes the value of the `minibuffer-local-ns-map` keymap as the `keymap` argument for that function. Since the keymap `minibuffer-local-ns-map` does not rebind `C-q`, it is possible to put a space into the string, by quoting it.

This function discards text properties, regardless of the value of `minibuffer-allow-text-properties`.

```

(read-no-blanks-input prompt initial)
≡
(let (minibuffer-allow-text-properties)
  (read-from-minibuffer prompt initial minibuffer-local-ns-map))

```

`minibuffer-local-ns-map` [Variable]

This built-in variable is the keymap used as the minibuffer local keymap in the function `read-no-blanks-input`. By default, it makes the following bindings, in addition to those of `minibuffer-local-map`:

```

SPC      exit-minibuffer
TAB      exit-minibuffer
?        self-insert-and-exit

```

`format-prompt prompt default &rest format-args` [Function]

Format `prompt` with default value `default` according to the `minibuffer-default-prompt-format` variable.

`minibuffer-default-prompt-format` is a format string (defaulting to "`(default %s)`" that says how the "default" bit in prompts like "`"Local filename (default somefile): "`" are to be formatted.

To allow the users to customize how this is displayed, code that prompts the user for a value (and has a default) should look something along the lines of this code snippet:

```

(read-file-name
 (format-prompt "Local filename" file)
 nil file)

```

If `format-args` is `nil`, `prompt` is used as a literal string. If `format-args` is non-`nil`, `prompt` is used as a format control string, and `prompt` and `format-args` are passed to `format` (see Section 4.7 [Formatting Strings], page 66).

`minibuffer-default-prompt-format` can be "", in which case no default values are displayed.

If `default` is `nil`, there is no default value, and therefore no "default value" string is included in the result value. If `default` is a non-`nil` list, the first element of the list is used in the prompt.

Both `prompt` and `minibuffer-default-prompt-format` are run through `substitute-command-keys` (see Section 25.3 [Keys in Documentation], page 598).

`read-minibuffer-restore-windows` [Variable]

If this option is non-`nil` (the default), getting input from the minibuffer will restore, on exit, the window configurations of the frame where the minibuffer was entered from and, if it is different, the frame that owns the minibuffer window. This means that if, for example, a user splits a window while getting input from the minibuffer on the same frame, that split will be undone when exiting the minibuffer.

If this option is `nil`, no such restorations are done. Hence, the window split mentioned above will persist after exiting the minibuffer.

21.3 Reading Lisp Objects with the Minibuffer

This section describes functions for reading Lisp objects with the minibuffer.

`read-minibuffer prompt &optional initial` [Function]

This function reads a Lisp object using the minibuffer, and returns it without evaluating it. The arguments `prompt` and `initial` are used as in `read-from-minibuffer`.

This is a simplified interface to the `read-from-minibuffer` function:

```
(read-minibuffer prompt initial)
≡
(let (minibuffer-allow-text-properties)
  (read-from-minibuffer prompt initial nil t))
```

Here is an example in which we supply the string "(testing)" as initial input:

```
(read-minibuffer
  "Enter an expression: " (format "%s" '(testing)))
```

; ; Here is how the minibuffer is displayed:

```
----- Buffer: Minibuffer -----
Enter an expression: (testing)☆
----- Buffer: Minibuffer -----
```

The user can type RET immediately to use the initial input as a default, or can edit the input.

`eval-minibuffer prompt &optional initial` [Function]

This function reads a Lisp expression using the minibuffer, evaluates it, then returns the result. The arguments `prompt` and `initial` are used as in `read-from-minibuffer`.

This function simply evaluates the result of a call to `read-minibuffer`:

```
(eval-minibuffer prompt initial)
≡
(eval (read-minibuffer prompt initial))
```

edit-and-eval-command *prompt form* [Function]

This function reads a Lisp expression in the minibuffer, evaluates it, then returns the result. The difference between this command and **eval-minibuffer** is that here the initial *form* is not optional and it is treated as a Lisp object to be converted to printed representation rather than as a string of text. It is printed with **prin1**, so if it is a string, double-quote characters ("") appear in the initial text. See Section 20.5 [Output Functions], page 377.

In the following example, we offer the user an expression with initial text that is already a valid form:

```
(edit-and-eval-command "Please edit: " '(forward-word 1))

;; After evaluation of the preceding expression,
;; the following appears in the minibuffer:

----- Buffer: Minibuffer -----
Please edit: (forward-word 1)*
----- Buffer: Minibuffer -----
```

Typing RET right away would exit the minibuffer and evaluate the expression, thus moving point forward one word.

21.4 Minibuffer History

A *minibuffer history list* records previous minibuffer inputs so the user can reuse them conveniently. It is a variable whose value is a list of strings (previous inputs), most recent first.

There are many separate minibuffer history lists, used for different kinds of inputs. It's the Lisp programmer's job to specify the right history list for each use of the minibuffer.

You specify a minibuffer history list with the optional *history* argument to **read-from-minibuffer** or **completing-read**. Here are the possible values for it:

variable Use *variable* (a symbol) as the history list.

(variable . startpos)

Use *variable* (a symbol) as the history list, and assume that the initial history position is *startpos* (a nonnegative integer).

Specifying 0 for *startpos* is equivalent to just specifying the symbol *variable*. **previous-history-element** will display the most recent element of the history list in the minibuffer. If you specify a positive *startpos*, the minibuffer history functions behave as if **(elt variable (1- startpos))** were the history element currently shown in the minibuffer.

For consistency, you should also specify that element of the history as the initial minibuffer contents, using the *initial* argument to the minibuffer input function (see Section 21.5 [Initial Input], page 394).

If you don't specify *history*, then the default history list **minibuffer-history** is used. For other standard history lists, see below. You can also create your own history list variable; just initialize it to **nil** before the first use. If the variable is buffer local, then each buffer will have its own input history list.

Both `read-from-minibuffer` and `completing-read` add new elements to the history list automatically, and provide commands to allow the user to reuse items on the list (see Section 21.10 [Minibuffer Commands], page 417). The only thing your program needs to do to use a history list is to initialize it and to pass its name to the input functions when you wish. But it is safe to modify the list by hand when the minibuffer input functions are not using it.

By default, when `M-n` (`next-history-element`, see Section 21.10 [next-history-element], page 417) reaches the end of the list of default values provided by the command which initiated reading input from the minibuffer, `M-n` adds all of the completion candidates, as specified by `minibuffer-completion-table` (see Section 21.6.3 [Completion Commands], page 400), to the list of defaults, so that all those candidates are available as “future history”. Your program can control that via the variable `minibuffer-default-add-function`: if its value is not a function, this automatic addition is disabled, and you can also set this variable to your own function which adds only some candidates, or some other values, to the “future history”.

Emacs functions that add a new element to a history list can also delete old elements if the list gets too long. The variable `history-length` specifies the maximum length for most history lists. To specify a different maximum length for a particular history list, put the length in the `history-length` property of the history list symbol. The variable `history-delete-duplicates` specifies whether to delete duplicates in history.

add-to-history *history-var* *newelt* &**optional** *maxelt* *keep-all* [Function]

This function adds a new element *newelt*, if it isn’t the empty string, to the history list stored in the variable *history-var*, and returns the updated history list. It limits the list length to the value of *maxelt* (if non-`nil`) or `history-length` (described below). The possible values of *maxelt* have the same meaning as the values of `history-length`. *history-var* cannot refer to a lexical variable.

Normally, `add-to-history` removes duplicate members from the history list if `history-delete-duplicates` is non-`nil`. However, if *keep-all* is non-`nil`, that says not to remove duplicates, and to add *newelt* to the list even if it is empty.

history-add-new-input [Variable]

If the value of this variable is `nil`, standard functions that read from the minibuffer don’t add new elements to the history list. This lets Lisp programs explicitly manage input history by using `add-to-history`. The default value is `t`.

history-length [User Option]

The value of this variable specifies the maximum length for all history lists that don’t specify their own maximum lengths. If the value is `t`, that means there is no maximum (don’t delete old elements). If a history list variable’s symbol has a non-`nil` `history-length` property, it overrides this variable for that particular history list.

history-delete-duplicates [User Option]

If the value of this variable is `t`, that means when adding a new history element, all previous identical elements are deleted.

Here are some of the standard minibuffer history list variables:

minibuffer-history	[Variable]
The default history list for minibuffer history input.	
query-replace-history	[Variable]
A history list for arguments to <code>query-replace</code> (and similar arguments to other commands).	
file-name-history	[Variable]
A history list for file-name arguments.	
buffer-name-history	[Variable]
A history list for buffer-name arguments.	
regexp-history	[Variable]
A history list for regular expression arguments.	
extended-command-history	[Variable]
A history list for arguments that are names of extended commands.	
shell-command-history	[Variable]
A history list for arguments that are shell commands.	
read-expression-history	[Variable]
A history list for arguments that are Lisp expressions to evaluate.	
face-name-history	[Variable]
A history list for arguments that are faces.	
custom-variable-history	[Variable]
A history list for variable-name arguments read by <code>read-variable</code> .	
read-number-history	[Variable]
A history list for numbers read by <code>read-number</code> .	
goto-line-history	[Variable]
A history list for arguments to <code>goto-line</code> . This variable can be made local in every buffer by customizing the user option <code>goto-line-history-local</code> .	

21.5 Initial Input

Several of the functions for minibuffer input have an argument called `initial`. This is a mostly-deprecated feature for specifying that the minibuffer should start out with certain text, instead of empty as usual.

If `initial` is a string, the minibuffer starts out containing the text of the string, with point at the end, when the user starts to edit the text. If the user simply types RET to exit the minibuffer, it will use the initial input string to determine the value to return.

We discourage use of a non-nil value for `initial`, because initial input is an intrusive interface. History lists and default values provide a much more convenient method to offer useful default inputs to the user.

There is just one situation where you should specify a string for an *initial* argument. This is when you specify a cons cell for the *history* argument. See Section 21.4 [Minibuffer History], page 392.

initial can also be a cons cell of the form (*string . position*). This means to insert *string* in the minibuffer but put point at *position* within the string's text.

As a historical accident, *position* was implemented inconsistently in different functions. In `completing-read`, *position*'s value is interpreted as origin-zero; that is, a value of 0 means the beginning of the string, 1 means after the first character, etc. In `read-minibuffer`, and the other non-completion minibuffer input functions that support this argument, 1 means the beginning of the string, 2 means after the first character, etc.

Use of a cons cell as the value for *initial* arguments is deprecated.

21.6 Completion

Completion is a feature that fills in the rest of a name starting from an abbreviation for it. Completion works by comparing the user's input against a list of valid names and determining how much of the name is determined uniquely by what the user has typed. For example, when you type `C-x b (switch-to-buffer)` and then type the first few letters of the name of the buffer to which you wish to switch, and then type TAB (`minibuffer-complete`), Emacs extends the name as far as it can.

Standard Emacs commands offer completion for names of symbols, files, buffers, and processes; with the functions in this section, you can implement completion for other kinds of names.

The `try-completion` function is the basic primitive for completion: it returns the longest determined completion of a given initial string, with a given set of strings to match against.

The function `completing-read` provides a higher-level interface for completion. A call to `completing-read` specifies how to determine the list of valid names. The function then activates the minibuffer with a local keymap that binds a few keys to commands useful for completion. Other functions provide convenient simple interfaces for reading certain kinds of names with completion.

21.6.1 Basic Completion Functions

The following completion functions have nothing in themselves to do with minibuffers. We describe them here to keep them near the higher-level completion features that do use the minibuffer.

try-completion *string collection &optional predicate* [Function]

This function returns the longest common substring of all possible completions of *string* in *collection*.

collection is called the *completion table*. Its value must be a list of strings or cons cells, an obarray, a hash table, or a completion function.

`try-completion` compares *string* against each of the permissible completions specified by the completion table. If no permissible completions match, it returns `nil`. If there is just one matching completion, and the match is exact, it returns `t`. Otherwise, it returns the longest initial sequence common to all possible matching completions.

If *collection* is a list, the permissible completions are specified by the elements of the list, each of which should be either a string, or a cons cell whose CAR is either a string or a symbol (a symbol is converted to a string using `symbol-name`). If the list contains elements of any other type, those are ignored.

If *collection* is an obarray (see Section 9.3 [Creating Symbols], page 135), the names of all symbols in the obarray form the set of permissible completions.

If *collection* is a hash table, then the keys that are strings or symbols are the possible completions. Other keys are ignored.

You can also use a function as *collection*. Then the function is solely responsible for performing completion; `try-completion` returns whatever this function returns. The function is called with three arguments: *string*, *predicate* and *nil* (the third argument is so that the same function can be used in `all-completions` and do the appropriate thing in either case). See Section 21.6.7 [Programmed Completion], page 409.

If the argument *predicate* is non-*nil*, then it must be a function of one argument, unless *collection* is a hash table, in which case it should be a function of two arguments. It is used to test each possible match, and the match is accepted only if *predicate* returns non-*nil*. The argument given to *predicate* is either a string or a cons cell (the CAR of which is a string) from the alist, or a symbol (*not* a symbol name) from the obarray. If *collection* is a hash table, *predicate* is called with two arguments, the string key and the associated value.

In addition, to be acceptable, a completion must also match all the regular expressions in `completion-regexp-list`. (Unless *collection* is a function, in which case that function has to handle `completion-regexp-list` itself.)

In the first of the following examples, the string ‘foo’ is matched by three of the alist CARS. All of the matches begin with the characters ‘fooba’, so that is the result. In the second example, there is only one possible match, and it is exact, so the return value is `t`.

```
(try-completion
  "foo"
  '(("foobar1" 1) ("barfoo" 2) ("foobaz" 3) ("foobar2" 4)))
  ⇒ "fooba"

(try-completion "foo" '(("barfoo" 2) ("foo" 3)))
  ⇒ t
```

In the following example, numerous symbols begin with the characters ‘forw’, and all of them begin with the word ‘forward’. In most of the symbols, this is followed with a ‘-’, but not in all, so no more than ‘forward’ can be completed.

```
(try-completion "forw" obarray)
  ⇒ "forward"
```

Finally, in the following example, only two of the three possible matches pass the predicate `test` (the string ‘foobaz’ is too short). Both of those begin with the string ‘foobar’.

```
(defun test (s)
  (> (length (car s)) 6))
  ⇒ test
```

```
(try-completion
  "foo"
  '(("foobar1" 1) ("barfoo" 2) ("foobaz" 3) ("foobar2" 4))
  'test)
  ⇒ "foobar"
```

all-completions *string collection &optional predicate* [Function]

This function returns a list of all possible completions of *string*. The arguments to this function are the same as those of **try-completion**, and it uses **completion-regexp-list** in the same way that **try-completion** does.

If *collection* is a function, it is called with three arguments: *string*, *predicate* and *t*; then **all-completions** returns whatever the function returns. See Section 21.6.7 [Programmed Completion], page 409.

Here is an example, using the function **test** shown in the example for **try-completion**:

```
(defun test (s)
  (> (length (car s)) 6))
  ⇒ test

(all-completions
  "foo"
  '(("foobar1" 1) ("barfoo" 2) ("foobaz" 3) ("foobar2" 4))
  'test)
  ⇒ ("foobar1" "foobar2")
```

test-completion *string collection &optional predicate* [Function]

This function returns non-nil if *string* is a valid completion alternative specified by *collection* and *predicate*. The arguments are the same as in **try-completion**. For instance, if *collection* is a list of strings, this is true if *string* appears in the list and *predicate* is satisfied.

This function uses **completion-regexp-list** in the same way that **try-completion** does.

If *predicate* is non-nil and if *collection* contains several strings that are equal to each other, as determined by **compare-strings** according to **completion-ignore-case**, then *predicate* should accept either all or none of them. Otherwise, the return value of **test-completion** is essentially unpredictable.

If *collection* is a function, it is called with three arguments, the values *string*, *predicate* and *lambda*; whatever it returns, **test-completion** returns in turn.

completion-boundaries *string collection predicate suffix* [Function]

This function returns the boundaries of the field on which *collection* will operate, assuming that *string* holds the text before point and *suffix* holds the text after point.

Normally completion operates on the whole string, so for all normal collections, this will always return (0 . (length *suffix*)). But more complex completion, such as completion on files, is done one field at a time. For example, completion of "/usr/sh" will include "/usr/share/" but not "/usr/share/doc" even if "/usr/share/doc" exists. Also **all-completions** on "/usr/sh" will not include "/usr/share/" but only "share/". So if *string* is "/usr/sh" and *suffix* is "e/doc", **completion-boundaries** will return (5 . 1) which tells us that the *collection* will only return completion information that pertains to the area after "/usr/" and before "/doc". **try-completion**

is not affected by nontrivial boundaries; e.g., `try-completion` on `"/usr/sh"` might still return `"/usr/share/",` not `"share/"`.

If you store a completion alist in a variable, you should mark the variable as risky by giving it a non-`nil` `risky-local-variable` property. See Section 12.12 [File Local Variables], page 213.

completion-ignore-case

[Variable]

If the value of this variable is `non-nil`, case is not considered significant in completion. Within `read-file-name`, this variable is overridden by `read-file-name-completion-ignore-case` (see Section 21.6.5 [Reading File Names], page 404); within `read-buffer`, it is overridden by `read-buffer-completion-ignore-case` (see Section 21.6.4 [High-Level Completion], page 402).

completion-regexp-list

[Variable]

This is a list of regular expressions. The completion functions only consider a completion acceptable if it matches all regular expressions in this list, with `case-fold-search` (see Section 35.2 [Searching and Case], page 995) bound to the value of `completion-ignore-case`.

Do not set this variable to a `non-nil` value globally, as that is not safe and will probably cause errors in completion commands. This variable should be only let-bound to `non-nil` values around calls to basic completion functions: `try-completion`, `test-completion`, and `all-completions`.

lazy-completion-table var fun

[Macro]

This macro provides a way to initialize the variable `var` as a collection for completion in a lazy way, not computing its actual contents until they are first needed. You use this macro to produce a value that you store in `var`. The actual computation of the proper value is done the first time you do completion using `var`. It is done by calling `fun` with no arguments. The value `fun` returns becomes the permanent value of `var`.

Here is an example:

```
(defvar foo (lazy-completion-table foo make-my-alist))
```

There are several functions that take an existing completion table and return a modified version. `completion-table-case-fold` returns a case-insensitive table. `completion-table-in-turn` and `completion-table-merge` combine multiple input tables in different ways. `completion-table-subvert` alters a table to use a different initial prefix. `completion-table-with-quoting` returns a table suitable for operating on quoted text. `completion-table-with-predicate` filters a table with a predicate function. `completion-table-with-terminator` adds a terminating string.

21.6.2 Completion and the Minibuffer

This section describes the basic interface for reading from the minibuffer with completion.

completing-read prompt collection &optional predicate

[Function]

require-match initial history default inherit-input-method

This function reads a string in the minibuffer, assisting the user by providing completion. It activates the minibuffer with prompt `prompt`, which must be a string.

The actual completion is done by passing the completion table *collection* and the completion predicate *predicate* to the function `try-completion` (see Section 21.6.1 [Basic Completion], page 395). This happens in certain commands bound in the local keymaps used for completion. Some of these commands also call `test-completion`. Thus, if *predicate* is non-`nil`, it should be compatible with *collection* and `completion-ignore-case`. See [Definition of test-completion], page 397.

See Section 21.6.7 [Programmed Completion], page 409, for detailed requirements when *collection* is a function.

The value of the optional argument *require-match* determines how the user may exit the minibuffer:

- If `nil`, the usual minibuffer exit commands work regardless of the input in the minibuffer.
- If `t`, the usual minibuffer exit commands won't exit unless the input completes to an element of *collection*.
- If `confirm`, the user can exit with any input, but is asked for confirmation if the input is not an element of *collection*.
- If `confirm-after-completion`, the user can exit with any input, but is asked for confirmation if the preceding command was a completion command (i.e., one of the commands in `minibuffer-confirm-exit-commands`) and the resulting input is not an element of *collection*. See Section 21.6.3 [Completion Commands], page 400.
- If a function, it is called with the input as the only argument. The function should return a non-`nil` value if the input is acceptable.
- Any other value of *require-match* behaves like `t`, except that the exit commands won't exit if it performs completion.

However, empty input is always permitted, regardless of the value of *require-match*; in that case, `completing-read` returns the first element of *default*, if it is a list; "", if *default* is `nil`; or *default*. The string or strings in *default* are also available to the user through the history commands (see Section 21.10 [Minibuffer Commands], page 417). In addition, the completion candidates are added to the “future history” when the values in *default* are exhausted by `M-n`; see Section 21.4 [minibuffer-default-add-function], page 392.

The function `completing-read` uses `minibuffer-local-completion-map` as the keymap if *require-match* is `nil`, and uses `minibuffer-local-must-match-map` if *require-match* is non-`nil`. See Section 21.6.3 [Completion Commands], page 400.

The argument *history* specifies which history list variable to use for saving the input and for minibuffer history commands. It defaults to `minibuffer-history`. If *history* is the symbol `t`, history is not recorded. See Section 21.4 [Minibuffer History], page 392.

The argument *initial* is mostly deprecated; we recommend using a non-`nil` value only in conjunction with specifying a cons cell for *history*. See Section 21.5 [Initial Input], page 394. For default input, use *default* instead.

If the argument *inherit-input-method* is non-`nil`, then the minibuffer inherits the current input method (see Section 34.11 [Input Methods], page 990) and the setting of

`enable-multibyte-characters` (see Section 34.1 [Text Representations], page 963) from whichever buffer was current before entering the minibuffer.

If the variable `completion-ignore-case` is non-`nil`, completion ignores case when comparing the input against the possible matches. See Section 21.6.1 [Basic Completion], page 395. In this mode of operation, `predicate` must also ignore case, or you will get surprising results.

Here's an example of using `completing-read`:

```
(completing-read
  "Complete a foo: "
  '(("foobar1" 1) ("barfoo" 2) ("foobaz" 3) ("foobar2" 4))
  nil t "fo")
;; After evaluation of the preceding expression,
;;   the following appears in the minibuffer:
----- Buffer: Minibuffer -----
Complete a foo: fo*
----- Buffer: Minibuffer -----
```

If the user then types `DEL DEL b RET`, `completing-read` returns `barfoo`.

The `completing-read` function binds variables to pass information to the commands that actually do completion. They are described in the following section.

`completing-read-function`

[Variable]

The value of this variable must be a function, which is called by `completing-read` to actually do its work. It should accept the same arguments as `completing-read`. This can be bound to a different function to completely override the normal behavior of `completing-read`.

21.6.3 Minibuffer Commands that Do Completion

This section describes the keymaps, commands and user options used in the minibuffer to do completion.

`minibuffer-completion-table`

[Variable]

The value of this variable is the completion table (see Section 21.6.1 [Basic Completion], page 395) used for completion in the minibuffer. This is the buffer-local variable that contains what `completing-read` passes to `try-completion`. It is used by minibuffer completion commands such as `minibuffer-complete`.

`minibuffer-completion-predicate`

[Variable]

This variable's value is the predicate that `completing-read` passes to `try-completion`. The variable is also used by the other minibuffer completion functions.

`minibuffer-completion-confirm`

[Variable]

This variable determines whether Emacs asks for confirmation before exiting the minibuffer; `completing-read` sets this variable, and the function `minibuffer-complete-and-exit` checks the value before exiting. If the value is `nil`, confirmation is not required. If the value is `confirm`, the user may exit with an input that is not a valid completion alternative, but Emacs asks for confirmation. If the value is

`confirm-after-completion`, the user may exit with an input that is not a valid completion alternative, but Emacs asks for confirmation if the user submitted the input right after any of the completion commands in `minibuffer-confirm-exit-commands`.

minibuffer-confirm-exit-commands [Variable]

This variable holds a list of commands that cause Emacs to ask for confirmation before exiting the minibuffer, if the `require-match` argument to `completing-read` is `confirm-after-completion`. The confirmation is requested if the user attempts to exit the minibuffer immediately after calling any command in this list.

minibuffer-complete-word [Command]

This function completes the minibuffer contents by at most a single word. Even if the minibuffer contents have only one completion, `minibuffer-complete-word` does not add any characters beyond the first character that is not a word constituent. See Chapter 36 [Syntax Tables], page 1022.

minibuffer-complete [Command]

This function completes the minibuffer contents as far as possible.

minibuffer-complete-and-exit [Command]

This function completes the minibuffer contents, and exits if confirmation is not required, i.e., if `minibuffer-completion-confirm` is `nil`. If confirmation *is* required, it is given by repeating this command immediately—the command is programmed to work without confirmation when run twice in succession.

minibuffer-completion-help [Command]

This function creates a list of the possible completions of the current minibuffer contents. It works by calling `all-completions` using the value of the variable `minibuffer-completion-table` as the `collection` argument, and the value of `minibuffer-completion-predicate` as the `predicate` argument. The list of completions is displayed as text in a buffer named `*Completions*`.

display-completion-list *completions* [Function]

This function displays *completions* to the stream in `standard-output`, usually a buffer. (See Chapter 20 [Read and Print], page 371, for more information about streams.) The argument *completions* is normally a list of completions just returned by `all-completions`, but it does not have to be. Each element may be a symbol or a string, either of which is simply printed. It can also be a list of two strings, which is printed as if the strings were concatenated. The first of the two strings is the actual completion, the second string serves as annotation.

This function is called by `minibuffer-completion-help`. A common way to use it is together with `with-output-to-temp-buffer`, like this:

```
(with-output-to-temp-buffer "*Completions*"
  (display-completion-list
    (all-completions (buffer-string) my-alist)))
```

completion-auto-help [User Option]

If this variable is non-`nil`, the completion commands automatically display a list of possible completions whenever nothing can be completed because the next character is not uniquely determined.

minibuffer-local-completion-map [Variable]

`completing-read` uses this value as the local keymap when an exact match of one of the completions is not required. By default, this keymap makes the following bindings:

?	<code>minibuffer-completion-help</code>
SPC	<code>minibuffer-complete-word</code>
TAB	<code>minibuffer-complete</code>

and uses `minibuffer-local-map` as its parent keymap (see [Definition of minibuffer-local-map], page 389).

minibuffer-local-must-match-map [Variable]

`completing-read` uses this value as the local keymap when an exact match of one of the completions is required. Therefore, no keys are bound to `exit-minibuffer`, the command that exits the minibuffer unconditionally. By default, this keymap makes the following bindings:

<i>C-j</i>	<code>minibuffer-complete-and-exit</code>
RET	<code>minibuffer-complete-and-exit</code>

and uses `minibuffer-local-completion-map` as its parent keymap.

minibuffer-local-filename-completion-map [Variable]

This is a sparse keymap that simply unbinds SPC; because filenames can contain spaces. The function `read-file-name` combines this keymap with either `minibuffer-local-completion-map` or `minibuffer-local-must-match-map`.

minibuffer-beginning-of-buffer-movement [Variable]

If non-*nil*, the `M-<` command will move to the end of the prompt if point is after the end of the prompt. If point is at or before the end of the prompt, move to the start of the buffer. If this variable is *nil*, the command behaves like `beginning-of-buffer`.

21.6.4 High-Level Completion Functions

This section describes the higher-level convenience functions for reading certain sorts of names with completion.

In most cases, you should not call these functions in the middle of a Lisp function. When possible, do all minibuffer input as part of reading the arguments for a command, in the `interactive` specification. See Section 22.2 [Defining Commands], page 424.

read-buffer *prompt* &*optional default require-match predicate* [Function]

This function reads the name of a buffer and returns it as a string. It prompts with *prompt*. The argument *default* is the default name to use, the value to return if the user exits with an empty minibuffer. If non-*nil*, it should be a string, a list of strings, or a buffer. If it is a list, the default value is the first element of this list. It is mentioned in the prompt, but is not inserted in the minibuffer as initial input.

The argument *prompt* should be a string ending with a colon and a space. If *default* is non-*nil*, the function inserts it in *prompt* before the colon to follow the convention for reading from the minibuffer with a default value (see Section D.3 [Programming Tips], page 1335).

The optional argument `require-match` has the same meaning as in `completing-read`. See Section 21.6.2 [Minibuffer Completion], page 398.

The optional argument `predicate`, if non-`nil`, specifies a function to filter the buffers that should be considered: the function will be called with every potential candidate as its argument, and should return `nil` to reject the candidate, non-`nil` to accept it. In the following example, the user enters ‘`minibuffer.t`’, and then types RET. The argument `require-match` is `t`, and the only buffer name starting with the given input is ‘`minibuffer.texi`’, so that name is the value.

```
(read-buffer "Buffer name: " "foo" t)
;; After evaluation of the preceding expression,
;;   the following prompt appears,
;;   with an empty minibuffer:

----- Buffer: Minibuffer -----
Buffer name (default foo): *
----- Buffer: Minibuffer -----

;; The user types minibuffer.t RET.
⇒ "minibuffer.texi"
```

read-buffer-function

[User Option]

This variable, if non-`nil`, specifies a function for reading buffer names. `read-buffer` calls this function instead of doing its usual work, with the same arguments passed to `read-buffer`.

read-buffer-completion-ignore-case

[User Option]

If this variable is non-`nil`, `read-buffer` ignores case when performing completion while reading the buffer name.

read-command prompt &optional default

[Function]

This function reads the name of a command and returns it as a Lisp symbol. The argument `prompt` is used as in `read-from-minibuffer`. Recall that a command is anything for which `commandp` returns `t`, and a command name is a symbol for which `commandp` returns `t`. See Section 22.3 [Interactive Call], page 432.

The argument `default` specifies what to return if the user enters null input. It can be a symbol, a string or a list of strings. If it is a string, `read-command` interns it before returning it. If it is a list, `read-command` interns the first element of this list. If `default` is `nil`, that means no default has been specified; then if the user enters null input, the return value is `(intern "")`, that is, a symbol whose name is an empty string, and whose printed representation is `##` (see Section 2.4.4 [Symbol Type], page 14).

```
(read-command "Command name? ")

;; After evaluation of the preceding expression,
;;   the following prompt appears with an empty minibuffer:

----- Buffer: Minibuffer -----
Command name?
----- Buffer: Minibuffer -----
```

If the user types `forward-c` RET, then this function returns `forward-char`.

The `read-command` function is a simplified interface to `completing-read`. It uses the variable `obarray` so as to complete in the set of extant Lisp symbols, and it uses the `commandp` predicate so as to accept only command names:

```
(read-command prompt)
≡
(intern (completing-read prompt obarray
                           'commandp t nil))
```

`read-variable` *prompt* &`optional` *default* [Function]

This function reads the name of a customizable variable and returns it as a symbol. Its arguments have the same form as those of `read-command`. It behaves just like `read-command`, except that it uses the predicate `custom-variable-p` instead of `commandp`.

`read-color` &`optional` *prompt* `convert` `allow-empty` *display* [Command]

This function reads a string that is a color specification, either the color's name or an RGB hex value such as `#RRRGGBBB`. It prompts with *prompt* (default: "Color (name or #RGB triplet):") and provides completion for color names, but not for hex RGB values. In addition to names of standard colors, completion candidates include the foreground and background colors at point.

Valid RGB values are described in Section 30.23 [Color Names], page 846.

The function's return value is the string typed by the user in the minibuffer. However, when called interactively or if the optional argument `convert` is non-`nil`, it converts any input color name into the corresponding RGB value string and instead returns that. This function requires a valid color specification to be input. Empty color names are allowed when `allow-empty` is non-`nil` and the user enters null input.

Interactively, or when *display* is non-`nil`, the return value is also displayed in the echo area.

See also the functions `read-coding-system` and `read-non-nil-coding-system`, in Section 34.10.4 [User-Chosen Coding Systems], page 982, and `read-input-method-name`, in Section 34.11 [Input Methods], page 990.

21.6.5 Reading File Names

The high-level completion functions `read-file-name`, `read-directory-name`, and `read-shell-command` are designed to read file names, directory names, and shell commands, respectively. They provide special features, including automatic insertion of the default directory.

`read-file-name` *prompt* &`optional` *directory* *default* `require-match` [Function] *initial predicate*

This function reads a file name, prompting with *prompt* and providing completion.

As an exception, this function reads a file name using a graphical file dialog instead of the minibuffer, if all of the following are true:

1. It is invoked via a mouse command.

2. The selected frame is on a graphical display supporting such dialogs.
3. The variable `use-dialog-box` is non-`nil`. See Section “Dialog Boxes” in *The GNU Emacs Manual*.
4. The `directory` argument, described below, does not specify a remote file. See Section “Remote Files” in *The GNU Emacs Manual*.

The exact behavior when using a graphical file dialog is platform-dependent. Here, we simply document the behavior when using the minibuffer.

`read-file-name` does not automatically expand the returned file name. You can call `expand-file-name` yourself if an absolute file name is required.

The optional argument `require-match` has the same meaning as in `completing-read`. See Section 21.6.2 [Minibuffer Completion], page 398.

The argument `directory` specifies the directory to use for completing relative file names. It should be an absolute directory name. If the variable `insert-default-directory` is non-`nil`, `directory` is also inserted in the minibuffer as initial input. It defaults to the current buffer’s value of `default-directory`.

If you specify `initial`, that is an initial file name to insert in the buffer (after `directory`, if that is inserted). In this case, point goes at the beginning of `initial`. The default for `initial` is `nil`—don’t insert any file name. To see what `initial` does, try the command `C-x C-v` in a buffer visiting a file. **Please note:** we recommend using `default` rather than `initial` in most cases.

If `default` is non-`nil`, then the function returns `default` if the user exits the minibuffer with the same non-empty contents that `read-file-name` inserted initially. The initial minibuffer contents are always non-empty if `insert-default-directory` is non-`nil`, as it is by default. `default` is not checked for validity, regardless of the value of `require-match`. However, if `require-match` is non-`nil`, the initial minibuffer contents should be a valid file (or directory) name. Otherwise `read-file-name` attempts completion if the user exits without any editing, and does not return `default`. `default` is also available through the history commands.

If `default` is `nil`, `read-file-name` tries to find a substitute default to use in its place, which it treats in exactly the same way as if it had been specified explicitly. If `default` is `nil`, but `initial` is non-`nil`, then the default is the absolute file name obtained from `directory` and `initial`. If both `default` and `initial` are `nil` and the buffer is visiting a file, `read-file-name` uses the absolute file name of that file as default. If the buffer is not visiting a file, then there is no default. In that case, if the user types RET without any editing, `read-file-name` simply returns the pre-inserted contents of the minibuffer.

If the user types RET in an empty minibuffer, this function returns an empty string, regardless of the value of `require-match`. This is, for instance, how the user can make the current buffer visit no file using `M-x set-visisted-file-name`.

If `predicate` is non-`nil`, it specifies a function of one argument that decides which file names are acceptable completion alternatives. A file name is an acceptable value if `predicate` returns non-`nil` for it.

Here is an example of using `read-file-name`:

```
(read-file-name "The file is ")

;; After evaluation of the preceding expression,
;; the following appears in the minibuffer:

----- Buffer: Minibuffer -----
The file is /gp/gnu/elisp/*
----- Buffer: Minibuffer -----
```

Typing *manual* TAB results in the following:

```
----- Buffer: Minibuffer -----
The file is /gp/gnu/elisp/manual.texi*
----- Buffer: Minibuffer -----
```

If the user types RET, `read-file-name` returns the file name as the string `"/gp/gnu/elisp/manual.texi"`.

`read-file-name-function`

[Variable]

If non-nil, this should be a function that accepts the same arguments as `read-file-name`. When `read-file-name` is called, it calls this function with the supplied arguments instead of doing its usual work.

`read-file-name-completion-ignore-case`

[User Option]

If this variable is non-nil, `read-file-name` ignores case when performing completion.

`read-directory-name prompt &optional directory default`

[Function]

`require-match initial`

This function is like `read-file-name` but allows only directory names as completion alternatives.

If `default` is nil and `initial` is non-nil, `read-directory-name` constructs a substitute default by combining `directory` (or the current buffer's default directory if `directory` is nil) and `initial`. If both `default` and `initial` are nil, this function uses `directory` as substitute default, or the current buffer's default directory if `directory` is nil.

`insert-default-directory`

[User Option]

This variable is used by `read-file-name`, and thus, indirectly, by most commands reading file names. (This includes all commands that use the code letters 'f' or 'F' in their interactive form. See Section 22.2.2 [Code Characters for interactive], page 427.) Its value controls whether `read-file-name` starts by placing the name of the default directory in the minibuffer, plus the initial file name, if any. If the value of this variable is nil, then `read-file-name` does not place any initial input in the minibuffer (unless you specify initial input with the `initial` argument). In that case, the default directory is still used for completion of relative file names, but is not displayed.

If this variable is nil and the initial minibuffer contents are empty, the user may have to explicitly fetch the next history element to access a default value. If the variable is non-nil, the initial minibuffer contents are always non-empty and the user can always request a default value by immediately typing RET in an unedited minibuffer. (See above.)

For example:

```
; ; Here the minibuffer starts out with the default directory.
(let ((insert-default-directory t))
  (read-file-name "The file is ")

----- Buffer: Minibuffer -----
The file is ~lewis/manual/*
----- Buffer: Minibuffer -----

; ; Here the minibuffer is empty and only the prompt
; ; appears on its line.
(let ((insert-default-directory nil))
  (read-file-name "The file is ")

----- Buffer: Minibuffer -----
The file is *
----- Buffer: Minibuffer -----
```

read-shell-command *prompt* &**optional** *initial history &rest args* [Function]

This function reads a shell command from the minibuffer, prompting with *prompt* and providing intelligent completion. It completes the first word of the command using candidates that are appropriate for command names, and the rest of the command words as file names.

This function uses `minibuffer-local-shell-command-map` as the keymap for minibuffer input. The *history* argument specifies the history list to use; if is omitted or `nil`, it defaults to `shell-command-history` (see Section 21.4 [Minibuffer History], page 392). The optional argument *initial* specifies the initial content of the minibuffer (see Section 21.5 [Initial Input], page 394). The rest of *args*, if present, are used as the *default* and *inherit-input-method* arguments in `read-from-minibuffer` (see Section 21.2 [Text from Minibuffer], page 386).

minibuffer-local-shell-command-map [Variable]

This keymap is used by `read-shell-command` for completing command and file names that are part of a shell command. It uses `minibuffer-local-map` as its parent keymap, and binds TAB to `completion-at-point`.

21.6.6 Completion Variables

Here are some variables that can be used to alter the default completion behavior.

completion-styles [User Option]

The value of this variable is a list of completion style (symbols) to use for performing completion. A *completion style* is a set of rules for generating completions. Each symbol occurring this list must have a corresponding entry in `completion-styles-alist`.

completion-styles-alist [Variable]

This variable stores a list of available completion styles. Each element in the list has the form

```
(style try-completion all-completions doc)
```

Here, *style* is the name of the completion style (a symbol), which may be used in the `completion-styles` variable to refer to this style; *try-completion* is the function that does the completion; *all-completions* is the function that lists the completions; and *doc* is a string describing the completion style.

The *try-completion* and *all-completions* functions should each accept four arguments: *string*, *collection*, *predicate*, and *point*. The *string*, *collection*, and *predicate* arguments have the same meanings as in `try-completion` (see Section 21.6.1 [Basic Completion], page 395), and the *point* argument is the position of point within *string*. Each function should return a non-`nil` value if it performed its job, and `nil` if it did not (e.g., if there is no way to complete *string* according to the completion style).

When the user calls a completion command like `minibuffer-complete` (see Section 21.6.3 [Completion Commands], page 400), Emacs looks for the first style listed in `completion-styles` and calls its *try-completion* function. If this function returns `nil`, Emacs moves to the next listed completion style and calls its *try-completion* function, and so on until one of the *try-completion* functions successfully performs completion and returns a non-`nil` value. A similar procedure is used for listing completions, via the *all-completions* functions.

See Section “Completion Styles” in *The GNU Emacs Manual*, for a description of the available completion styles.

`completion-category-overrides`

[User Option]

This variable specifies special completion styles and other completion behaviors to use when completing certain types of text. Its value should be an alist with elements of the form `(category . alist)`. *category* is a symbol describing what is being completed; currently, the `buffer`, `file`, and `unicode-name` categories are defined, but others can be defined via specialized completion functions (see Section 21.6.7 [Programmed Completion], page 409). *alist* is an association list describing how completion should behave for the corresponding category. The following alist keys are supported:

styles The value should be a list of completion styles (symbols).

cycle The value should be a value for `completion-cycle-threshold` (see Section “Completion Options” in *The GNU Emacs Manual*) for this category.

Additional alist entries may be defined in the future.

`completion-extra-properties`

[Variable]

This variable is used to specify extra properties of the current completion command. It is intended to be let-bound by specialized completion commands. Its value should be a list of property and value pairs. The following properties are supported:

`:annotation-function`

The value should be a function to add annotations in the completions buffer. This function must accept one argument, a completion, and should either return `nil` or a string to be displayed next to the completion. Unless this function puts own face on the annotation suffix string, the `completions-annotations` face is added by default to that string.

:affixation-function

The value should be a function to add prefixes and suffixes to completions. This function must accept one argument, a list of completions, and should return a list of annotated completions. Each element of the returned list must be a three-element list, the completion, a prefix string, and a suffix string. This function takes priority over **:annotation-function**.

:exit-function

The value should be a function to run after performing completion. The function should accept two arguments, *string* and *status*, where *string* is the text to which the field was completed, and *status* indicates what kind of operation happened: **finished** if text is now complete, **sole** if the text cannot be further completed but completion is not finished, or **exact** if the text is a valid completion but may be further completed.

21.6.7 Programmed Completion

Sometimes it is not possible or convenient to create an alist or an obarray containing all the intended possible completions ahead of time. In such a case, you can supply your own function to compute the completion of a given string. This is called *programmed completion*. Emacs uses programmed completion when completing file names (see Section 26.9.6 [File Name Completion], page 643), among many other cases.

To use this feature, pass a function as the *collection* argument to **completing-read**. The function **completing-read** arranges to pass your completion function along to **try-completion**, **all-completions**, and other basic completion functions, which will then let your function do all the work.

The completion function should accept three arguments:

- The string to be completed.
- A predicate function with which to filter possible matches, or **nil** if none. The function should call the predicate for each possible match, and ignore the match if the predicate returns **nil**.
- A flag specifying the type of completion operation to perform; see Section 21.6.1 [Basic Completion], page 395, for the details of those operations. This flag may be one of the following values.

nil This specifies a **try-completion** operation. The function should return **nil** if there are no matches; it should return **t** if the specified string is a unique and exact match; and it should return the longest common prefix substring of all matches otherwise.

t This specifies an **all-completions** operation. The function should return a list of all possible completions of the specified string.

lambda This specifies a **test-completion** operation. The function should return **t** if the specified string is an exact match for some completion alternative; **nil** otherwise.

(boundaries . suffix)

This specifies a **completion-boundaries** operation. The function should return **(boundaries start . end)**, where *start* is the position of the begin-

ning boundary in the specified string, and *end* is the position of the end boundary in *suffix*.

If a Lisp program returns nontrivial boundaries, it should make sure that the `all-completions` operation is consistent with them. The completions returned by `all-completions` should only pertain to the piece of the prefix and suffix covered by the completion boundaries. See Section 21.6.1 [Basic Completion], page 395, for the precise expected semantics of completion boundaries.

- metadata** This specifies a request for information about the state of the current completion. The return value should have the form `(metadata . alist)`, where *alist* is an alist whose elements are described below.

If the flag has any other value, the completion function should return `nil`.

The following is a list of metadata entries that a completion function may return in response to a `metadata` flag argument:

- category** The value should be a symbol describing what kind of text the completion function is trying to complete. If the symbol matches one of the keys in `completion-category-overrides`, the usual completion behavior is overridden. See Section 21.6.6 [Completion Variables], page 407.

annotation-function

The value should be a function for *annotating* completions. The function should take one argument, *string*, which is a possible completion. It should return a string, which is displayed after the completion *string* in the `*Completions*` buffer. Unless this function puts own face on the annotation suffix string, the `completions-annotations` face is added by default to that string.

affixation-function

The value should be a function for adding prefixes and suffixes to completions. The function should take one argument, *completions*, which is a list of possible completions. It should return such a list of *completions* where each element contains a list of three elements: a completion, a prefix which is displayed before the completion string in the `*Completions*` buffer, and a suffix displayed after the completion string. This function takes priority over `annotation-function`.

group-function

The value should be a function for grouping the completion candidates. The function must take two arguments, *completion*, which is a completion candidate and *transform*, which is a boolean flag. If *transform* is `nil`, the function must return the group title of the group to which the candidate belongs. The returned title can also be `nil`. Otherwise the function must return the transformed candidate. The transformation can for example remove a redundant prefix, which is displayed in the group title.

display-sort-function

The value should be a function for sorting completions. The function should take one argument, a list of completion strings, and return a sorted list of completion strings. It is allowed to alter the input list destructively.

cycle-sort-function

The value should be a function for sorting completions, when `completion-cycle-threshold` is non-`nil` and the user is cycling through completion alternatives. See Section “Completion Options” in *The GNU Emacs Manual*. Its argument list and return value are the same as for `display-sort-function`.

completion-table-dynamic *function &optional switch-buffer* [Function]

This function is a convenient way to write a function that can act as a programmed completion function. The argument *function* should be a function that takes one argument, a string, and returns a completion table (see Section 21.6.1 [Basic Completion], page 395) containing all the possible completions. The table returned by *function* can also include elements that don’t match the string argument; they are automatically filtered out by `completion-table-dynamic`. In particular, *function* can ignore its argument and return a full list of all possible completions. You can think of `completion-table-dynamic` as a transducer between *function* and the interface for programmed completion functions.

If the optional argument *switch-buffer* is non-`nil`, and completion is performed in the minibuffer, *function* will be called with current buffer set to the buffer from which the minibuffer was entered.

The return value of `completion-table-dynamic` is a function that can be used as the 2nd argument to `try-completion` and `all-completions`. Note that this function will always return empty metadata and trivial boundaries.

completion-table-with-cache *function &optional ignore-case* [Function]

This is a wrapper for `completion-table-dynamic` that saves the last argument-result pair. This means that multiple lookups with the same argument only need to call *function* once. This can be useful when a slow operation is involved, such as calling an external process.

21.6.8 Completion in Ordinary Buffers

Although completion is usually done in the minibuffer, the completion facility can also be used on the text in ordinary Emacs buffers. In many major modes, in-buffer completion is performed by the `C-M-i` or `M-TAB` command, bound to `completion-at-point`. See Section “Symbol Completion” in *The GNU Emacs Manual*. This command uses the abnormal hook variable `completion-at-point-functions`:

completion-at-point-functions [Variable]

The value of this abnormal hook should be a list of functions, which are used to compute a completion table (see Section 21.6.1 [Basic Completion], page 395) for completing the text at point. It can be used by major modes to provide mode-specific completion tables (see Section 24.2.1 [Major Mode Conventions], page 528).

When the command `completion-at-point` runs, it calls the functions in the list one by one, without any argument. Each function should return `nil` unless it can and wants to take responsibility for the completion data for the text at point. Otherwise it should return a list of the following form:

```
(start end collection . props)
```

start and *end* delimit the text to complete (which should enclose point). *collection* is a completion table for completing that text, in a form suitable for passing as the second argument to `try-completion` (see Section 21.6.1 [Basic Completion], page 395); completion alternatives will be generated from this completion table in the usual way, via the completion styles defined in `completion-styles` (see Section 21.6.6 [Completion Variables], page 407). *props* is a property list for additional information; any of the properties in `completion-extra-properties` are recognized (see Section 21.6.6 [Completion Variables], page 407), as well as the following additional ones:

:predicate

The value should be a predicate that completion candidates need to satisfy.

:exclusive

If the value is `no`, then if the completion table fails to match the text at point, `completion-at-point` moves on to the next function in `completion-at-point-functions` instead of reporting a completion failure.

The functions on this hook should generally return quickly, since they may be called very often (e.g., from `post-command-hook`). Supplying a function for *collection* is strongly recommended if generating the list of completions is an expensive operation. Emacs may internally call functions in `completion-at-point-functions` many times, but care about the value of *collection* for only some of these calls. By supplying a function for *collection*, Emacs can defer generating completions until necessary. You can use `completion-table-dynamic` to create a wrapper function:

```
;; Avoid this pattern.
(let ((beg ...) (end ...) (my-completions (my-make-completions)))
  (list beg end my-completions))

;; Use this instead.
(let ((beg ...) (end ...))
  (list beg
        end
        (completion-table-dynamic
         (lambda (_)
           (my-make-completions)))))
```

Additionally, the *collection* should generally not be pre-filtered based on the current text between *start* and *end*, because that is the responsibility of the caller of `completion-at-point-functions` to do that according to the completion styles it decides to use.

A function in `completion-at-point-functions` may also return a function instead of a list as described above. In that case, that returned function is called, with no argument, and it is entirely responsible for performing the completion. We discourage this usage; it is only intended to help convert old code to using `completion-at-point`.

The first function in `completion-at-point-functions` to return a non-`nil` value is used by `completion-at-point`. The remaining functions are not called. The exception to this is when there is an `:exclusive` specification, as described above.

The following function provides a convenient way to perform completion on an arbitrary stretch of text in an Emacs buffer:

completion-in-region *start end collection &optional predicate* [Function]

This function completes the text in the current buffer between the positions *start* and *end*, using *collection*. The argument *collection* has the same meaning as in **try-completion** (see Section 21.6.1 [Basic Completion], page 395).

This function inserts the completion text directly into the current buffer. Unlike **completing-read** (see Section 21.6.2 [Minibuffer Completion], page 398), it does not activate the minibuffer.

For this function to work, point must be somewhere between *start* and *end*.

21.7 Yes-or-No Queries

This section describes functions used to ask the user a yes-or-no question. The function **y-or-n-p** can be answered with a single character; it is useful for questions where an inadvertent wrong answer will not have serious consequences. **yes-or-no-p** is suitable for more momentous questions, since it requires three or four characters to answer.

If either of these functions is called in a command that was invoked using the mouse or some other window-system gesture, or in a command invoked via a menu, then they use a dialog box or pop-up menu to ask the question if dialog boxes are supported. Otherwise, they use keyboard input. You can force use either of the mouse or of keyboard input by binding **last-nonmenu-event** to a suitable value around the call—bind it to **t** to force keyboard interaction, and to a list to force dialog boxes.

Both **yes-or-no-p** and **y-or-n-p** use the minibuffer.

y-or-n-p *prompt* [Function]

This function asks the user a question, expecting input in the minibuffer. It returns **t** if the user types **y**, **nil** if the user types **n**. This function also accepts SPC to mean yes and DEL to mean no. It accepts **C-J** and **C-g** to quit, because the question uses the minibuffer and for that reason the user might try to use **C-J** to get out. The answer is a single character, with no RET needed to terminate it. Upper and lower case are equivalent.

“Asking the question” means printing *prompt* in the minibuffer, followed by the string ‘**(y or n)**’. If the input is not one of the expected answers (**y**, **n**, SPC, DEL, or something that quits), the function responds ‘**Please answer y or n.**’, and repeats the request.

This function actually uses the minibuffer, but does not allow editing of the answer. The cursor moves to the minibuffer while the question is being asked.

The answers and their meanings, even ‘**y**’ and ‘**n**’, are not hardwired, and are specified by the keymap **query-replace-map** (see Section 35.7 [Search and Replace], page 1016). In particular, if the user enters the special responses **recenter**, **scroll-up**, **scroll-down**, **scroll-other-window**, or **scroll-other-window-down** (respectively bound to **C-l**, **C-v**, **M-v**, **C-M-v** and **C-M-S-v** in **query-replace-map**), this function performs the specified window recentering or scrolling operation, and poses the question again.

If you bind **help-form** (see Section 25.6 [Help Functions], page 602) to a non-**nil** value while calling **y-or-n-p**, then pressing **help-char** causes it to evaluate **help-form** and display the result. **help-char** is automatically added to *prompt*.

y-or-n-p-with-timeout *prompt seconds default* [Function]

Like `y-or-n-p`, except that if the user fails to answer within `seconds` seconds, this function stops waiting and returns `default`. It works by setting up a timer; see Section 42.11 [Timers], page 1281. The argument `seconds` should be a number.

yes-or-no-p *prompt* [Function]

This function asks the user a question, expecting input in the minibuffer. It returns `t` if the user enters ‘yes’, `nil` if the user types ‘no’. The user must type RET to finalize the response. Upper and lower case are equivalent.

`yes-or-no-p` starts by displaying *prompt* in the minibuffer, followed by ‘(yes or no)’. The user must type one of the expected responses; otherwise, the function responds ‘Please answer yes or no.’, waits about two seconds and repeats the request.

`yes-or-no-p` requires more work from the user than `y-or-n-p` and is appropriate for more crucial decisions.

Here is an example:

```
(yes-or-no-p "Do you really want to remove everything? ")

;; After evaluation of the preceding expression,
;;   the following prompt appears,
;;   with an empty minibuffer:

----- Buffer: minibuffer -----
Do you really want to remove everything? (yes or no)
----- Buffer: minibuffer -----
```

If the user first types `y` RET, which is invalid because this function demands the entire word ‘yes’, it responds by displaying these prompts, with a brief pause between them:

```
----- Buffer: minibuffer -----
Please answer yes or no.
Do you really want to remove everything? (yes or no)
----- Buffer: minibuffer -----
```

21.8 Asking Multiple-Choice Questions

This section describes facilities for asking the user more complex questions or several similar questions.

When you have a series of similar questions to ask, such as “Do you want to save this buffer?” for each buffer in turn, you should use `map-y-or-n-p` to ask the collection of questions, rather than asking each question individually. This gives the user certain convenient facilities such as the ability to answer the whole series at once.

map-y-or-n-p *prompter actor list &optional help action-alist* [Function]
no-cursor-in-echo-area

This function asks the user a series of questions, reading a single-character answer in the echo area for each one.

The value of *list* specifies the objects to ask questions about. It should be either a list of objects or a generator function. If it is a function, it will be called with no arguments, and should return either the next object to ask about, or `nil`, meaning to stop asking questions.

The argument *prompter* specifies how to ask each question. If *prompter* is a string, the question text is computed like this:

`(format prompter object)`

where *object* is the next object to ask about (as obtained from *list*). See Section 4.7 [Formatting Strings], page 66, for more information about `format`.

If *prompter* is not a string, it should be a function of one argument (the object to ask about) and should return the question text for that object. If the value *prompter* returns is a string, that is the question to ask the user. The function can also return `t`, meaning to act on this object without asking the user, or `nil`, which means to silently ignore this object.

The argument *actor* says how to act on the objects for which the user answers yes. It should be a function of one argument, and will be called with each object from *list* for which the user answers yes.

If the argument *help* is given, it should be a list of this form:

`(singular plural action)`

where *singular* is a string containing a singular noun that describes a single object to be acted on, *plural* is the corresponding plural noun, and *action* is a transitive verb describing what *actor* does with the objects.

If you don't specify *help*, it defaults to the list `("object" "objects" "act on")`.

Each time a question is asked, the user can answer as follows:

y, *Y*, or SPC

act on the object

n, *N*, or DEL

skip the object

!

act on all the following objects

ESC or *q*

exit (skip all following objects)

. (period)

act on the object and then exit

C-h

get help

These are the same answers that `query-replace` accepts. The keymap `query-replace-map` defines their meaning for `map-y-or-n-p` as well as for `query-replace`; see Section 35.7 [Search and Replace], page 1016.

You can use *action-alist* to specify additional possible answers and what they mean. If provided, *action-alist* should be an alist whose elements are of the form `(char function help)`. Each of the alist elements defines one additional answer. In each element, *char* is a character (the answer); *function* is a function of one argument (an object from *list*); and *help* is a string. When the user responds with *char*, `map-y-or-n-p` calls *function*. If it returns non-`nil`, the object is considered to have been acted upon, and `map-y-or-n-p` advances to the next object in *list*. If it returns `nil`, the prompt is repeated for the same object. If the user requests help, the text in *help* is used to describe these additional answers.

Normally, `map-y-or-n-p` binds `cursor-in-echo-area` while prompting. But if `no-cursor-in-echo-area` is non-`nil`, it does not do that.

If `map-y-or-n-p` is called in a command that was invoked using the mouse or some other window-system gesture, or a command invoked via a menu, then it uses a dialog box or pop-up menu to ask the question if dialog boxes are supported. In this case, it does not use keyboard input or the echo area. You can force use either of the mouse or of keyboard input by binding `last-nonmenu-event` to a suitable value around the call—bind it to `t` to force keyboard interaction, and to a list to force dialog boxes.

The return value of `map-y-or-n-p` is the number of objects acted on.

If you need to ask the user a question that might have more than just 2 answers, use `read-answer`.

read-answer *question answers*

[Function]

This function prompts the user with text in *question*, which should end in the ‘SPC’ character. The function includes in the prompt the possible responses in *answers* by appending them to the end of *question*. The possible responses are provided in *answers* as an alist whose elements are of the following form:

(*long-answer* *short-answer* *help-message*)

where *long-answer* is the complete text of the user response, a string; *short-answer* is a short form of the same response, a single character or a function key; and *help-message* is the text that describes the meaning of the answer. If the variable `read-answer-short` is non-`nil`, the prompt will show the short variants of the possible answers and the user is expected to type the single characters/keys shown in the prompt; otherwise the prompt will show the long variants of the answers, and the user is expected to type the full text of one of the answers and end by pressing RET. If `use-dialog-box` is non-`nil`, and this function was invoked by mouse events, the question and the answers will be displayed in a GUI dialog box.

The function returns the text of the *long-answer* selected by the user, regardless of whether long or short answers were shown in the prompt and typed by the user.

Here is an example of using this function:

```
(let ((read-answer-short t))
  (read-answer "Foo "
    '(("yes" ?y "perform the action")
      ("no" ?n "skip to the next")
      ("all" ?! "perform for the rest without more questions")
      ("help" ?h "show help")
      ("quit" ?q "exit"))))
```

read-char-from-minibuffer *prompt &optional chars history*

[Function]

This function uses the minibuffer to read and return a single character. Optionally, it ignores any input that is not a member of *chars*, a list of accepted characters. The *history* argument specifies the history list symbol to use; if it is omitted or `nil`, this function doesn’t use the history.

If you bind `help-form` (see Section 25.6 [Help Functions], page 602) to a non-`nil` value while calling `read-char-from-minibuffer`, then pressing `help-char` causes it to evaluate `help-form` and display the result.

21.9 Reading a Password

To read a password to pass to another program, you can use the function `read-passwd`.

read-passwd *prompt* &optional *confirm* *default* [Function]

This function reads a password, prompting with *prompt*. It does not echo the password as the user types it; instead, it echoes '*' for each character in the password. If you want to apply another character to hide the password, let-bind the variable `read-hide-char` with that character.

The optional argument *confirm*, if non-`nil`, says to read the password twice and insist it must be the same both times. If it isn't the same, the user has to type it over and over until the last two times match.

The optional argument *default* specifies the default password to return if the user enters empty input. If *default* is `nil`, then `read-passwd` returns the null string in that case.

21.10 Minibuffer Commands

This section describes some commands meant for use in the minibuffer.

exit-minibuffer [Command]

This command exits the active minibuffer. It is normally bound to keys in minibuffer local keymaps. The command throws an error if the current buffer is a minibuffer, but not the active minibuffer.

self-insert-and-exit [Command]

This command exits the active minibuffer after inserting the last character typed on the keyboard (found in `last-command-event`; see Section 22.5 [Command Loop Info], page 436).

previous-history-element *n* [Command]

This command replaces the minibuffer contents with the value of the *n*th previous (older) history element.

next-history-element *n* [Command]

This command replaces the minibuffer contents with the value of the *n*th more recent history element. The position in the history can go beyond the current position and invoke “future history” (see Section 21.2 [Text from Minibuffer], page 386).

previous-matching-history-element *pattern n* [Command]

This command replaces the minibuffer contents with the value of the *n*th previous (older) history element that matches *pattern* (a regular expression).

next-matching-history-element *pattern n* [Command]

This command replaces the minibuffer contents with the value of the *n*th next (newer) history element that matches *pattern* (a regular expression).

previous-complete-history-element *n* [Command]

This command replaces the minibuffer contents with the value of the *n*th previous (older) history element that completes the current contents of the minibuffer before the point.

next-complete-history-element *n* [Command]

This command replaces the minibuffer contents with the value of the *n*th next (newer) history element that completes the current contents of the minibuffer before the point.

goto-history-element *nabs* [Command]

This function puts element of the minibuffer history in the minibuffer. The argument *nabs* specifies the absolute history position in descending order, where 0 means the current element and a positive number *n* means the *n*th previous element. NABS being a negative number *-n* means the *n*th entry of “future history”. When this function reaches the end of the default values provided by **read-from-minibuffer** (see Section 21.2 [Text from Minibuffer], page 386) and **completing-read** (see Section 21.6.2 [Minibuffer Completion], page 398), it adds the completion candidates to “future history”, see Section 21.4 [minibuffer-default-add-function], page 392.

21.11 Minibuffer Windows

These functions access and select minibuffer windows, test whether they are active and control how they get resized.

minibuffer-window &optional *frame* [Function]

This function returns the minibuffer window used for frame *frame*. If *frame* is **nil**, that stands for the selected frame.

Note that the minibuffer window used by a frame need not be part of that frame—a frame that has no minibuffer of its own necessarily uses some other frame’s minibuffer window. The minibuffer window of a minibuffer-less frame can be changed by setting that frame’s **minibuffer** frame parameter (see Section 30.4.3.5 [Buffer Parameters], page 812).

set-minibuffer-window *window* [Function]

This function specifies *window* as the minibuffer window to use. This affects where the minibuffer is displayed if you put text in it without invoking the usual minibuffer commands. It has no effect on the usual minibuffer input functions because they all start by choosing the minibuffer window according to the selected frame.

window-minibuffer-p &optional *window* [Function]

This function returns **t** if *window* is a minibuffer window. *window* defaults to the selected window.

The following function returns the window showing the currently active minibuffer.

active-minibuffer-window [Function]

This function returns the window of the currently active minibuffer, or **nil** if there is no active minibuffer.

It is not sufficient to determine whether a given window shows the currently active minibuffer by comparing it with the result of (**minibuffer-window**), because there can be more than one minibuffer window if there is more than one frame.

minibuffer-window-active-p *window* [Function]

This function returns non-**nil** if *window* shows the currently active minibuffer.

The following two options control whether minibuffer windows are resized automatically and how large they can get in the process.

resize-mini-windows

[User Option]

This option specifies whether minibuffer windows are resized automatically. The default value is `grow-only`, which means that a minibuffer window by default expands automatically to accommodate the text it displays and shrinks back to one line as soon as the minibuffer gets empty. If the value is `t`, Emacs will always try to fit the height of a minibuffer window to the text it displays (with a minimum of one line). If the value is `nil`, a minibuffer window never changes size automatically. In that case the window resizing commands (see Section 29.5 [Resizing Windows], page 703) can be used to adjust its height.

max-mini-window-height

[User Option]

This option provides a maximum height for resizing minibuffer windows automatically. A floating-point number specifies the maximum height as a fraction of the frame's height; an integer specifies the maximum height in units of the frame's canonical character height (see Section 30.3.2 [Frame Font], page 797). The default value is 0.25.

Note that the values of the above two variables take effect at display time, so let-binding them around code which produces echo-area messages will not work. If you want to prevent resizing of minibuffer windows when displaying long messages, bind the `message-truncate-lines` variable instead (see Section 41.4.4 [Echo Area Customization], page 1138).

The option `resize-mini-windows` does not affect the behavior of minibuffer-only frames (see Section 30.3.1 [Frame Layout], page 791). The following option allows to automatically resize such frames as well.

resize-mini-frames

[User Option]

If this is `nil`, minibuffer-only frames are never resized automatically.

If this is a function, that function is called with the minibuffer-only frame to be resized as sole argument. At the time this function is called, the buffer of the minibuffer window of that frame is the buffer whose contents will be shown the next time that window is redisplayed. The function is expected to fit the frame to the buffer in some appropriate way.

Any other non-`nil` value means to resize minibuffer-only frames by calling `fit-mini-frame-to-buffer`, a function that behaves like `fit-frame-to-buffer` (see Section 29.5 [Resizing Windows], page 703) but does not strip leading or trailing empty lines from the buffer text.

21.12 Minibuffer Contents

These functions access the minibuffer prompt and contents.

minibuffer-prompt

[Function]

This function returns the prompt string of the currently active minibuffer. If no minibuffer is active, it returns `nil`.

minibuffer-prompt-end

[Function]

This function returns the current position of the end of the minibuffer prompt, if a minibuffer is current. Otherwise, it returns the minimum valid buffer position.

minibuffer-prompt-width [Function]

This function returns the current display-width of the minibuffer prompt, if a minibuffer is current. Otherwise, it returns zero.

minibuffer-contents [Function]

This function returns the editable contents of the minibuffer (that is, everything except the prompt) as a string, if a minibuffer is current. Otherwise, it returns the entire contents of the current buffer.

minibuffer-contents-no-properties [Function]

This is like `minibuffer-contents`, except that it does not copy text properties, just the characters themselves. See Section 33.19 [Text Properties], page 917.

delete-minibuffer-contents [Command]

This command erases the editable contents of the minibuffer (that is, everything except the prompt), if a minibuffer is current. Otherwise, it erases the entire current buffer.

21.13 Recursive Minibuffers

These functions and variables deal with recursive minibuffers (see Section 22.13 [Recursive Editing], page 475):

minibuffer-depth [Function]

This function returns the current depth of activations of the minibuffer, a nonnegative integer. If no minibuffers are active, it returns zero.

enable-recursive-minibuffers [User Option]

If this variable is non-`nil`, you can invoke commands (such as `find-file`) that use minibuffers even while the minibuffer is active. Such invocation produces a recursive editing level for a new minibuffer. By default, the outer-level minibuffer is invisible while you are editing the inner one. If you have `minibuffer-follows-selected-frame` set to `nil`, you can have minibuffers visible on several frames at the same time. See Section “Basic Minibuffer” in `emacs`.

If this variable is `nil`, you cannot invoke minibuffer commands when the minibuffer is active, not even if you switch to another window to do it.

If a command name has a property `enable-recursive-minibuffers` that is non-`nil`, then the command can use the minibuffer to read arguments even if it is invoked from the minibuffer. A command can also achieve this by binding `enable-recursive-minibuffers` to `t` in the interactive declaration (see Section 22.2.1 [Using Interactive], page 424). The minibuffer command `next-matching-history-element` (normally `M-s` in the minibuffer) does the latter.

21.14 Inhibiting Interaction

It’s sometimes useful to be able to run Emacs as a headless server process that responds to commands given over a network connection. However, Emacs is primarily a platform for interactive usage, so many commands prompt the user for feedback in certain anomalous situations. This makes this use case more difficult, since the server process will just hang waiting for user input.

Binding the `inhibit-interaction` variable to something non-`nil` makes Emacs signal a `inhibited-interaction` error instead of prompting, which can then be used by the server process to handle these situations.

Here's a typical use case:

```
(let ((inhibit-interaction t))
  (respond-to-client
   (condition-case err
       (my-client-handling-function)
     (inhibited-interaction err))))
```

If `my-client-handling-function` ends up calling something that asks the user for something (via `y-or-n-p` or `read-from-minibuffer` or the like), an `inhibited-interaction` error is signaled instead. The server code then catches that error and reports it to the client.

21.15 Minibuffer Miscellany

`minibufferp` &optional `buffer-or-name` live

[Function]

This function returns non-`nil` if `buffer-or-name` is a minibuffer. If `buffer-or-name` is omitted or `nil`, it tests the current buffer. When `live` is non-`nil`, the function returns non-`nil` only when `buffer-or-name` is an active minibuffer.

`minibuffer-setup-hook`

[Variable]

This is a normal hook that is run whenever a minibuffer is entered. See Section 24.1 [Hooks], page 524.

`minibuffer-with-setup-hook` `function` &rest `body`

[Macro]

This macro executes `body` after arranging for the specified `function` to be called via `minibuffer-setup-hook`. By default, `function` is called before the other functions in the `minibuffer-setup-hook` list, but if `function` is of the form `(:append func)`, `func` will be called *after* the other hook functions.

The `body` forms should not use the minibuffer more than once. If the minibuffer is re-entered recursively, `function` will only be called once, for the outermost use of the minibuffer.

`minibuffer-exit-hook`

[Variable]

This is a normal hook that is run whenever a minibuffer is exited. See Section 24.1 [Hooks], page 524.

`minibuffer-help-form`

[Variable]

The current value of this variable is used to rebind `help-form` locally inside the minibuffer (see Section 25.6 [Help Functions], page 602).

`minibuffer-scroll-window`

[Variable]

If the value of this variable is non-`nil`, it should be a window object. When the function `scroll-other-window` is called in the minibuffer, it scrolls this window (see Section 29.21 [Textual Scrolling], page 763).

`minibuffer-selected-window`

[Function]

This function returns the window that was selected just before the minibuffer window was selected. If the selected window is not a minibuffer window, it returns `nil`.

minibuffer-message *string &rest args* [Function]

This function is like `message` (see Section 41.4.1 [Displaying Messages], page 1131), but it displays the messages specially when the user types in the minibuffer, typically because Emacs prompted the user for some input. When the minibuffer is the current buffer, this function displays the message specified by *string* temporarily at the end of the minibuffer text, and thus avoids hiding the minibuffer text by the echo-area display of the message. It leaves the message on display for a few seconds, or until the next input event arrives, whichever comes first. The variable `minibuffer-message-timeout` specifies the number of seconds to wait in the absence of input. It defaults to 2. If *args* is non-`nil`, the actual message is obtained by passing *string* and *args* through `format-message`. See Section 4.7 [Formatting Strings], page 66.

If called when the minibuffer is not the current buffer, this function just calls `message`, and thus *string* will be shown in the echo-area.

minibuffer-inactive-mode [Command]

This is the major mode used in inactive minibuffers. It uses keymap `minibuffer-inactive-mode-map`. This can be useful if the minibuffer is in a separate frame. See Section 30.9 [Minibuffers and Frames], page 824.

22 Command Loop

When you run Emacs, it enters the *editor command loop* almost immediately. This loop reads key sequences, executes their definitions, and displays the results. In this chapter, we describe how these things are done, and the subroutines that allow Lisp programs to do them.

22.1 Command Loop Overview

The first thing the command loop must do is read a key sequence, which is a sequence of input events that translates into a command. It does this by calling the function `read-key-sequence`. Lisp programs can also call this function (see Section 22.8.1 [Key Sequence Input], page 461). They can also read input at a lower level with `read-key` or `read-event` (see Section 22.8.2 [Reading One Event], page 462), or discard pending input with `discard-input` (see Section 22.8.6 [Event Input Misc], page 468).

The key sequence is translated into a command through the currently active keymaps. See Section 23.10 [Key Lookup], page 494, for information on how this is done. The result should be a keyboard macro or an interactively callable function. If the key is `M-x`, then it reads the name of another command, which it then calls. This is done by the command `execute-extended-command` (see Section 22.3 [Interactive Call], page 432).

Prior to executing the command, Emacs runs `undo-boundary` to create an undo boundary. See Section 33.10 [Maintaining Undo], page 898.

To execute a command, Emacs first reads its arguments by calling `command-execute` (see Section 22.3 [Interactive Call], page 432). For commands written in Lisp, the `interactive` specification says how to read the arguments. This may use the prefix argument (see Section 22.12 [Prefix Command Arguments], page 473) or may read with prompting in the minibuffer (see Chapter 21 [Minibuffers], page 385). For example, the command `find-file` has an `interactive` specification which says to read a file name using the minibuffer. The function body of `find-file` does not use the minibuffer, so if you call `find-file` as a function from Lisp code, you must supply the file name string as an ordinary Lisp function argument.

If the command is a keyboard macro (i.e., a string or vector), Emacs executes it using `execute-kbd-macro` (see Section 22.16 [Keyboard Macros], page 478).

`pre-command-hook` [Variable]

This normal hook is run by the editor command loop before it executes each command. At that time, `this-command` contains the command that is about to run, and `last-command` describes the previous command. See Section 22.5 [Command Loop Info], page 436.

`post-command-hook` [Variable]

This normal hook is run by the editor command loop after it executes each command (including commands terminated prematurely by quitting or by errors). At that time, `this-command` refers to the command that just ran, and `last-command` refers to the command before that.

This hook is also run when Emacs first enters the command loop (at which point `this-command` and `last-command` are both `nil`).

Quitting is suppressed while running `pre-command-hook` and `post-command-hook`. If an error happens while executing one of these hooks, it does not terminate execution of the hook; instead the error is silenced and the function in which the error occurred is removed from the hook.

A request coming into the Emacs server (see Section “Emacs Server” in *The GNU Emacs Manual*) runs these two hooks just as a keyboard command does.

Note that, when the buffer text includes very long lines, these two hooks are called as if they were in a `with-restriction` form (see Section 31.4 [Narrowing], page 865), with a `long-line-optimizations-in-command-hooks` label and with the buffer narrowed to a portion around point.

22.2 Defining Commands

The special form `interactive` turns a Lisp function into a command. The `interactive` form must be located at top-level in the function body, usually as the first form in the body; this applies to both lambda expressions (see Section 13.2 [Lambda Expressions], page 232) and `defun` forms (see Section 13.4 [Defining Functions], page 237). This form does nothing during the actual execution of the function; its presence serves as a flag, telling the Emacs command loop that the function can be called interactively. The argument of the `interactive` form specifies how the arguments for an interactive call should be read.

Alternatively, an `interactive` form may be specified in a function symbol’s `interactive-form` property. A non-`nil` value for this property takes precedence over any `interactive` form in the function body itself. This feature is seldom used.

Sometimes, a function is only intended to be called interactively, never directly from Lisp. In that case, give the function a non-`nil` `interactive-only` property, either directly or via `declare` (see Section 13.15 [Declare Form], page 263). This causes the byte compiler to warn if the command is called from Lisp. The output of `describe-function` will include similar information. The value of the property can be: a string, which the byte-compiler will use directly in its warning (it should end with a period, and not start with a capital, e.g., “use (`system-name`) instead.”); `t`; any other symbol, which should be an alternative function to use in Lisp code.

Generic functions (see Section 13.8 [Generic Functions], page 245) cannot be turned into commands by adding the `interactive` form to them.

22.2.1 Using `interactive`

This section describes how to write the `interactive` form that makes a Lisp function an interactively-callable command, and how to examine a command’s `interactive` form.

`interactive &optional arg-descriptor &rest modes` [Special Form]

This special form declares that a function is a command, and that it may therefore be called interactively (via `M-x` or by entering a key sequence bound to it). The argument `arg-descriptor` declares how to compute the arguments to the command when the command is called interactively.

A command may be called from Lisp programs like any other function, but then the caller supplies the arguments and `arg-descriptor` has no effect.

The `interactive` form must be located at top-level in the function body, or in the function symbol’s `interactive-form` property (see Section 9.4 [Symbol Properties], page 138). It has its effect because the command loop looks for it before calling the function (see Section 22.3 [Interactive Call], page 432). Once the function is called, all its body forms are executed; at this time, if the `interactive` form occurs within the body, the form simply returns `nil` without even evaluating its argument.

The `modes` list allows specifying which modes the command is meant to be used in. See Section 22.2.4 [Command Modes], page 430, for more details about the effect of specifying `modes`, and when to use it.

By convention, you should put the `interactive` form in the function body, as the first top-level form. If there is an `interactive` form in both the `interactive-form` symbol property and the function body, the former takes precedence. The `interactive-form` symbol property can be used to add an interactive form to an existing function, or change how its arguments are processed interactively, without redefining the function.

There are three possibilities for the argument `arg-descriptor`:

- It may be omitted or `nil`; then the command is called with no arguments. This leads quickly to an error if the command requires one or more arguments.
- It may be a string; its contents are a sequence of elements separated by newlines, one for each argument¹. Each element consists of a code character (see Section 22.2.2 [Interactive Codes], page 427) optionally followed by a prompt (which some code characters use and some ignore). Here is an example:

```
(interactive "P\nbFrobnicate buffer: ")
```

The code letter ‘P’ sets the command’s first argument to the raw command prefix (see Section 22.12 [Prefix Command Arguments], page 473). ‘bFrobnicate buffer: ’ prompts the user with ‘Frobnicate buffer: ’ to enter the name of an existing buffer, which becomes the second and final argument.

The prompt string can use ‘%’ to include previous argument values (starting with the first argument) in the prompt. This is done using `format-message` (see Section 4.7 [Formatting Strings], page 66). For example, here is how you could read the name of an existing buffer followed by a new name to give to that buffer:

```
(interactive "bBuffer to rename: \nsRename buffer %s to: ")
```

If ‘*’ appears at the beginning of the string, then an error is signaled if the buffer is read-only.

If ‘@’ appears at the beginning of the string, and if the key sequence used to invoke the command includes any mouse events, then the window associated with the first of those events is selected before the command is run.

If ‘^’ appears at the beginning of the string, and if the command was invoked through `shift-translation`, set the mark and activate the region temporarily, or extend an already active region, before the command is run. If the command was invoked without `shift-translation`, and the region is temporarily active, deactivate the region before the command is run. Shift-translation is controlled on the user level by `shift-select-mode`; see Section “Shift Selection” in *The GNU Emacs Manual*.

¹ Some elements actually supply two arguments.

You can use ‘*’, ‘@’, and ‘^’ together; the order does not matter. Actual reading of arguments is controlled by the rest of the prompt string (starting with the first character that is not ‘*’, ‘@’, or ‘^’).

- It may be a Lisp expression that is not a string; then it should be a form that is evaluated to get a list of arguments to pass to the command. Usually this form will call various functions to read input from the user, most often through the minibuffer (see Chapter 21 [Minibuffers], page 385) or directly from the keyboard (see Section 22.8 [Reading Input], page 460).

Providing point or the mark as an argument value is also common, but if you do this *and* read input (whether using the minibuffer or not), be sure to get the integer values of point or the mark after reading. The current buffer may be receiving subprocess output; if subprocess output arrives while the command is waiting for input, it could relocate point and the mark.

Here’s an example of what *not* to do:

```
(interactive
  (list (region-beginning) (region-end)
        (read-string "Foo: " nil 'my-history)))
```

Here’s how to avoid the problem, by examining point and the mark after reading the keyboard input:

```
(interactive
  (let ((string (read-string "Foo: " nil 'my-history)))
    (list (region-beginning) (region-end) string)))
```

Warning: the argument values should not include any data types that can’t be printed and then read. Some facilities save `command-history` in a file to be read in the subsequent sessions; if a command’s arguments contain a data type that prints using ‘#<...>’ syntax, those facilities won’t work.

There are, however, a few exceptions: it is ok to use a limited set of expressions such as `(point)`, `(mark)`, `(region-beginning)`, and `(region-end)`, because Emacs recognizes them specially and puts the expression (rather than its value) into the command history. To see whether the expression you wrote is one of these exceptions, run the command, then examine `(car command-history)`.

`interactive-form` function

[Function]

This function returns the `interactive` form of *function*. If *function* is an interactively callable function (see Section 22.3 [Interactive Call], page 432), the value is the command’s `interactive` form (`interactive spec`), which specifies how to compute its arguments. Otherwise, the value is `nil`. If *function* is a symbol, its function definition is used. When called on an OClosure, the work is delegated to the generic function `closure-interactive-form`.

`closure-interactive-form` function

[Function]

Just like `interactive-form`, this function takes a command and returns its interactive form. The difference is that it is a generic function and it is only called when *function* is an OClosure (see Section 13.11 [OClosures], page 250). The purpose is to make it possible for some OClosure types to compute their interactive forms dynamically instead of carrying it in one of their slots.

This is used for example for `kmacro` functions in order to reduce their memory size, since they all share the same interactive form. It is also used for `advice` functions, where the interactive form is computed from the interactive forms of its components, so as to make this computation more lazily and to correctly adjust the interactive form when one of its component's is redefined.

22.2.2 Code Characters for `interactive`

The code character descriptions below contain a number of key words, defined here as follows:

Completion

Provide completion. `TAB`, `SPC`, and `RET` perform name completion because the argument is read using `completing-read` (see Section 21.6 [Completion], page 395). `?` displays a list of possible completions.

Existing Require the name of an existing object. An invalid name is not accepted; the commands to exit the minibuffer do not exit if the current input is not valid.

Default A default value of some sort is used if the user enters no text in the minibuffer. The default depends on the code character.

No I/O This code letter computes an argument without reading any input. Therefore, it does not use a prompt string, and any prompt string you supply is ignored. Even though the code letter doesn't use a prompt string, you must follow it with a newline if it is not the last code character in the string.

Prompt A prompt immediately follows the code character. The prompt ends either with the end of the string or with a newline.

Special This code character is meaningful only at the beginning of the interactive string, and it does not look for a prompt or a newline. It is a single, isolated character.

Here are the code character descriptions for use with `interactive`:

- ‘*’ Signal an error if the current buffer is read-only. Special.
- ‘@’ Select the window mentioned in the first mouse event in the key sequence that invoked this command. Special.
- ‘~’ If the command was invoked through shift-translation, set the mark and activate the region temporarily, or extend an already active region, before the command is run. If the command was invoked without shift-translation, and the region is temporarily active, deactivate the region before the command is run. Special.
- ‘a’ A function name (i.e., a symbol satisfying `fboundp`). Existing, Completion, Prompt.
- ‘b’ The name of an existing buffer. By default, uses the name of the current buffer (see Chapter 28 [Buffers], page 671). Existing, Completion, Default, Prompt.
- ‘B’ A buffer name. The buffer need not exist. By default, uses the name of a recently used buffer other than the current buffer. Completion, Default, Prompt.
- ‘c’ A character. The cursor does not move into the echo area. Prompt.

'C'	A command name (i.e., a symbol satisfying <code>commandp</code>). Existing, Completion, Prompt.
'd'	The position of point, as an integer (see Section 31.1 [Point], page 853). No I/O.
'D'	A directory. The default is the current default directory of the current buffer, <code>default-directory</code> (see Section 26.9.4 [File Name Expansion], page 639). Existing, Completion, Default, Prompt.
'e'	<p>The first or next non-keyboard event in the key sequence that invoked the command. More precisely, ‘e’ gets events that are lists, so you can look at the data in the lists. See Section 22.7 [Input Events], page 440. No I/O.</p> <p>You use ‘e’ for mouse events and for special system events (see Section 22.7.12 [Misc Events], page 450). The event list that the command receives depends on the event. See Section 22.7 [Input Events], page 440, which describes the forms of the list for each event in the corresponding subsections.</p> <p>You can use ‘e’ more than once in a single command’s interactive specification. If the key sequence that invoked the command has n events that are lists, the nth ‘e’ provides the nth such event. Events that are not lists, such as function keys and ASCII characters, do not count where ‘e’ is concerned.</p>
'f'	A file name of an existing file (see Section 26.9 [File Names], page 634). See Section 21.6.5 [Reading File Names], page 404, for details about default values. Existing, Completion, Default, Prompt.
'F'	A file name. The file need not exist. Completion, Default, Prompt.
'G'	A file name. The file need not exist. If the user enters just a directory name, then the value is just that directory name, with no file name within the directory added. Completion, Default, Prompt.
'i'	An irrelevant argument. This code always supplies <code>nil</code> as the argument’s value. No I/O.
'k'	<p>A key sequence (see Section 23.1 [Key Sequences], page 480). This keeps reading events until a command (or undefined command) is found in the current key maps. The key sequence argument is represented as a string or vector. The cursor does not move into the echo area. Prompt.</p> <p>If ‘k’ reads a key sequence that ends with a down-event, it also reads and discards the following up-event. You can get access to that up-event with the ‘U’ code character.</p> <p>This kind of input is used by commands such as <code>describe-key</code> and <code>keymap-global-set</code>.</p>
'K'	A key sequence on a form that can be used as input to functions like <code>keymap-set</code> . This works like ‘k’, except that it suppresses, for the last input event in the key sequence, the conversions that are normally used (when necessary) to convert an undefined key into a defined one (see Section 22.8.1 [Key Sequence Input], page 461), so this form is usually used when prompting for a new key sequence that is to be bound to a command.
'm'	The position of the mark, as an integer. No I/O.

'M'	Arbitrary text, read in the minibuffer using the current buffer's input method, and returned as a string (see Section "Input Methods" in <i>The GNU Emacs Manual</i>). Prompt.
'n'	A number, read with the minibuffer. If the input is not a number, the user has to try again. 'n' never uses the prefix argument. Prompt.
'N'	The numeric prefix argument; but if there is no prefix argument, read a number as with <code>n</code> . The value is always a number. See Section 22.12 [Prefix Command Arguments], page 473. Prompt.
'p'	The numeric prefix argument. (Note that this 'p' is lower case.) No I/O.
'P'	The raw prefix argument. (Note that this 'P' is upper case.) No I/O.
'r'	Point and the mark, as two numeric arguments, smallest first. This is the only code letter that specifies two successive arguments rather than one. This will signal an error if the mark is not set in the buffer which is current when the command is invoked. If Transient Mark mode is turned on (see Section 32.7 [The Mark], page 873) — as it is by default — and user option <code>mark-even-if-inactive</code> is <code>nil</code> , Emacs will signal an error even if the mark <i>is</i> set, but is inactive. No I/O.
's'	Arbitrary text, read in the minibuffer and returned as a string (see Section 21.2 [Text from Minibuffer], page 386). Terminate the input with either <code>C-j</code> or RET. (<code>C-q</code> may be used to include either of these characters in the input.) Prompt.
'S'	An interned symbol whose name is read in the minibuffer. Terminate the input with either <code>C-j</code> or RET. Other characters that normally terminate a symbol (e.g., whitespace, parentheses and brackets) do not do so here. Prompt.
'U'	A key sequence or <code>nil</code> . Can be used after a 'k' or 'K' argument to get the up-event that was discarded (if any) after 'k' or 'K' read a down-event. If no up-event has been discarded, 'U' provides <code>nil</code> as the argument. No I/O.
'v'	A variable declared to be a user option (i.e., satisfying the predicate <code>custom-variable-p</code>). This reads the variable using <code>read-variable</code> . See [Definition of read-variable], page 404. Existing, Completion, Prompt.
'x'	A Lisp object, specified with its read syntax, terminated with a <code>C-j</code> or RET. The object is not evaluated. See Section 21.3 [Object from Minibuffer], page 391. Prompt.
'X'	A Lisp form's value. 'X' reads as 'x' does, then evaluates the form so that its value becomes the argument for the command. Prompt.
'z'	A coding system name (a symbol). If the user enters null input, the argument value is <code>nil</code> . See Section 34.10 [Coding Systems], page 976. Completion, Existing, Prompt.
'Z'	A coding system name (a symbol)—but only if this command has a prefix argument. With no prefix argument, 'Z' provides <code>nil</code> as the argument value. Completion, Existing, Prompt.

22.2.3 Examples of Using `interactive`

Here are some examples of `interactive`:

```
(defun foo1 () ; foo1 takes no arguments,
  (interactive) ; just moves forward two words.
  (forward-word 2))
  ⇒ foo1

(defun foo2 (n) ; foo2 takes one argument,
  (interactive "^p") ; which is the numeric prefix.
  ; under shift-select-mode,
  ; will activate or extend region.
  (forward-word (* 2 n)))
  ⇒ foo2

(defun foo3 (n) ; foo3 takes one argument,
  (interactive "nCount:") ; which is read with the Minibuffer.
  (forward-word (* 2 n)))
  ⇒ foo3

(defun three-b (b1 b2 b3)
  "Select three existing buffers.
Put them into three windows, selecting the last one."
  (interactive "bBuffer1:\\nbBuffer2:\\nbBuffer3:")
  (delete-other-windows)
  (split-window (selected-window) 8)
  (switch-to-buffer b1)
  (other-window 1)
  (split-window (selected-window) 8)
  (switch-to-buffer b2)
  (other-window 1)
  (switch-to-buffer b3))
  ⇒ three-b
(three-b "*scratch*" "declarations.texi" "*mail*")
  ⇒ nil
```

22.2.4 Specifying Modes For Commands

Many commands in Emacs are general, and not tied to any specific mode. For instance, `M-x kill-region` can be used in pretty much any mode that has editable text, and commands that display information (like `M-x list-buffers`) can be used in pretty much any context.

Many other commands, however, are specifically tied to a mode, and make no sense outside of that context. For instance, `M-x dired-diff` will just signal an error if used outside of a `Dired` buffer.

Emacs therefore has a mechanism for specifying what mode (or modes) a command “belongs” to:

```
(defun dired-diff (...)
```

```
...
(interactive "p" dired-mode)
...)
```

This will mark the command as applicable to `dired-mode` only (or any modes that are derived from `dired-mode`). Any number of modes can be added to the `interactive` form.

Specifying modes affects command completion in `M-S-x` (`execute-extended-command-for-buffer`, see Section 22.3 [Interactive Call], page 432). It may also affect completion in `M-x`, depending on the value of `read-extended-command-predicate`.

For instance, when using the `command-completion-default-include-p` predicate as the value of `read-extended-command-predicate`, `M-x` won't list commands that have been marked as being applicable to a specific mode (unless you are in a buffer that uses that mode, of course). This goes for both major and minor modes. (By contrast, `M-S-x` always omits inapplicable commands from the completion candidates.)

By default, `read-extended-command-predicate` is `nil`, and completion in `M-x` lists all the commands that match what the user has typed, whether those commands are or aren't marked as applicable to the current buffer's mode.

Marking commands to be applicable to a mode will also make `C-h m` list these commands (if they aren't bound to any keys).

If using this extended `interactive` form isn't convenient (because the code is supposed to work in older versions of Emacs that don't support the extended `interactive` form), the following equivalent declaration (see Section 13.15 [Declare Form], page 263) can be used instead:

```
(declare (modes dired-mode))
```

Which commands to tag with modes is to some degree a matter of taste, but commands that clearly do not work outside of the mode should be tagged. This includes commands that will signal an error if called from somewhere else, but also commands that are destructive when called from an unexpected mode. (This usually includes most of the commands that are written for special (i.e., non-editing) modes.)

Some commands may be harmless, and “work” when called from other modes, but should still be tagged with a mode if they don't actually make much sense to use elsewhere. For instance, many special modes have commands to exit the buffer bound to `q`, and may not do anything but issue a message like “Goodbye from this mode” and then call `kill-buffer`. This command will “work” from any mode, but it is highly unlikely that anybody would actually want to use the command outside the context of this special mode.

Many modes have a set of different commands that start the mode in different ways (e.g., `eww-open-in-new-buffer` and `eww-open-file`). Commands like that should never be tagged as mode-specific, as they can be issued by the user from pretty much any context.

22.2.5 Select among Command Alternatives

Sometimes it is useful to define a command that serves as a “generic dispatcher” capable of invoking one of a set of commands according to the user's needs. For example, imagine that you want to define a command named ‘open’ that can “open” and display several different types of objects. Or you could have a command named ‘mua’ (which stands for Mail User Agent) that can read and send email using one of several email backends, such

as Rmail, Gnus, or MH-E. The macro `define-alternatives` can be used to define such generic commands. A generic command is an interactive function whose implementation can be selected from several alternatives, as a matter of user preference.

`define-alternatives command &rest customizations` [Macro]

This macro defines the new generic `command`, which can have several alternative implementations. The argument `command` should be an unquoted symbol.

When invoked, the macro creates an interactive Lisp closure (see Section 13.10 [Closures], page 249). When the user runs `M-x command RET` for the first time, Emacs asks to select one of the alternative implementations of `command`, offering completion for the names of these alternatives. These names come from the user option whose name is `command-alternatives`, which the macro creates (if it didn't exist before). To be useful, this variable's value should be an alist whose elements have the form `(alt-name . alt-func)`, where `alt-name` is the name of the alternative and `alt-func` is the interactive function to be called if this alternative is selected. When the user selects an alternative, Emacs remembers the selection, and will thereafter automatically call that selected alternative without prompting when the user invokes `M-x command` again. To choose a different alternative, type `C-u M-x command RET`—then Emacs will again prompt for one of the alternatives, and the selection will override the previous one.

The variable `command-alternatives` can be created before calling `define-alternatives`, with the appropriate values; otherwise the macro creates the variable with a `nil` value, and it should then be populated with the associations describing the alternatives. Packages that wish to provide their own implementation of an existing generic command can use `autoload` cookies (see Section 16.5 [Autoload], page 304) to add to the alist, for example:

```
;;;;##autoload (push '("My name" . my-foo-symbol) foo-alternatives
```

If the optional argument `customizations` is non-`nil`, it should consist of alternating `defcustom` keywords (typically `:group` and `:version`) and values to add to the definition of the `defcustom` `command-alternatives`.

Here is an example of a simple generic dispatcher command named `open` with 3 alternative implementations:

```
(define-alternatives open
  :group 'files
  :version "42.1")
(setq open-alternatives
  '(("file" . find-file)
    ("directory" . direfd)
    ("hexl" . hexl-find-file)))
```

22.3 Interactive Call

After the command loop has translated a key sequence into a command, it invokes that command using the function `command-execute`. If the command is a function, `command-execute` calls `call-interactively`, which reads the arguments and calls the command. You can also call these functions yourself.

Note that the term “command”, in this context, refers to an interactively callable function (or function-like object), or a keyboard macro. It does not refer to the key sequence used to invoke a command (see Chapter 23 [Keymaps], page 480).

commandp *object* &optional *for-call-interactively* [Function]

This function returns `t` if *object* is a command. Otherwise, it returns `nil`.

Commands include strings and vectors (which are treated as keyboard macros), lambda expressions that contain a top-level `interactive` form (see Section 22.2.1 [Using Interactive], page 424), byte-code function objects made from such lambda expressions, autoload objects that are declared as interactive (non-`nil` fourth argument to `autoload`), and some primitive functions. Also, a symbol is considered a command if it has a non-`nil` `interactive-form` property, or if its function definition satisfies `commandp`.

If *for-call-interactively* is non-`nil`, then `commandp` returns `t` only for objects that `call-interactively` could call—thus, not for keyboard macros.

See documentation in Section 25.2 [Accessing Documentation], page 596, for a realistic example of using `commandp`.

call-interactively *command* &optional *record-flag* *keys* [Function]

This function calls the interactively callable function *command*, providing arguments according to its interactive calling specifications. It returns whatever *command* returns.

If, for instance, you have a function with the following signature:

```
(defun foo (begin end)
  (interactive "r")
  ...)
```

then saying

```
(call-interactively 'foo)
```

will call `foo` with the region (`point` and `mark`) as the arguments.

An error is signaled if *command* is not a function or if it cannot be called interactively (i.e., is not a command). Note that keyboard macros (strings and vectors) are not accepted, even though they are considered commands, because they are not functions. If *command* is a symbol, then `call-interactively` uses its function definition.

If *record-flag* is non-`nil`, then this command and its arguments are unconditionally added to the list `command-history`. Otherwise, the command is added only if it uses the minibuffer to read an argument. See Section 22.15 [Command History], page 477.

The argument *keys*, if given, should be a vector which specifies the sequence of events to supply if the command inquires which events were used to invoke it. If *keys* is omitted or `nil`, the default is the return value of `this-command-keys-vector`. See [Definition of this-command-keys-vector], page 437.

funcall-interactively *function* &rest *arguments* [Function]

This function works like `funcall` (see Section 13.5 [Calling Functions], page 239), but it makes the call look like an interactive invocation: a call to `called-interactively-p` inside *function* will return `t`. If *function* is not a command, it is called without signaling an error.

command-execute *command* &*optional record-flag keys special* [Function]

This function executes *command*. The argument *command* must satisfy the `commandp` predicate; i.e., it must be an interactively callable function or a keyboard macro.

A string or vector as *command* is executed with `execute-kbd-macro`. A function is passed to `call-interactively` (see above), along with the *record-flag* and *keys* arguments.

If *command* is a symbol, its function definition is used in its place. A symbol with an `autoload` definition counts as a command if it was declared to stand for an interactively callable function. Such a definition is handled by loading the specified library and then rechecking the definition of the symbol.

The argument *special*, if given, means to ignore the prefix argument and not clear it. This is used for executing special events (see Section 22.9 [Special Events], page 470).

execute-extended-command *prefix-argument* [Command]

This function reads a command name from the minibuffer using `completing-read` (see Section 21.6 [Completion], page 395). Then it uses `command-execute` to call the specified command. Whatever that command returns becomes the value of `execute-extended-command`.

If the command asks for a prefix argument, it receives the value *prefix-argument*. If `execute-extended-command` is called interactively, the current raw prefix argument is used for *prefix-argument*, and thus passed on to whatever command is run.

`execute-extended-command` is the normal definition of `M-x`, so it uses the string ‘`M-x`’ as a prompt. (It would be better to take the prompt from the events used to invoke `execute-extended-command`, but that is painful to implement.) A description of the value of the prefix argument, if any, also becomes part of the prompt.

```
(execute-extended-command 3)
----- Buffer: Minibuffer -----
3 M-x forward-word RET
----- Buffer: Minibuffer -----
⇒ t
```

This command heeds the `read-extended-command-predicate` variable, which can filter out commands that are not applicable to the current major mode (or enabled minor modes). By default, the value of this variable is `nil`, and no commands are filtered out. However, customizing it to invoke the function `command-completion-default-include-p` will perform mode-dependent filtering. `read-extended-command-predicate` can be any predicate function; it will be called with two parameters: the command’s symbol and the current buffer. It should return `non-nil` if the command is to be included when completing in that buffer.

execute-extended-command-for-buffer *prefix-argument* [Command]

This is like `execute-extended-command`, but limits the commands offered for completion to those commands that are of particular relevance to the current major mode (and enabled minor modes). This includes commands that are tagged with the modes (see Section 22.2.1 [Using Interactive], page 424), and also commands that are bound to locally active keymaps. This command is the normal definition of `M-S-x` (that’s “meta shift x”).

Both these commands prompt for a command name, but with different completion rules. You can toggle between these two modes by using the *M-S-x* command while being prompted.

22.4 Distinguish Interactive Calls

Sometimes a command should display additional visual feedback (such as an informative message in the echo area) for interactive calls only. There are three ways to do this. The recommended way to test whether the function was called using `call-interactively` is to give it an optional argument `print-message` and use the `interactive` spec to make it `non-nil` in interactive calls. Here's an example:

```
(defun foo (&optional print-message)
  (interactive "p")
  (when print-message
    (message "foo")))
```

We use "`p`" because the numeric prefix argument is never `nil`. Defined in this way, the function does display the message when called from a keyboard macro.

The above method with the additional argument is usually best, because it allows callers to say “treat this call as interactive”. But you can also do the job by testing `called-interactively-p`.

`called-interactively-p kind` [Function]
 This function returns `t` when the calling function was called using `call-interactively`.

The argument `kind` should be either the symbol `interactive` or the symbol `any`. If it is `interactive`, then `called-interactively-p` returns `t` only if the call was made directly by the user—e.g., if the user typed a key sequence bound to the calling function, but *not* if the user ran a keyboard macro that called the function (see Section 22.16 [Keyboard Macros], page 478). If `kind` is `any`, `called-interactively-p` returns `t` for any kind of interactive call, including keyboard macros.

If in doubt, use `any`; the only known proper use of `interactive` is if you need to decide whether to display a helpful message while a function is running.

A function is never considered to be called interactively if it was called via Lisp evaluation (or with `apply` or `funcall`).

Here is an example of using `called-interactively-p`:

```
(defun foo ()
  (interactive)
  (when (called-interactively-p 'any)
    (message "Interactive!")
    'foo-called-interactively))

;; Type M-x foo.
;+ Interactive!

(foo)
⇒ nil
```

Here is another example that contrasts direct and indirect calls to `called-interactively-p`.

```
(defun bar ()
  (interactive)
  (message "%s" (list (foo) (called-interactively-p 'any)))))

;; Type M-x bar.
→ (nil t)
```

22.5 Information from the Command Loop

The editor command loop sets several Lisp variables to keep status records for itself and for commands that are run. With the exception of `this-command` and `last-command` it's generally a bad idea to change any of these variables in a Lisp program.

`last-command`

[Variable]

This variable records the name of the previous command executed by the command loop (the one before the current command). Normally the value is a symbol with a function definition, but this is not guaranteed.

The value is copied from `this-command` when a command returns to the command loop, except when the command has specified a prefix argument for the following command.

This variable is always local to the current terminal and cannot be buffer-local. See Section 30.2 [Multiple Terminals], page 787.

`real-last-command`

[Variable]

This variable is set up by Emacs just like `last-command`, but never altered by Lisp programs.

`last-repeatable-command`

[Variable]

This variable stores the most recently executed command that was not part of an input event. This is the command `repeat` will try to repeat, See Section “Repeating” in *The GNU Emacs Manual*.

`this-command`

[Variable]

This variable records the name of the command now being executed by the editor command loop. Like `last-command`, it is normally a symbol with a function definition.

The command loop sets this variable just before running a command, and copies its value into `last-command` when the command finishes (unless the command specified a prefix argument for the following command).

Some commands set this variable during their execution, as a flag for whatever command runs next. In particular, the functions for killing text set `this-command` to `kill-region` so that any kill commands immediately following will know to append the killed text to the previous kill.

If you do not want a particular command to be recognized as the previous command in the case where it got an error, you must code that command to prevent this. One way is to

set `this-command` to `t` at the beginning of the command, and set `this-command` back to its proper value at the end, like this:

```
(defun foo (args...)
  (interactive ...)
  (let ((old-this-command this-command))
    (setq this-command t)
    ...do the work...
    (setq this-command old-this-command)))
```

We do not bind `this-command` with `let` because that would restore the old value in case of error—a feature of `let` which in this case does precisely what we want to avoid.

`this-original-command`

[Variable]

This has the same value as `this-command` except when command remapping occurs (see Section 23.14 [Remapping Commands], page 503). In that case, `this-command` gives the command actually run (the result of remapping), and `this-original-command` gives the command that was specified to run but remapped into another command.

`current-minibuffer-command`

[Variable]

This has the same value as `this-command`, but is bound recursively when entering a minibuffer. This variable can be used from minibuffer hooks and the like to determine what command opened the current minibuffer session.

`this-command-keys`

[Function]

This function returns a string or vector containing the key sequence that invoked the present command. Any events read by the command using `read-event` without a timeout get tacked on to the end.

However, if the command has called `read-key-sequence`, it returns the last read key sequence. See Section 22.8.1 [Key Sequence Input], page 461. The value is a string if all events in the sequence were characters that fit in a string. See Section 22.7 [Input Events], page 440.

```
(this-command-keys)
;; Now use C-u C-x C-e to evaluate that.
⇒ "^\u00c7E"
```

`this-command-keys-vector`

[Function]

Like `this-command-keys`, except that it always returns the events in a vector, so you don't need to deal with the complexities of storing input events in a string (see Section 22.7.17 [Strings of Events], page 459).

`clear-this-command-keys &optional keep-record`

[Function]

This function empties out the table of events for `this-command-keys` to return. Unless `keep-record` is non-`nil`, it also empties the records that the function `recent-keys` (see Section 42.13.2 [Recording Input], page 1286) will subsequently return. This is useful after reading a password, to prevent the password from echoing inadvertently as part of the next command in certain cases.

last-nonmenu-event

[Variable]

This variable holds the last input event read as part of a key sequence, not counting events resulting from mouse menus.

One use of this variable is for telling `x-popup-menu` where to pop up a menu. It is also used internally by `y-or-n-p` (see Section 21.7 [Yes-or-No Queries], page 413).

last-command-event

[Variable]

This variable is set to the last input event that was read by the command loop as part of a command. The principal use of this variable is in `self-insert-command`, which uses it to decide which character to insert, and in `post-self-insert-hook` (see Section 33.5 [Commands for Insertion], page 884), which uses it to access the character that was just inserted.

last-command-event

`; ; Now use C-u C-x C-e to evaluate that.`

$\Rightarrow 5$

The value is 5 because that is the ASCII code for `C-e`.

last-event-frame

[Variable]

This variable records which frame the last input event was directed to. Usually this is the frame that was selected when the event was generated, but if that frame has redirected input focus to another frame, the value is the frame to which the event was redirected. See Section 30.10 [Input Focus], page 824.

If the last event came from a keyboard macro, the value is `macro`.

Input events must come from somewhere; sometimes, that is a keyboard macro, a signal, or ‘unread-command-events’, but it is usually a physical input device connected to a computer that is controlled by the user. Those devices are referred to as *input devices*, and Emacs associates each input event with the input device from which it originated. They are identified by a name that is unique to each input device.

The ability to determine the precise input device used depends on the details of each system. When that information is unavailable, Emacs reports keyboard events as originating from the “Virtual core keyboard”, and other events as originating from the “Virtual core pointer”. (These values are used on every platform because the X server reports them when detailed device information is not known.)

last-event-device

[Variable]

This variable records the name of the input device from which the last input event read was generated. It is `nil` if no such device exists, i.e., the last input event was read from `unread-command-events`, or it came from a keyboard macro.

When the X Input Extension is being used on X Windows, the device name is a string that is unique to each physical keyboard, pointing device and touchscreen attached to the X server. Otherwise, it is either the string “Virtual core pointer” or “Virtual core keyboard”, depending on whether the event was generated by a pointing device (such as a mouse) or a keyboard.

device-class *frame name* [Function]

There are various different types of devices, which can be determined from their names. This function can be used to determine the correct type of the device *name* for an event originating from *frame*.

The return value is one of the following symbols (“device classes”):

core-keyboard

The core keyboard; this means the device is a keyboard-like device, but no other characteristics are unknown.

core-pointer

The core pointer; this means the device is a pointing device, but no other characteristics are known.

mouse A computer mouse.

trackpoint

A trackpoint or joystick (or other similar control.)

eraser The other end of a stylus on a graphics tablet, or a standalone eraser.

pen The pointed end of a pen on a graphics tablet, a stylus, or some other similar device.

puck A device that looks like a computer mouse, but reports absolute coordinates relative to some other surface.

power-button

A power button or volume button (or other similar control.)

keyboard A computer keyboard.

touchscreen

A computer touchpad.

pad A collection of sensitive buttons, rings, and strips commonly found around a drawing tablet.

touchpad An indirect touch device such as a touchpad.

piano A musical instrument such as an electronic keyboard.

test A device used by the XTEST extension to report input.

22.6 Adjusting Point After Commands

Emacs cannot display the cursor when point is in the middle of a sequence of text that has the **display** or **composition** property, or is invisible. Therefore, after a command finishes and returns to the command loop, if point is within such a sequence, the command loop normally moves point to the edge of the sequence, making this sequence effectively intangible.

A command can inhibit this feature by setting the variable **disable-point-adjustment**:

disable-point-adjustment

[Variable]

If this variable is non-`nil` when a command returns to the command loop, then the command loop does not check for those text properties, and does not move point out of sequences that have them.

The command loop sets this variable to `nil` before each command, so if a command sets it, the effect applies only to that command.

global-disable-point-adjustment

[Variable]

If you set this variable to a non-`nil` value, the feature of moving point out of these sequences is completely turned off.

22.7 Input Events

The Emacs command loop reads a sequence of *input events* that represent keyboard or mouse activity, or system events sent to Emacs. The events for keyboard activity are characters or symbols; other events are always lists. This section describes the representation and meaning of input events in detail.

eventp object

[Function]

This function returns non-`nil` if *object* is an input event or event type.

Note that any non-`nil` symbol might be used as an event or an event type; `eventp` cannot distinguish whether a symbol is intended by Lisp code to be used as an event.

22.7.1 Keyboard Events

There are two kinds of input you can get from the keyboard: ordinary keys, and function keys. Ordinary keys correspond to (possibly modified) characters; the events they generate are represented in Lisp as characters. The event type of a *character event* is the character itself (an integer), which might have some modifier bits set; see Section 22.7.14 [Classifying Events], page 455.

An input character event consists of a *basic code* between 0 and 524287, plus any or all of these *modifier bits*:

`meta` The 2^{27} bit in the character code indicates a character typed with the meta key held down.

`control` The 2^{26} bit in the character code indicates a non-ASCII control character. ASCII control characters such as `C-a` have special basic codes of their own, so Emacs needs no special bit to indicate them. Thus, the code for `C-a` is just 1. But if you type a control combination not in ASCII, such as `%` with the control key, the numeric value you get is the code for `%` plus 2^{26} (assuming the terminal supports non-ASCII control characters), i.e. with the 27th bit set.

`shift` The 2^{25} bit (the 26th bit) in the character event code indicates an ASCII control character typed with the shift key held down.

For letters, the basic code itself indicates upper versus lower case; for digits and punctuation, the shift key selects an entirely different character with a different basic code. In order to keep within the ASCII character set whenever possible, Emacs avoids using the 2^{25} bit for those character events.

However, ASCII provides no way to distinguish *C-A* from *C-a*, so Emacs uses the 2^{25} bit in *C-A* and not in *C-a*.

hyper	The 2^{24} bit in the character event code indicates a character typed with the hyper key held down.
super	The 2^{23} bit in the character event code indicates a character typed with the super key held down.
alt	The 2^{22} bit in the character event code indicates a character typed with the alt key held down. (The key labeled Alt on most keyboards is actually treated as the meta key, not this.)

It is best to avoid mentioning specific bit numbers in your program. To test the modifier bits of a character, use the function `event-modifiers` (see Section 22.7.14 [Classifying Events], page 455). When making key bindings with `keymap-set`, you specify these events using strings like ‘*C-H-x*’ instead (for “control hyper x”) (see Section 23.12 [Changing Key Bindings], page 497).

22.7.2 Function Keys

Most keyboards also have *function keys*—keys that have names or symbols that are not characters. Function keys are represented in Emacs Lisp as symbols; the symbol’s name is the function key’s label, in lower case. For example, pressing a key labeled F1 generates an input event represented by the symbol `f1`.

The event type of a function key event is the event symbol itself. See Section 22.7.14 [Classifying Events], page 455.

Here are a few special cases in the symbol-naming convention for function keys:

`backspace`, `tab`, `newline`, `return`, `delete`

These keys correspond to common ASCII control characters that have special keys on most keyboards.

In ASCII, *C-i* and **TAB** are the same character. If the terminal can distinguish between them, Emacs conveys the distinction to Lisp programs by representing the former as the integer 9, and the latter as the symbol `tab`.

Most of the time, it’s not useful to distinguish the two. So normally `local-function-key-map` (see Section 23.15 [Translation Keystrokes], page 504) is set up to map `tab` into 9. Thus, a key binding for character code 9 (the character *C-i*) also applies to `tab`. Likewise for the other symbols in this group. The function `read-char` likewise converts these events into characters.

In ASCII, **BS** is really *C-h*. But `backspace` converts into the character code 127 (`DEL`), not into code 8 (`BS`). This is what most users prefer.

`left`, `up`, `right`, `down`

Cursor arrow keys

`kp-add`, `kp-decimal`, `kp-divide`, ...

Keypad keys (to the right of the regular keyboard).

`kp-0`, `kp-1`, ...

Keypad keys with digits.

kp-f1, kp-f2, kp-f3, kp-f4

Keypad PF keys.

kp-home, kp-left, kp-up, kp-right, kp-down

Keypad arrow keys. Emacs normally translates these into the corresponding non-keypad keys `home`, `left`, ...

kp-prior, kp-next, kp-end, kp-begin, kp-insert, kp-delete

Additional keypad duplicates of keys ordinarily found elsewhere. Emacs normally translates these into the like-named non-keypad keys.

You can use the modifier keys ALT, CTRL, HYPER, META, SHIFT, and SUPER with function keys. The way to represent them is with prefixes in the symbol name:

‘A-’ The alt modifier.

‘C-’ The control modifier.

‘H-’ The hyper modifier.

‘M-’ The meta modifier.

‘S-’ The shift modifier.

‘s-’ The super modifier.

Thus, the symbol for the key F3 with META held down is `M-f3`. When you use more than one prefix, we recommend you write them in alphabetical order; but the order does not matter in arguments to the key-binding lookup and modification functions.

22.7.3 Mouse Events

Emacs supports four kinds of mouse events: click events, drag events, button-down events, and motion events. All mouse events are represented as lists. The CAR of the list is the event type; this says which mouse button was involved, and which modifier keys were used with it. The event type can also distinguish double or triple button presses (see Section 22.7.7 [Repeat Events], page 446). The rest of the list elements give position and time information.

For key lookup, only the event type matters: two events of the same type necessarily run the same command. The command can access the full values of these events using the ‘e’ interactive code. See Section 22.2.2 [Interactive Codes], page 427.

A key sequence that starts with a mouse event is read using the keymaps of the buffer in the window that the mouse was in, not the current buffer. This does not imply that clicking in a window selects that window or its buffer—that is entirely under the control of the command binding of the key sequence.

22.7.4 Click Events

When the user presses a mouse button and releases it at the same location, that generates a *click* event. Depending on how your window-system reports mouse-wheel events, turning the mouse wheel can generate either a mouse click or a mouse-wheel event. All mouse event share the same format:

`(event-type position click-count)`

event-type This is a symbol that indicates which mouse button was used. It is one of the symbols `mouse-1`, `mouse-2`, ..., where the buttons are numbered left to right. For mouse-wheel event, it can be `wheel-up` or `wheel-down`.

You can also use prefixes ‘A-’, ‘C-’, ‘H-’, ‘M-’, ‘S-’ and ‘s-’ for modifiers alt, control, hyper, meta, shift and super, just as you would with function keys.

This symbol also serves as the event type of the event. Key bindings describe events by their types; thus, if there is a key binding for `mouse-1`, that binding would apply to all events whose *event-type* is `mouse-1`.

position This is a *mouse position list* specifying where the mouse event occurred; see below for details.

click-count

This is the number of rapid repeated presses so far of the same mouse button or the number of repeated turns of the wheel. See Section 22.7.7 [Repeat Events], page 446.

To access the contents of a mouse position list in the *position* slot of a mouse event, you should typically use the functions documented in Section 22.7.15 [Accessing Mouse], page 456.

The explicit format of the list depends on where the event occurred. For clicks in the text area, mode line, header line, tab line, or in the fringe or marginal areas, the mouse position list has the form

```
(window pos-or-area (x . y) timestamp
      object text-pos (col . row)
      image (dx . dy) (width . height))
```

The meanings of these list elements are as follows:

window The window in which the mouse event occurred.

pos-or-area

The buffer position of the character clicked on in the text area; or, if the event was outside the text area, the window area where it occurred. It is one of the symbols `mode-line`, `header-line`, `tab-line`, `vertical-line`, `left-margin`, `right-margin`, `left-fringe`, or `right-fringe`.

In one special case, *pos-or-area* is a list containing a symbol (one of the symbols listed above) instead of just the symbol. This happens after the imaginary prefix keys for the event are registered by Emacs. See Section 22.8.1 [Key Sequence Input], page 461.

x, y The relative pixel coordinates of the event. For events in the text area of a window, the coordinate origin (0 . 0) is taken to be the top left corner of the text area. See Section 29.4 [Window Sizes], page 699. For events in a mode line, header line or tab line, the coordinate origin is the top left corner of the window itself. For fringes, margins, and the vertical border, *x* does not have meaningful data. For fringes and margins, *y* is relative to the bottom edge of the header line. In all cases, the *x* and *y* coordinates increase rightward and downward respectively.

timestamp

The time at which the event occurred, as an integer number of milliseconds since a system-dependent initial time.

<i>object</i>	Either <code>nil</code> , which means the event occurred on buffer text, or a cons cell of the form <code>(string . string-pos)</code> if there is a string from a text property or an overlay at the event position.
<i>string</i>	The string which was clicked on, including any properties.
<i>string-pos</i>	The position in the string where the click occurred.
<i>text-pos</i>	For clicks on a marginal area or on a fringe, this is the buffer position of the first visible character in the corresponding line in the window. For clicks on the mode line, the header line or the tab line, this is <code>nil</code> . For other events, it is the buffer position closest to the click.
<i>col, row</i>	These are the actual column and row coordinate numbers of the glyph under the <i>x, y</i> position. If <i>x</i> lies beyond the last column of actual text on its line, <i>col</i> is reported by adding fictional extra columns that have the default character width. Row 0 is taken to be the header line if the window has one, or Row 1 if the window also has the tab line, or the topmost row of the text area otherwise. Column 0 is taken to be the leftmost column of the text area for clicks on a window text area, or the leftmost mode line or header line column for clicks there. For clicks on fringes or vertical borders, these have no meaningful data. For clicks on margins, <i>col</i> is measured from the left edge of the margin area and <i>row</i> is measured from the top of the margin area.
<i>image</i>	If there is an image at the click location, this is the image object as returned by <code>find-image</code> (see Section 41.17.8 [Defining Images], page 1220); otherwise this is <code>nil</code> .
<i>dx, dy</i>	These are the pixel offsets of the click relative to the top left corner of the <i>object</i> 's glyph that is the nearest one to the click. The relevant <i>objects</i> can be either a buffer, or a string, or an image, see above. If <i>object</i> is <code>nil</code> or a string, the coordinates are relative to the top left corner of the character glyph clicked on. Note that the offsets are always zero on text-mode frames, when <i>object</i> is <code>nil</code> , since each glyph there is considered to have exactly 1x1 pixel dimensions.
<i>width, height</i>	If the click is on a character, either from buffer text or from overlay or display string, these are the pixel width and height of that character's glyph; otherwise they are dimensions of <i>object</i> clicked on.
For clicks on a scroll bar, <i>position</i> has this form:	
<code>(window area (portion . whole) timestamp part)</code>	
<i>window</i>	The window whose scroll bar was clicked on.
<i>area</i>	This is the symbol <code>vertical-scroll-bar</code> .
<i>portion</i>	The number of pixels from the top of the scroll bar to the click position. On some toolkits, including GTK+, Emacs cannot extract this data, so the value is always 0.
<i>whole</i>	The total length, in pixels, of the scroll bar. On some toolkits, including GTK+, Emacs cannot extract this data, so the value is always 0.

timestamp

The time at which the event occurred, in milliseconds. On some toolkits, including GTK+, Emacs cannot extract this data, so the value is always 0.

part The part of the scroll bar on which the click occurred. It is one of the symbols **handle** (the scroll bar handle), **above-handle** (the area above the handle), **below-handle** (the area below the handle), **up** (the up arrow at one end of the scroll bar), or **down** (the down arrow at one end of the scroll bar).

For clicks on the frame's internal border (see Section 30.3.1 [Frame Layout], page 791), the frame's tool bar (see Section 23.18.6 [Tool Bar], page 517) or tab bar, *position* has this form:

```
(frame part (X . Y) timestamp)
```

frame The frame whose internal border or tool bar or tab bar was clicked on.

part The part of the frame which was clicked on. This can be one of the following:

tool-bar The frame has a tool bar, and the event was in the tool-bar area.

tab-bar The frame has a tab bar, and the event was in the tab-bar area.

left-edge

top-edge

right-edge

bottom-edge

The click was on the corresponding border at an offset of at least one canonical character from the border's nearest corner.

top-left-corner

top-right-corner

bottom-right-corner

bottom-left-corner

The click was on the corresponding corner of the internal border.

nil The frame does not have an internal border, and the event was not on the tab bar or the tool bar. This usually happens on text-mode frames. This can also happen on GUI frames with internal border if the frame doesn't have its **drag-internal-border** parameter (see Section 30.4.3.7 [Mouse Dragging Parameters], page 813) set to a non-nil value.

22.7.5 Drag Events

With Emacs, you can have a drag event without even changing your clothes. A *drag* event happens every time the user presses a mouse button and then moves the mouse to a different character position before releasing the button. Like all mouse events, drag events are represented in Lisp as lists. The lists record both the starting mouse position and the final position, like this:

```
(event-type
  (window1 START-POSITION)
  (window2 END-POSITION))
```

For a drag event, the name of the symbol *event-type* contains the prefix ‘drag-’. For example, dragging the mouse with button 2 held down generates a `drag-mouse-2` event. The second and third elements of the event give the starting and ending position of the drag, as mouse position lists (see Section 22.7.4 [Click Events], page 442). You can access the second element of any mouse event in the same way. However, the drag event may end outside the boundaries of the frame that was initially selected. In that case, the third element’s position list contains that frame in place of a window.

The ‘drag-’ prefix follows the modifier key prefixes such as ‘C-’ and ‘M-’.

If `read-key-sequence` receives a drag event that has no key binding, and the corresponding click event does have a binding, it changes the drag event into a click event at the drag’s starting position. This means that you don’t have to distinguish between click and drag events unless you want to.

22.7.6 Button-Down Events

Click and drag events happen when the user releases a mouse button. They cannot happen earlier, because there is no way to distinguish a click from a drag until the button is released.

If you want to take action as soon as a button is pressed, you need to handle *button-down* events.² These occur as soon as a button is pressed. They are represented by lists that look exactly like click events (see Section 22.7.4 [Click Events], page 442), except that the *event-type* symbol name contains the prefix ‘down-’. The ‘down-’ prefix follows modifier key prefixes such as ‘C-’ and ‘M-’.

The function `read-key-sequence` ignores any button-down events that don’t have command bindings; therefore, the Emacs command loop ignores them too. This means that you need not worry about defining button-down events unless you want them to do something. The usual reason to define a button-down event is so that you can track mouse motion (by reading motion events) until the button is released. See Section 22.7.8 [Motion Events], page 447.

22.7.7 Repeat Events

If you press the same mouse button more than once in quick succession without moving the mouse, Emacs generates special *repeat* mouse events for the second and subsequent presses.

The most common repeat events are *double-click* events. Emacs generates a double-click event when you click a button twice; the event happens when you release the button (as is normal for all click events).

The event type of a double-click event contains the prefix ‘double-’. Thus, a double click on the second mouse button with `meta` held down comes to the Lisp program as `M-double-mouse-2`. If a double-click event has no binding, the binding of the corresponding ordinary click event is used to execute it. Thus, you need not pay attention to the double click feature unless you really want to.

When the user performs a double click, Emacs generates first an ordinary click event, and then a double-click event. Therefore, you must design the command binding of the double click event to assume that the single-click command has already run. It must produce the desired results of a double click, starting from the results of a single click.

² Button-down is the conservative antithesis of drag.

This is convenient, if the meaning of a double click somehow builds on the meaning of a single click—which is recommended user interface design practice for double clicks.

If you click a button, then press it down again and start moving the mouse with the button held down, then you get a *double-drag* event when you ultimately release the button. Its event type contains ‘**double-drag**’ instead of just ‘**drag**’. If a double-drag event has no binding, Emacs looks for an alternate binding as if the event were an ordinary drag.

Before the double-click or double-drag event, Emacs generates a *double-down* event when the user presses the button down for the second time. Its event type contains ‘**double-down**’ instead of just ‘**down**’. If a double-down event has no binding, Emacs looks for an alternate binding as if the event were an ordinary button-down event. If it finds no binding that way either, the double-down event is ignored.

To summarize, when you click a button and then press it again right away, Emacs generates a down event and a click event for the first click, a double-down event when you press the button again, and finally either a double-click or a double-drag event.

If you click a button twice and then press it again, all in quick succession, Emacs generates a *triple-down* event, followed by either a *triple-click* or a *triple-drag*. The event types of these events contain ‘**triple**’ instead of ‘**double**’. If any triple event has no binding, Emacs uses the binding that it would use for the corresponding double event.

If you click a button three or more times and then press it again, the events for the presses beyond the third are all triple events. Emacs does not have separate event types for quadruple, quintuple, etc. events. However, you can look at the event list to find out precisely how many times the button was pressed.

event-click-count event

[Function]

This function returns the number of consecutive button presses that led up to *event*.

If *event* is a double-down, double-click or double-drag event, the value is 2. If *event* is a triple event, the value is 3 or greater. If *event* is an ordinary mouse event (not a repeat event), the value is 1.

double-click-fuzz

[User Option]

To generate repeat events, successive mouse button presses must be at approximately the same screen position. The value of **double-click-fuzz** specifies the maximum number of pixels the mouse may be moved (horizontally or vertically) between two successive clicks to make a double-click.

This variable is also the threshold for motion of the mouse to count as a drag.

double-click-time

[User Option]

To generate repeat events, the number of milliseconds between successive button presses must be less than the value of **double-click-time**. Setting **double-click-time** to **nil** disables multi-click detection entirely. Setting it to **t** removes the time limit; Emacs then detects multi-clicks by position only.

22.7.8 Motion Events

Emacs sometimes generates *mouse motion* events to describe motion of the mouse without any button activity. Mouse motion events are represented by lists that look like this:

(**mouse-movement** POSITION)

position is a mouse position list (see Section 22.7.4 [Click Events], page 442), specifying the current position of the mouse cursor. As with the end-position of a drag event, this position list may represent a location outside the boundaries of the initially selected frame, in which case the list contains that frame in place of a window.

The **track-mouse** macro enables generation of motion events within its body. Outside of **track-mouse** body, Emacs does not generate events for mere motion of the mouse, and these events do not appear. See Section 30.15 [Mouse Tracking], page 835.

mouse-fine-grained-tracking

[Variable]

When non-*nil*, mouse motion events are generated even for very small movements. Otherwise, motion events are not generated as long as the mouse cursor remains pointing to the same glyph in the text.

22.7.9 Touchscreen Events

Some window systems provide support for input devices that react to the user’s touching the screen and moving fingers while touching the screen. These input devices are known as touchscreens, and Emacs reports the events they generate as *touchscreen events*.

Most individual events generated by a touchscreen only have meaning as part of a larger sequence of other events: for instance, the simple operation of tapping the touchscreen involves the user placing and raising a finger on the touchscreen, and swiping the display to scroll it involves placing a finger, moving it many times upwards or downwards, and then raising the finger.

While a simplistic model consisting of one finger is adequate for taps and scrolling, more complicated gestures require support for keeping track of multiple fingers, where the position of each finger is represented by a *touch point*. For example, a “pinch to zoom” gesture might consist of the user placing two fingers and moving them individually in opposite directions, where the distance between the positions of their individual points determine the amount by which to zoom the display, and the center of an imaginary line between those positions determines where to pan the display after zooming.

The low-level touchscreen events described below can be used to implement all the touch sequences described above. In those events, each point is represented by a cons of an arbitrary number identifying the point and a mouse position list (see Section 22.7.4 [Click Events], page 442) specifying the position of the finger when the event occurred.

(touchscreen-begin point)

This event is sent when *point* is created by the user pressing a finger against the touchscreen.

(touchscreen-update points)

This event is sent when a point on the touchscreen has changed position. *points* is a list of touch points containing the up-to-date positions of each touch point currently on the touchscreen.

(touchscreen-end point)

This event is sent when *point* is no longer present on the display, because another program took the grab, or because the user raised the finger from the touchscreen.

22.7.10 Focus Events

Window systems provide general ways for the user to control which window gets keyboard input. This choice of window is called the *focus*. When the user does something to switch between Emacs frames, that generates a *focus* event. The normal definition of a focus event, in the global keymap, is to select a new frame within Emacs, as the user would expect. See Section 30.10 [Input Focus], page 824, which also describes hooks related to focus events.

Focus events are represented in Lisp as lists that look like this:

`(switch-frame new-frame)`

where *new-frame* is the frame switched to.

Some X window managers are set up so that just moving the mouse into a window is enough to set the focus there. Usually, there is no need for a Lisp program to know about the focus change until some other kind of input arrives. Emacs generates a focus event only when the user actually types a keyboard key or presses a mouse button in the new frame; just moving the mouse between frames does not generate a focus event.

A focus event in the middle of a key sequence would garble the sequence. So Emacs never generates a focus event in the middle of a key sequence. If the user changes focus in the middle of a key sequence—that is, after a prefix key—then Emacs reorders the events so that the focus event comes either before or after the multi-event key sequence, and not within it.

22.7.11 Xwidget events

Xwidgets (see Section 41.19 [Xwidgets], page 1228) can send events to update Lisp programs on their status. These events are dubbed `xwidget-events`, and contain various data describing the nature of the change.

`(xwidget-event kind xwidget arg)`

This event is sent whenever some kind of update occurs in `xwidget`. There are several types of updates, identified by their *kind*.

It is a special event (see Section 22.9 [Special Events], page 470), which should be handled by adding a callback to an xwidget that is called whenever an xwidget event for `xwidget` is received.

You can add a callback by setting the `callback` of an xwidget's property list, which should be a function that accepts `xwidget` and *kind* as arguments.

`load-changed`

This xwidget event indicates that the `xwidget` has reached a particular point of the page-loading process. When these events are sent, *arg* will contain a string that further describes the status of the widget:

`'load-started'`

This means the widget has begun a page-loading operation.

`'load-finished'`

This means the `xwidget` has finished processing whatever page-loading operation that it was previously performing.

'load-redirected'

This means the xwidget has encountered and followed a redirect during the page-loading operation.

'load-committed'

This means the xwidget has committed to a given URL during the page-loading operation, i.e. the URL is the final URL that will be rendered by xwidget during the current page-loading operation.

download-callback

This event indicates that a download of some kind has been completed.

In the above events, there can be arguments after *arg*, which itself indicates the URL from which the download file was retrieved: the first argument after *arg* indicates the MIME type of the download, as a string, while the second argument contains the full file name of the downloaded file.

download-started

This event indicates that a download has been started. In these events, *arg* contains the URL of the file that is currently being downloaded.

javascript-callback

This event contains JavaScript callback data. These events are used internally by **xwidget-webkit-execute-script**.

(xwidget-display-event *xwidget source*)

This event is sent whenever an xwidget requests that another xwidget be displayed. *xwidget* is the xwidget that should be displayed, and *source* is the xwidget that asked to display *xwidget*.

It is also a special event which should be handled through callbacks. You can add such a callback by setting the **display-callback** of *source*'s property list, which should be a function that accepts *xwidget* and *source* as arguments.

xwidget's buffer will be set to a temporary buffer. When displaying the widget, care should be taken to replace the buffer with the buffer in which the xwidget will be displayed, using **set-xwidget-buffer** (see Section 41.19 [Xwidgets], page 1228).

22.7.12 Miscellaneous System Events

A few other event types represent occurrences within the system.

(delete-frame (*frame*))

This kind of event indicates that the user gave the window manager a command to delete a particular window, which happens to be an Emacs frame.

The standard definition of the **delete-frame** event is to delete *frame*.

(iconify-frame (*frame*))

This kind of event indicates that the user iconified *frame* using the window manager. Its standard definition is **ignore**; since the frame has already been

iconified, Emacs has no work to do. The purpose of this event type is so that you can keep track of such events if you want to.

(make-frame-visible (frame))

This kind of event indicates that the user deiconified *frame* using the window manager. Its standard definition is `ignore`; since the frame has already been made visible, Emacs has no work to do.

(touch-end (position))

This kind of event indicates that the user's finger moved off the mouse wheel or the touchpad. The *position* element is a mouse position list (see Section 22.7.4 [Click Events], page 442), specifying the position of the mouse cursor when the finger moved off the mouse wheel.

(wheel-up position clicks lines pixel-delta)

(wheel-down position clicks lines pixel-delta)

These events are generated by moving a mouse wheel. The *position* element is a mouse position list (see Section 22.7.4 [Click Events], page 442), specifying the position of the mouse cursor when the event occurred.

clicks, if present, is the number of times that the wheel was moved in quick succession. See Section 22.7.7 [Repeat Events], page 446. *lines*, if present and not `nil`, is the positive number of screen lines that should be scrolled (either up, when the event is `wheel-up`, or down when the event is `wheel-down`). *pixel-delta*, if present, is a cons cell of the form `(x . y)`, where *x* and *y* are the numbers of pixels by which to scroll in each axis, a.k.a. *pixelwise deltas*. Usually, only one of the two will be non-zero, the other will be either zero or very close to zero; the larger number indicates the axis to scroll the window. When the variable `mwheel-coalesce-scroll-events` is `nil`, the scroll commands ignore the *lines* element, even if it's non-`nil`, and use the *pixel-delta* data instead; in that case, the direction of scrolling is determined by the sign of the pixelwise deltas, and the direction (up or down) implied by the event kind is ignored.

You can use these *x* and *y* pixelwise deltas to determine how much the mouse wheel has actually moved at pixel resolution. For example, the pixelwise deltas could be used to scroll the display at pixel resolution, exactly according to the user's turning the mouse wheel. This pixelwise scrolling is possible only when `mwheel-coalesce-scroll-events` is `nil`, and in general the *pixel-delta* data is not generated when that variable is non-`nil`.

The `wheel-up` and `wheel-down` events are generated only on some kinds of systems. On other systems, `mouse-4` and `mouse-5` are used instead. For portable code, use the variables `mouse-wheel-up-event`, `mouse-wheel-up-alternate-event`, `mouse-wheel-down-event` and `mouse-wheel-down-alternate-event` defined in `mwheel.el` to determine what event types to expect from the mouse wheel.

Similarly, some mice can generate `mouse-wheel-left-event` and `mouse-wheel-right-event` and can be used to scroll if `mouse-wheel-tilt-scroll` is non-`nil`. However, some mice also generate other events at the same time as they're generating these scroll events which may get in the way. The way to fix this is

generally to unbind these events (for instance, `mouse-6` or `mouse-7`, but this is very hardware and operating system dependent).

(pinch *position* *dx* *dy* *scale* *angle*)

This kind of event is generated by the user performing a “pinch” gesture by placing two fingers on a touchpad and moving them towards or away from each other. *position* is a mouse position list (see Section 22.7.4 [Click Events], page 442) that provides the position of the mouse pointer when the event occurred, *dx* is the change in the horizontal distance between the fingers since the last event in the same sequence, *dy* is the vertical movement of the fingers since the last event in the same sequence, *scale* is the ratio of the current distance between the fingers to that distance at the start of the sequence, and *angle* is the angular difference in degrees between the direction of the line connecting the fingers in this event and the direction of that line in the last event of the same sequence.

As pinch events are only sent at the beginning or during a pinch sequence, they do not report gestures where the user moves two fingers on a touchpad in a rotating fashion without pinching the fingers.

All arguments after *position* are floating point numbers.

This event is usually sent as part of a sequence, which begins with the user placing two fingers on the touchpad, and ends with the user removing those fingers. *dx*, *dy*, and *angle* will be `0.0` in the first event of a sequence; subsequent events will report non-zero values for these members of the event structure.

dx and *dy* are reported in imaginary relative units, in which `1.0` is the width and height of the touchpad respectively. They are usually interpreted as being relative to the size of the object beneath the gesture: image, window, etc.

(preedit-text *arg*)

This event is sent when a system input method tells Emacs to display some text to indicate to the user what will be inserted. The contents of *arg* are dependent on the window system being used.

On X, *arg* is a string describing some text to place behind the cursor. It can be `nil`, which means to remove any text previously displayed.

On PGTK frames (see Chapter 30 [Frames], page 785), *arg* is a list of strings with information about their color and underline attributes. It has the following form:

```
((string1
  (ul . underline-color)
  (bg . background-color)
  (fg . foreground-color))
 (string2
  (ul . underline-color)
  (bg . background-color)
  (fg . foreground-color))
 ...
)
```

Color information can be omitted, leaving just the text of the strings. *underline-color* can be `t`, meaning underlined text with default underline color, or it can be a string, the name of the color to draw the underline.

This is a special event (see Section 22.9 [Special Events], page 470), which normally should not be bound by the user to any command. Emacs will typically display the text contained in the event in an overlay behind point when it is received.

`(drag-n-drop position files)`

This kind of event is generated when a group of files is selected in an application outside of Emacs, and then dragged and dropped onto an Emacs frame.

The element *position* is a list describing the position of the event, in the same format as used in a mouse-click event (see Section 22.7.4 [Click Events], page 442), and *files* is the list of file names that were dragged and dropped. The usual way to handle this event is by visiting these files.

This kind of event is generated, at present, only on some kinds of systems.

`help-echo`

This kind of event is generated when a mouse pointer moves onto a portion of buffer text which has a `help-echo` text property. The generated event has this form:

`(help-echo frame help window object pos)`

The precise meaning of the event parameters and the way these parameters are used to display the help-echo text are described in [Text help-echo], page 926.

`sigusr1`

`sigusr2`

These events are generated when the Emacs process receives the signals `SIGUSR1` and `SIGUSR2`. They contain no additional data because signals do not carry additional information. They can be useful for debugging (see Section 19.1.1 [Error Debugging], page 333).

To catch a user signal, bind the corresponding event to an interactive command in the `special-event-map` (see Section 23.9 [Controlling Active Maps], page 491). The command is called with no arguments, and the specific signal event is available in `last-input-event` (see Section 22.8.6 [Event Input Misc], page 468). For example:

```
(defun sigusr-handler ()
  (interactive)
  (message "Caught signal %S" last-input-event))

(keymap-set special-event-map "<sigusr1>" 'sigusr-handler)
```

To test the signal handler, you can make Emacs send a signal to itself:

```
(signal-process (emacs-pid) 'sigusr1)
```

`language-change`

This kind of event is generated on MS-Windows when the input language has changed. This typically means that the keyboard keys will send to Emacs characters from a different language. The generated event has this form:

```
(language-change frame codepage language-id)
```

Here *frame* is the frame which was current when the input language changed; *codepage* is the new codepage number; and *language-id* is the numerical ID of the new input language. The coding-system (see Section 34.10 [Coding Systems], page 976) that corresponds to *codepage* is `cpcodepage` or `windows-codepage`. To convert *language-id* to a string (e.g., to use it for various language-dependent features, such as `set-language-environment`), use the `w32-get-locale-info` function, like this:

```
; ; Get the abbreviated language name, such as "ENU" for English
(w32-get-locale-info language-id)
; ; Get the full English name of the language,
; ; such as "English (United States)"
(w32-get-locale-info language-id 4097)
; ; Get the full localized name of the language
(w32-get-locale-info language-id t)

end-session
```

This event is generated on MS-Windows when the operating system informs Emacs that the user terminated the interactive session, or that the system is shutting down. The standard definition of this event is to invoke the `kill-emacs` command (see Section 42.2.1 [Killing Emacs], page 1262) so as to shut down Emacs in an orderly fashion; if there are unsaved changes, this will produce auto-save files (see Section 27.2 [Auto-Saving], page 664) that the user can use after restarting the session to restore the unsaved edits.

If one of these events arrives in the middle of a key sequence—that is, after a prefix key—then Emacs reorders the events so that this event comes either before or after the multi-event key sequence, not within it.

Some of these special events, such as `delete-frame`, invoke Emacs commands by default; others are not bound. If you want to arrange for a special event to invoke a command, you can do that via `special-event-map`. The command you bind to a function key in that map can then examine the full event which invoked it in `last-input-event`. See Section 22.9 [Special Events], page 470.

22.7.13 Event Examples

If the user presses and releases the left mouse button over the same location, that generates a sequence of events like this:

```
(down-mouse-1 (#<window 18 on NEWS> 2613 (0 . 38) -864320))
(mouse-1      (#<window 18 on NEWS> 2613 (0 . 38) -864180))
```

While holding the control key down, the user might hold down the second mouse button, and drag the mouse from one line to the next. That produces two events, as shown here:

```
(C-down-mouse-2 (#<window 18 on NEWS> 3440 (0 . 27) -731219))
(C-drag-mouse-2 (#<window 18 on NEWS> 3440 (0 . 27) -731219)
                 (#<window 18 on NEWS> 3510 (0 . 28) -729648))
```

While holding down the meta and shift keys, the user might press the second mouse button on the window's mode line, and then drag the mouse into another window. That produces a pair of events like these:

```
(M-S-down-mouse-2 (#<window 18 on NEWS> mode-line (33 . 31) -457844))
(M-S-drag-mouse-2 (#<window 18 on NEWS> mode-line (33 . 31) -457844)
                  (#<window 20 on carlton-sanskrit.tex> 161 (33 . 3))
```

```
-453816))
```

The frame with input focus might not take up the entire screen, and the user might move the mouse outside the scope of the frame. Inside the `track-mouse` macro, that produces an event like this:

```
(mouse-movement (#<frame *ielm* 0x102849a30> nil (563 . 205) 532301936))
```

22.7.14 Classifying Events

Every event has an *event type*, which classifies the event for key binding purposes. For a keyboard event, the event type equals the event value; thus, the event type for a character is the character, and the event type for a function key symbol is the symbol itself. For events that are lists, the event type is the symbol in the CAR of the list. Thus, the event type is always a symbol or a character.

Two events of the same type are equivalent where key bindings are concerned; thus, they always run the same command. That does not necessarily mean they do the same things, however, as some commands look at the whole event to decide what to do. For example, some commands use the location of a mouse event to decide where in the buffer to act.

Sometimes broader classifications of events are useful. For example, you might want to ask whether an event involved the META key, regardless of which other key or mouse button was used.

The functions `event-modifiers` and `event-basic-type` are provided to get such information conveniently.

`event-modifiers` *event*

[Function]

This function returns a list of the modifiers that *event* has. The modifiers are symbols; they include `shift`, `control`, `meta`, `alt`, `hyper` and `super`. In addition, the modifiers list of a mouse event symbol always contains one of `click`, `drag`, and `down`. For double or triple events, it also contains `double` or `triple`.

The argument *event* may be an entire event object, or just an event type. If *event* is a symbol that has never been used in an event that has been read as input in the current Emacs session, then `event-modifiers` can return `nil`, even when *event* actually has modifiers.

Here are some examples:

```
(event-modifiers ?a)
  ⇒ nil
(event-modifiers ?A)
  ⇒ (shift)
(event-modifiers ?\C-a)
  ⇒ (control)
(event-modifiers ?\C-%)
  ⇒ (control)
(event-modifiers ?\C-\S-a)
  ⇒ (control shift)
(event-modifiers 'f5)
  ⇒ nil
(event-modifiers 's-f5)
```

```

⇒ (super)
(event-modifiers 'M-S-f5)
⇒ (meta shift)
(event-modifiers 'mouse-1)
⇒ (click)
(event-modifiers 'down-mouse-1)
⇒ (down)

```

The modifiers list for a click event explicitly contains `click`, but the event symbol name itself does not contain ‘`click`’. Similarly, the modifiers list for an ASCII control character, such as ‘`C-a`’, contains `control`, even though reading such an event via `read-char` will return the value 1 with the control modifier bit removed.

event-basic-type *event* [Function]

This function returns the key or mouse button that *event* describes, with all modifiers removed. The *event* argument is as in `event-modifiers`. For example:

```

(event-basic-type ?a)
⇒ 97
(event-basic-type ?A)
⇒ 97
(event-basic-type ?\C-a)
⇒ 97
(event-basic-type ?\C-\S-a)
⇒ 97
(event-basic-type 'f5)
⇒ f5
(event-basic-type 's-f5)
⇒ f5
(event-basic-type 'M-S-f5)
⇒ f5
(event-basic-type 'down-mouse-1)
⇒ mouse-1

```

mouse-movement-p *object* [Function]

This function returns non-`nil` if *object* is a mouse movement event. See Section 22.7.8 [Motion Events], page 447.

22.7.15 Accessing Mouse Events

This section describes convenient functions for accessing the data in a mouse button or motion event. Keyboard event data can be accessed using the same functions, but data elements that aren’t applicable to keyboard events are zero or `nil`.

The following two functions return a mouse position list (see Section 22.7.4 [Click Events], page 442), specifying the position of a mouse event.

event-start *event* [Function]

This returns the starting position of *event*.

If *event* is a click or button-down event, this returns the location of the event. If *event* is a drag event, this returns the drag’s starting position.

event-end *event* [Function]

This returns the ending position of *event*.

If *event* is a drag event, this returns the position where the user released the mouse button. If *event* is a click or button-down event, the value is actually the starting position, which is the only position such events have.

posnp *object* [Function]

This function returns non-*nil* if *object* is a mouse position list, in the format documented in Section 22.7.4 [Click Events], page 442); and *nil* otherwise.

These functions take a mouse position list as argument, and return various parts of it:

posn-window *position* [Function]

Return the window that *position* is in. If *position* represents a location outside the frame where the event was initiated, return that frame instead.

posn-area *position* [Function]

Return the window area recorded in *position*. It returns *nil* when the event occurred in the text area of the window; otherwise, it is a symbol identifying the area in which the event occurred.

posn-point *position* [Function]

Return the buffer position in *position*. When the event occurred in the text area of the window, in a marginal area, or on a fringe, this is an integer specifying a buffer position. Otherwise, the value is undefined.

posn-x-y *position* [Function]

Return the pixel-based x and y coordinates in *position*, as a cons cell (*x* . *y*). These coordinates are relative to the window given by **posn-window**.

This example shows how to convert the window-relative coordinates in the text area of a window into frame-relative coordinates:

```
(defun frame-relative-coordinates (position)
  "Return frame-relative coordinates from POSITION.
POSITION is assumed to lie in a window text area."
  (let* ((x-y (posn-x-y position))
         (window (posn-window position))
         (edges (window-inside-pixel-edges window)))
    (cons (+ (car x-y) (car edges))
          (+ (cdr x-y) (cadr edges)))))
```

posn-col-row *position* &**optional** *use-window* [Function]

This function returns a cons cell (*col* . *row*), containing the estimated column and row corresponding to buffer position described by *position*. The return value is given in units of the frame's default character width and default line height (including spacing), as computed from the *x* and *y* values corresponding to *position*. (So, if the actual characters have non-default sizes, the actual row and column may differ from these computed values.) If the optional *window* argument is non-*nil*, use the default character width in the window indicated by *position* instead of the frame. (This makes

a difference if that window is showing a buffer with a non-default zooming level, for instance.)

Note that *row* is counted from the top of the text area. If the window given by *position* possesses a header line (see Section 24.4.7 [Header Lines], page 559) or a tab line, they are *not* included in the *row* count.

posn-actual-col-row *position*

[Function]

Return the actual row and column in *position*, as a cons cell (*col . row*). The values are the actual row and column numbers in the window given by *position*. See Section 22.7.4 [Click Events], page 442, for details. The function returns **nil** if *position* does not include actual position values; in that case **posn-col-row** can be used to get approximate values.

Note that this function doesn't account for the visual width of characters on display, like the number of visual columns taken by a tab character or an image. If you need the coordinates in canonical character units, use **posn-col-row** instead.

posn-string *position*

[Function]

Return the string object described by *position*, either **nil** (which means *position* describes buffer text), or a cons cell (*string . string-pos*).

posn-image *position*

[Function]

Return the image object in *position*, either **nil** (if there's no image at *position*), or an image spec (*image ...*).

posn-object *position*

[Function]

Return the image or string object described by *position*, either **nil** (which means *position* describes buffer text), an image (*image ...*), or a cons cell (*string . string-pos*).

posn-object-x-y *position*

[Function]

Return the pixel-based x and y coordinates relative to the upper left corner of the object described by *position*, as a cons cell (*dx . dy*). If the *position* describes buffer text, return the relative coordinates of the buffer-text character closest to that position.

posn-object-width-height *position*

[Function]

Return the pixel width and height of the object described by *position*, as a cons cell (*width . height*). If the *position* describes a buffer position, return the size of the character at that position.

posn-timestamp *position*

[Function]

Return the timestamp in *position*. This is the time at which the event occurred, in milliseconds. Such a timestamp is reported relative to an arbitrary starting time that varies according to the window system in use. On the X Window System, for example, it is the number of milliseconds since the X server was started.

These functions compute a position list given particular buffer position or screen position. You can access the data in this position list with the functions described above.

posn-at-point &optional pos window [Function]

This function returns a position list for position *pos* in *window*. *pos* defaults to point in *window*; *window* defaults to the selected window.

posn-at-point returns `nil` if *pos* is not visible in *window*.

posn-at-x-y x y &optional frame-or-window whole [Function]

This function returns position information corresponding to pixel coordinates *x* and *y* in a specified frame or window, *frame-or-window*, which defaults to the selected window. The coordinates *x* and *y* are relative to the text area of the selected window. If *whole* is non-`nil`, the *x* coordinate is relative to the entire window area including scroll bars, margins and fringes.

22.7.16 Accessing Scroll Bar Events

These functions are useful for decoding scroll bar events.

scroll-bar-event-ratio event [Function]

This function returns the fractional vertical position of a scroll bar event within the scroll bar. The value is a cons cell (*portion* . *whole*) containing two integers whose ratio is the fractional position.

scroll-bar-scale ratio total [Function]

This function multiplies (in effect) *ratio* by *total*, rounding the result to an integer. The argument *ratio* is not a number, but rather a pair (*num* . *denom*)—typically a value returned by **scroll-bar-event-ratio**.

This function is handy for scaling a position on a scroll bar into a buffer position. Here's how to do that:

```
(+ (point-min)
  (scroll-bar-scale
    (posn-x-y (event-start event))
    (- (point-max) (point-min))))
```

Recall that scroll bar events have two integers forming a ratio, in place of a pair of *x* and *y* coordinates.

22.7.17 Putting Keyboard Events in Strings

In most of the places where strings are used, we conceptualize the string as containing text characters—the same kind of characters found in buffers or files. Occasionally Lisp programs use strings that conceptually contain keyboard characters; for example, they may be key sequences or keyboard macro definitions. However, storing keyboard characters in a string is a complex matter, for reasons of historical compatibility, and it is not always possible.

We recommend that new programs avoid dealing with these complexities by not storing keyboard events in strings containing control characters or the like, but instead store them in the common Emacs format as understood by **key-valid-p**.

If you read a key sequence with **read-key-sequence-vector** (or **read-key-sequence**), or access a key sequence with **this-command-keys-vector** (or **this-command-keys**), you can transform this to the recommended format by using **key-description**.

The complexities stem from the modifier bits that keyboard input characters can include. Aside from the Meta modifier, none of these modifier bits can be included in a string, and the Meta modifier is allowed only in special cases.

The earliest GNU Emacs versions represented meta characters as codes in the range of 128 to 255. At that time, the basic character codes ranged from 0 to 127, so all keyboard character codes did fit in a string. Many Lisp programs used ‘\M-’ in string constants to stand for meta characters, especially in arguments to `define-key` and similar functions, and key sequences and sequences of events were always represented as strings.

When we added support for larger basic character codes beyond 127, and additional modifier bits, we had to change the representation of meta characters. Now the flag that represents the Meta modifier in a character is 2^{27} and such numbers cannot be included in a string.

To support programs with ‘\M-’ in string constants, there are special rules for including certain meta characters in a string. Here are the rules for interpreting a string as a sequence of input characters:

- If the keyboard character value is in the range of 0 to 127, it can go in the string unchanged.
- The meta variants of those characters, with codes in the range of 2^{27} to $2^{27} + 127$, can also go in the string, but you must change their numeric values. You must set the 2^7 bit instead of the 2^{27} bit, resulting in a value between 128 and 255. Only a unibyte string can include these codes.
- Non-ASCII characters above 256 can be included in a multibyte string.
- Other keyboard character events cannot fit in a string. This includes keyboard events in the range of 128 to 255.

Functions such as `read-key-sequence` that construct strings of keyboard input characters follow these rules: they construct vectors instead of strings, when the events won’t fit in a string.

When you use the read syntax ‘\M-’ in a string, it produces a code in the range of 128 to 255—the same code that you get if you modify the corresponding keyboard event to put it in the string. Thus, meta events in strings work consistently regardless of how they get into the strings.

However, most programs would do well to avoid these issues by following the recommendations at the beginning of this section.

22.8 Reading Input

The editor command loop reads key sequences using the function `read-key-sequence`, which uses `read-event`. These and other functions for event input are also available for use in Lisp programs. See also `momentary-string-display` in Section 41.8 [Temporary Displays], page 1146, and `sit-for` in Section 22.10 [Waiting], page 470. See Section 42.13 [Terminal Input], page 1285, for functions and variables for controlling terminal input modes and debugging terminal input.

For higher-level input facilities, see Chapter 21 [Minibuffers], page 385.

22.8.1 Key Sequence Input

The command loop reads input a key sequence at a time, by calling `read-key-sequence`. Lisp programs can also call this function; for example, `describe-key` uses it to read the key to describe.

`read-key-sequence` *prompt* &*optional continue-echo* [Function]
dont-downcase-last *switch-frame-ok* *command-loop*

This function reads a key sequence and returns it as a string or vector. It keeps reading events until it has accumulated a complete key sequence; that is, enough to specify a non-prefix command using the currently active keymaps. (Remember that a key sequence that starts with a mouse event is read using the keymaps of the buffer in the window that the mouse was in, not the current buffer.)

If the events are all characters and all can fit in a string, then `read-key-sequence` returns a string (see Section 22.7.17 [Strings of Events], page 459). Otherwise, it returns a vector, since a vector can hold all kinds of events—characters, symbols, and lists. The elements of the string or vector are the events in the key sequence.

Reading a key sequence includes translating the events in various ways. See Section 23.15 [Translation Keymaps], page 504.

The argument *prompt* is either a string to be displayed in the echo area as a prompt, or `nil`, meaning not to display a prompt. The argument *continue-echo*, if non-`nil`, means to echo this key as a continuation of the previous key.

Normally any upper case event is converted to lower case if the original event is undefined and the lower case equivalent is defined. The argument *dont-downcase-last*, if non-`nil`, means do not convert the last event to lower case. This is appropriate for reading a key sequence to be defined.

The argument *switch-frame-ok*, if non-`nil`, means that this function should process a `switch-frame` event if the user switches frames before typing anything. If the user switches frames in the middle of a key sequence, or at the start of the sequence but *switch-frame-ok* is `nil`, then the event will be put off until after the current key sequence.

The argument *command-loop*, if non-`nil`, means that this key sequence is being read by something that will read commands one after another. It should be `nil` if the caller will read just one key sequence.

In the following example, Emacs displays the prompt ‘?’ in the echo area, and then the user types *C-x C-f*.

```
(read-key-sequence "?")
-----
----- Echo Area -----
?C-x C-f
-----
----- Echo Area -----
⇒ "^\u00d7F"
```

The function `read-key-sequence` suppresses quitting: *C-g* typed while reading with this function works like any other character, and does not set `quit-flag`. See Section 22.11 [Quitting], page 471.

read-key-sequence-vector *prompt &optional continue-echo* [Function]
dont-downcase-last switch-frame-ok command-loop

This is like **read-key-sequence** except that it always returns the key sequence as a vector, never as a string. See Section 22.7.17 [Strings of Events], page 459.

If an input character is upper-case (or has the shift modifier) and has no key binding, but its lower-case equivalent has one, then **read-key-sequence** converts the character to lower case. (This behavior can be disabled by setting the **translate-upper-case-key-bindings** user option to `nil`.) Note that **lookup-key** does not perform case conversion in this way.

When reading input results in such a *shift-translation*, Emacs sets the variable **this-command-keys-shift-translated** to a non-`nil` value. Lisp programs can examine this variable if they need to modify their behavior when invoked by shift-translated keys. For example, the function **handle-shift-selection** examines the value of this variable to determine how to activate or deactivate the region (see Section 32.7 [The Mark], page 873).

The function **read-key-sequence** also transforms some mouse events. It converts unbound drag events into click events, and discards unbound button-down events entirely. It also reshuffles focus events and miscellaneous window events so that they never appear in a key sequence with any other events.

When mouse events occur in special parts of a window or frame, such as a mode line or a scroll bar, the event type shows nothing special—it is the same symbol that would normally represent that combination of mouse button and modifier keys. The information about the window part is kept elsewhere in the event—in the coordinates. But **read-key-sequence** translates this information into imaginary prefix keys, all of which are symbols: **tab-line**, **header-line**, **horizontal-scroll-bar**, **menu-bar**, **tab-bar**, **mode-line**, **vertical-line**, **vertical-scroll-bar**, **left-margin**, **right-margin**, **left-fringe**, **right-fringe**, **right-divider**, and **bottom-divider**. You can define meanings for mouse clicks in special window parts by defining key sequences using these imaginary prefix keys.

For example, if you call **read-key-sequence** and then click the mouse on the window's mode line, you get two events, like this:

```
(read-key-sequence "Click on the mode line: ")
⇒ [mode-line
  (mouse-1
   (#<window 6 on NEWS> mode-line
    (40 . 63) 5959987))]
```

num-input-keys [Variable]

This variable's value is the number of key sequences processed so far in this Emacs session. This includes key sequences read from the terminal and key sequences read from keyboard macros being executed.

22.8.2 Reading One Event

The lowest level functions for command input are **read-event**, **read-char**, and **read-char-exclusive**.

If you need a function to read a character using the minibuffer, use **read-char-from-minibuffer** (see Section 21.8 [Multiple Queries], page 414).

read-event &optional *prompt inherit-input-method seconds* [Function]

This function reads and returns the next event of command input, waiting if necessary until an event is available.

The returned event may come directly from the user, or from a keyboard macro. It is not decoded by the keyboard’s input coding system (see Section 34.10.8 [Terminal I/O Encoding], page 990).

If the optional argument *prompt* is non-*nil*, it should be a string to display in the echo area as a prompt. If *prompt* is *nil* or the string ‘“”’, **read-event** does not display any message to indicate it is waiting for input; instead, it prompts by echoing: it displays descriptions of the events that led to or were read by the current command. See Section 41.4 [The Echo Area], page 1131.

If *inherit-input-method* is non-*nil*, then the current input method (if any) is employed to make it possible to enter a non-ASCII character. Otherwise, input method handling is disabled for reading this event.

If **cursor-in-echo-area** is non-*nil*, then **read-event** moves the cursor temporarily to the echo area, to the end of any message displayed there. Otherwise **read-event** does not move the cursor.

If *seconds* is non-*nil*, it should be a number specifying the maximum time to wait for input, in seconds. If no input arrives within that time, **read-event** stops waiting and returns *nil*. A floating point *seconds* means to wait for a fractional number of seconds. Some systems support only a whole number of seconds; on these systems, *seconds* is rounded down. If *seconds* is *nil*, **read-event** waits as long as necessary for input to arrive.

If *seconds* is *nil*, Emacs is considered idle while waiting for user input to arrive. Idle timers—those created with **run-with-idle-timer** (see Section 42.12 [Idle Timers], page 1284)—can run during this period. However, if *seconds* is non-*nil*, the state of idleness remains unchanged. If Emacs is non-idle when **read-event** is called, it remains non-idle throughout the operation of **read-event**; if Emacs is idle (which can happen if the call happens inside an idle timer), it remains idle.

If **read-event** gets an event that is defined as a help character, then in some cases **read-event** processes the event directly without returning. See Section 25.6 [Help Functions], page 602. Certain other events, called *special events*, are also processed directly within **read-event** (see Section 22.9 [Special Events], page 470).

Here is what happens if you call **read-event** and then press the right-arrow function key:

```
(read-event)
⇒ right
```

read-char &optional *prompt inherit-input-method seconds* [Function]

This function reads and returns a character input event. If the user generates an event which is not a character (i.e., a mouse click or function key event), **read-char** signals an error. The arguments work as in **read-event**.

If the event has modifiers, Emacs attempts to resolve them and return the code of the corresponding character. For example, if the user types *C-a*, the function returns 1, which is the ASCII code of the ‘C-a’ character. If some of the modifiers cannot

be reflected in the character code, `read-char` leaves the unresolved modifier bits set in the returned event. For example, if the user types `C-M-a`, the function returns 134217729, 8000001 in hex, i.e. ‘C-a’ with the Meta modifier bit set. This value is not a valid character code: it fails the `characterp` test (see Section 34.5 [Character Codes], page 967). Use `event-basic-type` (see Section 22.7.14 [Classifying Events], page 455) to recover the character code with the modifier bits removed; use `event-modifiers` to test for modifiers in the character event returned by `read-char`.

In the first example below, the user types the character `1` (ASCII code 49). The second example shows a keyboard macro definition that calls `read-char` from the minibuffer using `eval-expression`. `read-char` reads the keyboard macro’s very next character, which is `1`. Then `eval-expression` displays its return value in the echo area.

```
(read-char)
⇒ 49
```

```
; ; We assume here you use M-: to evaluate this.
(symbol-function 'foo)
⇒ "^[:(read-char)^M1"
(execute-kbd-macro 'foo)
⇒ 49
⇒ nil
```

read-char-exclusive &optional prompt inherit-input-method [Function]
seconds

This function reads and returns a character input event. If the user generates an event which is not a character event, `read-char-exclusive` ignores it and reads another event, until it gets a character. The arguments work as in `read-event`. The returned value may include modifier bits, as with `read-char`.

None of the above functions suppress quitting.

num-nonmacro-input-events [Variable]

This variable holds the total number of input events received so far from the terminal—not counting those generated by keyboard macros.

We emphasize that, unlike `read-key-sequence`, the functions `read-event`, `read-char`, and `read-char-exclusive` do not perform the translations described in Section 23.15 [Translation Keymaps], page 504. If you wish to read a single key taking these translations into account (for example, to read Section 22.7.2 [Function Keys], page 441, in a terminal or Section 22.7.3 [Mouse Events], page 442, from `xterm-mouse-mode`), use the function `read-key`:

read-key &optional prompt disable-fallbacks [Function]

This function reads a single key. It is intermediate between `read-key-sequence` and `read-event`. Unlike the former, it reads a single key, not a key sequence. Unlike the latter, it does not return a raw event, but decodes and translates the user input according to `input-decode-map`, `local-function-key-map`, and `key-translation-map` (see Section 23.15 [Translation Keymaps], page 504).

The argument *prompt* is either a string to be displayed in the echo area as a prompt, or **nil**, meaning not to display a prompt.

If argument *disable-fallbacks* is non-**nil** then the usual fallback logic for unbound keys in **read-key-sequence** is not applied. This means that mouse button-down and multi-click events will not be discarded and **local-function-key-map** and **key-translation-map** will not get applied. If **nil** or unspecified, the only fallback disabled is downcasing of the last event.

read-char-choice *prompt chars &optional inhibit-quit* [Function]

This function uses **read-from-minibuffer** to read and return a single character that is a member of *chars*, which should be a list of single characters. It discards any input characters that are not members of *chars*, and shows a message to that effect.

The optional argument *inhibit-quit* is by default ignored, but if the variable **read-char-choice-use-read-key** is non-**nil**, this function uses **read-key** instead of **read-from-minibuffer**, and in that case *inhibit-quit* non-**nil** means ignore keyboard-quit events while waiting for valid input. In addition, if **read-char-choice-use-read-key** is non-**nil**, binding **help-form** (see Section 25.6 [Help Functions], page 602) to a non-**nil** value while calling this function causes it to evaluate **help-form** and display the result when the user presses **help-char**; it then continues to wait for a valid input character, or for keyboard-quit.

read-multiple-choice *prompt choices &optional help-string show-help long-form* [Function]

Ask user a multiple choice question. *prompt* should be a string that will be displayed as the prompt.

choices is an alist where the first element in each entry is a character to be entered, the second element is a short name for the entry to be displayed while prompting (if there's room, it might be shortened), and the third, optional entry is a longer explanation that will be displayed in a help buffer if the user requests more help.

If optional argument *help-string* is non-**nil**, it should be a string with a more detailed description of all choices. It will be displayed in a help buffer instead of the default auto-generated description when the user types **?**.

If optional argument *show-help* is non-**nil**, the help buffer will be displayed immediately, before any user input. If it is a string, use it as the name of the help buffer.

If optional argument *long-form* is non-**nil**, the user will have to type in long-form answers (using **completing-read**) instead of hitting a single key. The answers must be among the second elements of the values in the *choices* list.

The return value is the matching value from *choices*.

```
(read-multiple-choice
  "Continue connecting?"
  '((?a "always" "Accept certificate for this and future sessions.")
    (?s "session only" "Accept certificate this session only.")
    (?n "no" "Refuse to use certificate, close connection.")))
```

The **read-multiple-choice-face** face is used to highlight the matching characters in the name string on graphical terminals.

22.8.3 Modifying and Translating Input Events

Emacs modifies every event it reads according to `extra-keyboard-modifiers`, then translates it through `keyboard-translate-table` (if applicable), before returning it from `read-event`.

`extra-keyboard-modifiers`

[Variable]

This variable lets Lisp programs “press” the modifier keys on the keyboard. The value is a character. Only the modifiers of the character matter. Each time the user types a keyboard key, it is altered as if those modifier keys were held down. For instance, if you bind `extra-keyboard-modifiers` to `?\\C-\\M-a`, then all keyboard input characters typed during the scope of the binding will have the control and meta modifiers applied to them. The character `?\\C-0`, equivalent to the integer 0, does not count as a control character for this purpose, but as a character with no modifiers. Thus, setting `extra-keyboard-modifiers` to zero cancels any modification.

When using a window system, the program can press any of the modifier keys in this way. Otherwise, only the `CTL` and `META` keys can be virtually pressed.

Note that this variable applies only to events that really come from the keyboard, and has no effect on mouse events or any other events.

`keyboard-translate-table`

[Variable]

This terminal-local variable is the translate table for keyboard characters. It lets you reshuffle the keys on the keyboard without changing any command bindings. Its value is normally a char-table, or else `nil`. (It can also be a string or vector, but this is considered obsolete.)

If `keyboard-translate-table` is a char-table (see Section 6.6 [Char-Tables], page 119), then each character read from the keyboard is looked up in this char-table. If the value found there is non-`nil`, then it is used instead of the actual input character.

Note that this translation is the first thing that happens to a character after it is read from the terminal. Record-keeping features such as `recent-keys` and `dribble` files record the characters after translation.

Note also that this translation is done before the characters are supplied to input methods (see Section 34.11 [Input Methods], page 990). Use `translation-table-for-input` (see Section 34.9 [Translation of Characters], page 975), if you want to translate characters after input methods operate.

`key-translate from to`

[Function]

This function modifies `keyboard-translate-table` to translate character code `from` into character code `to`. It creates the keyboard translate table if necessary.

Here’s an example of using the `keyboard-translate-table` to make `C-x`, `C-c` and `C-v` perform the cut, copy and paste operations:

```
(key-translate "C-x" "<control-x>")
(key-translate "C-c" "<control-c>")
(key-translate "C-v" "<control-v>")
(keymap-global-set "<control-x>" 'kill-region)
(keymap-global-set "<control-c>" 'kill-ring-save)
```

```
(keymap-global-set "<control-v>" 'yank)
```

On a graphical terminal that supports extended ASCII input, you can still get the standard Emacs meanings of one of those characters by typing it with the shift key. That makes it a different character as far as keyboard translation is concerned, but it has the same usual meaning.

See Section 23.15 [Translation Keymaps], page 504, for mechanisms that translate event sequences at the level of `read-key-sequence`. If you need to translate input events that are not characters (i.e., `characterp` returns `nil` for them), you must use the event translation mechanism described there.

22.8.4 Invoking the Input Method

The event-reading functions invoke the current input method, if any (see Section 34.11 [Input Methods], page 990). If the value of `input-method-function` is non-`nil`, it should be a function; when `read-event` reads a printing character (including SPC) with no modifier bits, it calls that function, passing the character as an argument.

`input-method-function` [Variable]

If this is non-`nil`, its value specifies the current input method function.

Warning: don't bind this variable with `let`. It is often buffer-local, and if you bind it around reading input (which is exactly when you *would* bind it), switching buffers asynchronously while Emacs is waiting will cause the value to be restored in the wrong buffer.

The input method function should return a list of events which should be used as input. (If the list is `nil`, that means there is no input, so `read-event` waits for another event.) These events are processed before the events in `unread-command-events` (see Section 22.8.6 [Event Input Misc], page 468). Events returned by the input method function are not passed to the input method function again, even if they are printing characters with no modifier bits.

If the input method function calls `read-event` or `read-key-sequence`, it should bind `input-method-function` to `nil` first, to prevent recursion.

The input method function is not called when reading the second and subsequent events of a key sequence. Thus, these characters are not subject to input method processing. The input method function should test the values of `overriding-local-map` and `overriding-terminal-local-map`; if either of these variables is non-`nil`, the input method should put its argument into a list and return that list with no further processing.

22.8.5 Quoted Character Input

You can use the function `read-quoted-char` to ask the user to specify a character, and allow the user to specify a control or meta character conveniently, either literally or as an octal character code. The command `quoted-insert` uses this function.

`read-quoted-char &optional prompt` [Function]

This function is like `read-char`, except that if the first character read is an octal digit (0–7), it reads any number of octal digits (but stopping if a non-octal digit is found), and returns the character represented by that numeric character code. If the

character that terminates the sequence of octal digits is RET, it is discarded. Any other terminating character is used as input after this function returns.

Quitting is suppressed when the first character is read, so that the user can enter a *C-g*. See Section 22.11 [Quitting], page 471.

If *prompt* is supplied, it specifies a string for prompting the user. The prompt string is always displayed in the echo area, followed by a single ‘-’.

In the following example, the user types in the octal number 177 (which is 127 in decimal).

```
(read-quoted-char "What character")
```

```
----- Echo Area -----
What character 1 7 7-
----- Echo Area -----
```

```
⇒ 127
```

22.8.6 Miscellaneous Event Input Features

This section describes how to peek ahead at events without using them up, how to check for pending input, and how to discard pending input. See also the function `read-passwd` (see Section 21.9 [Reading a Password], page 417).

`unread-command-events`

[Variable]

This variable holds a list of events waiting to be read as command input. The events are used in the order they appear in the list, and removed one by one as they are used.

The variable is needed because in some cases a function reads an event and then decides not to use it. Storing the event in this variable causes it to be processed normally, by the command loop or by the functions to read command input.

For example, the function that implements numeric prefix arguments reads any number of digits. When it finds a non-digit event, it must unread the event so that it can be read normally by the command loop. Likewise, incremental search uses this feature to unread events with no special meaning in a search, because these events should exit the search and then execute normally.

The reliable and easy way to extract events from a key sequence so as to put them in `unread-command-events` is to use `listify-key-sequence` (see below).

Normally you add events to the front of this list, so that the events most recently unread will be reread first.

Events read from this list are not normally added to the current command’s key sequence (as returned by, e.g., `this-command-keys`), as the events will already have been added once as they were read for the first time. An element of the form (`t . event`) forces `event` to be added to the current command’s key sequence.

Elements read from this list are normally recorded by the record-keeping features (see Section 42.13.2 [Recording Input], page 1286) and while defining a keyboard macro (see Section 22.16 [Keyboard Macros], page 478). However, an element of the form (`no-record . event`) causes `event` to be processed normally without recording it.

listify-key-sequence *key* [Function]

This function converts the string or vector *key* to a list of individual events, which you can put in `unread-command-events`.

input-pending-p &optional *check-timers* [Function]

This function determines whether any command input is currently available to be read. It returns immediately, with value `t` if there is available input, `nil` otherwise. On rare occasions it may return `t` when no input is available.

If the optional argument *check-timers* is non-`nil`, then if no input is available, Emacs runs any timers which are ready. See Section 42.11 [Timers], page 1281.

last-input-event [Variable]

This variable records the last terminal input event read, whether as part of a command or explicitly by a Lisp program.

In the example below, the Lisp program reads the character `1`, ASCII code 49. It becomes the value of `last-input-event`, while `C-e` (we assume `C-x C-e` command is used to evaluate this expression) remains the value of `last-command-event`.

```
(progn (print (read-char))
        (print last-command-event)
        last-input-event)
⇒ 49
⇒ 5
⇒ 49
```

while-no-input *body...* [Macro]

This construct runs the *body* forms and returns the value of the last one—but only if no input arrives. If any input arrives during the execution of the *body* forms, it aborts them (working much like a quit). The `while-no-input` form returns `nil` if aborted by a real quit, and returns `t` if aborted by arrival of other input.

If a part of *body* binds `inhibit-quit` to non-`nil`, arrival of input during those parts won't cause an abort until the end of that part.

If you want to be able to distinguish all possible values computed by *body* from both kinds of abort conditions, write the code like this:

```
(while-no-input
  (list
    (progn . body)))
```

while-no-input-ignore-events [Variable]

This variable allow setting which special events `while-no-input` should ignore. It is a list of event symbols (see Section 22.7.13 [Event Examples], page 454).

discard-input [Function]

This function discards the contents of the terminal input buffer and cancels any keyboard macro that might be in the process of definition. It returns `nil`.

In the following example, the user may type a number of characters right after starting the evaluation of the form. After the `sleep-for` finishes sleeping, `discard-input` discards any characters typed during the sleep.

```
(progn (sleep-for 2)
```

```
(discard-input)
⇒ nil
```

22.9 Special Events

Certain *special events* are handled at a very low level—as soon as they are read. The `read-event` function processes these events itself, and never returns them. Instead, it keeps waiting for the first event that is not special and returns that one.

Special events do not echo, they are never grouped into key sequences, and they never appear in the value of `last-command-event` or `(this-command-keys)`. They do not discard a numeric argument, they cannot be unread with `unread-command-events`, they may not appear in a keyboard macro, and they are not recorded in a keyboard macro while you are defining one.

Special events do, however, appear in `last-input-event` immediately after they are read, and this is the way for the event’s definition to find the actual event.

The events types `iconify-frame`, `make-frame-visible`, `delete-frame`, `drag-n-drop`, `language-change`, and user signals like `sigusr1` are normally handled in this way. The keymap which defines how to handle special events—and which events are special—is in the variable `special-event-map` (see Section 23.9 [Controlling Active Maps], page 491).

22.10 Waiting for Elapsed Time or Input

The wait functions are designed to wait for a certain amount of time to pass or until there is input. For example, you may wish to pause in the middle of a computation to allow the user time to view the display. `sit-for` pauses and updates the screen, and returns immediately if input comes in, while `sleep-for` pauses without updating the screen.

`sit-for seconds &optional nodisp`

[Function]

This function performs redisplay (provided there is no pending input from the user), then waits `seconds` seconds, or until input is available. The usual purpose of `sit-for` is to give the user time to read text that you display. The value is `t` if `sit-for` waited the full time with no input arriving (see Section 22.8.6 [Event Input Misc], page 468). Otherwise, the value is `nil`.

The argument `seconds` need not be an integer. If it is floating point, `sit-for` waits for a fractional number of seconds. Some systems support only a whole number of seconds; on these systems, `seconds` is rounded down.

The expression `(sit-for 0)` is equivalent to `(redisplay)`, i.e., it requests a redisplay, without any delay, if there is no pending input. See Section 41.2 [Forcing Redisplay], page 1129.

If `nodisp` is non-`nil`, then `sit-for` does not redisplay, but it still returns as soon as input is available (or when the timeout elapses).

In batch mode (see Section 42.17 [Batch Mode], page 1289), `sit-for` cannot be interrupted, even by input from the standard input descriptor. It is thus equivalent to `sleep-for`, which is described below.

It is also possible to call `sit-for` with three arguments, as `(sit-for seconds milisec nodisp)`, but that is considered obsolete.

sleep-for *seconds* &**optional millisec**

[Function]

This function simply pauses for *seconds* seconds without updating the display. It pays no attention to available input. It returns `nil`.

The argument *seconds* need not be an integer. If it is floating point, **sleep-for** waits for a fractional number of seconds. Some systems support only a whole number of seconds; on these systems, *seconds* is rounded down.

The optional argument *millisec* specifies an additional waiting period measured in milliseconds. This adds to the period specified by *seconds*. If the system doesn't support waiting fractions of a second, you get an error if you specify nonzero *millisec*.

Use **sleep-for** when you wish to guarantee a delay.

See Section 42.5 [Time of Day], page 1270, for functions to get the current time.

22.11 Quitting

Typing *C-g* while a Lisp function is running causes Emacs to *quit* whatever it is doing. This means that control returns to the innermost active command loop.

Typing *C-g* while the command loop is waiting for keyboard input does not cause a quit; it acts as an ordinary input character. In the simplest case, you cannot tell the difference, because *C-g* normally runs the command **keyboard-quit**, whose effect is to quit. However, when *C-g* follows a prefix key, they combine to form an undefined key. The effect is to cancel the prefix key as well as any prefix argument.

In the minibuffer, *C-g* has a different definition: it aborts out of the minibuffer. This means, in effect, that it exits the minibuffer and then quits. (Simply quitting would return to the command loop *within* the minibuffer.) The reason why *C-g* does not quit directly when the command reader is reading input is so that its meaning can be redefined in the minibuffer in this way. *C-g* following a prefix key is not redefined in the minibuffer, and it has its normal effect of canceling the prefix key and prefix argument. This too would not be possible if *C-g* always quit directly.

When *C-g* does directly quit, it does so by setting the variable **quit-flag** to `t`. Emacs checks this variable at appropriate times and quits if it is not `nil`. Setting **quit-flag** non-`nil` in any way thus causes a quit.

At the level of C code, quitting cannot happen just anywhere; only at the special places that check **quit-flag**. The reason for this is that quitting at other places might leave an inconsistency in Emacs's internal state. Because quitting is delayed until a safe place, quitting cannot make Emacs crash.

Certain functions such as **read-key-sequence** or **read-quoted-char** prevent quitting entirely even though they wait for input. Instead of quitting, *C-g* serves as the requested input. In the case of **read-key-sequence**, this serves to bring about the special behavior of *C-g* in the command loop. In the case of **read-quoted-char**, this is so that *C-q* can be used to quote a *C-g*.

You can prevent quitting for a portion of a Lisp function by binding the variable **inhibit-quit** to a non-`nil` value. Then, although *C-g* still sets **quit-flag** to `t` as usual, the usual result of this—a quit—is prevented. Eventually, **inhibit-quit** will become `nil` again, such as when its binding is unwound at the end of a **let** form. At that time, if

`quit-flag` is still non-`nil`, the requested quit happens immediately. This behavior is ideal when you wish to make sure that quitting does not happen within a critical section of the program.

In some functions (such as `read-quoted-char`), *C-g* is handled in a special way that does not involve quitting. This is done by reading the input with `inhibit-quit` bound to `t`, and setting `quit-flag` to `nil` before `inhibit-quit` becomes `nil` again. This excerpt from the definition of `read-quoted-char` shows how this is done; it also shows that normal quitting is permitted after the first character of input.

```
(defun read-quoted-char (&optional prompt)
  "...documentation..."
  (let ((message-log-max nil) done (first t) (code 0) char)
    (while (not done)
      (let ((inhibit-quit first)
            ...)
        (and prompt (message "%s-" prompt))
        (setq char (read-event))
        (if inhibit-quit (setq quit-flag nil)))
      ...set the variable code...
      code)))
```

`quit-flag` [Variable]

If this variable is non-`nil`, then Emacs quits immediately, unless `inhibit-quit` is non-`nil`. Typing *C-g* ordinarily sets `quit-flag` non-`nil`, regardless of `inhibit-quit`.

`inhibit-quit` [Variable]

This variable determines whether Emacs should quit when `quit-flag` is set to a value other than `nil`. If `inhibit-quit` is non-`nil`, then `quit-flag` has no special effect.

`with-local-quit body...` [Macro]

This macro executes `body` forms in sequence, but allows quitting, at least locally, within `body` even if `inhibit-quit` was non-`nil` outside this construct. It returns the value of the last form in `body`, unless exited by quitting, in which case it returns `nil`.

If `inhibit-quit` is `nil` on entry to `with-local-quit`, it only executes the `body`, and setting `quit-flag` causes a normal quit. However, if `inhibit-quit` is non-`nil` so that ordinary quitting is delayed, a non-`nil` `quit-flag` triggers a special kind of local quit. This ends the execution of `body` and exits the `with-local-quit` body with `quit-flag` still non-`nil`, so that another (ordinary) quit will happen as soon as that is allowed. If `quit-flag` is already non-`nil` at the beginning of `body`, the local quit happens immediately and the body doesn't execute at all.

This macro is mainly useful in functions that can be called from timers, process filters, process sentinels, `pre-command-hook`, `post-command-hook`, and other places where `inhibit-quit` is normally bound to `t`.

`keyboard-quit` [Command]

This function signals the `quit` condition with (`(signal 'quit nil)`). This is the same thing that quitting does. (See `signal` in Section 11.7.3 [Errors], page 179.)

To quit without aborting a keyboard macro definition or execution, you can signal the `minibuffer-quit` condition. This has almost the same effect as the `quit` condition except that the error handling in the command loop handles it without exiting keyboard macro definition or execution.

You can specify a character other than `C-g` to use for quitting. See the function `set-input-mode` in Section 42.13.1 [Input Modes], page 1285.

22.12 Prefix Command Arguments

Most Emacs commands can use a *prefix argument*, a number specified before the command itself. (Don't confuse prefix arguments with prefix keys.) The prefix argument is at all times represented by a value, which may be `nil`, meaning there is currently no prefix argument. Each command may use the prefix argument or ignore it.

There are two representations of the prefix argument: *raw* and *numeric*. The editor command loop uses the raw representation internally, and so do the Lisp variables that store the information, but commands can request either representation.

Here are the possible values of a raw prefix argument:

- `nil`, meaning there is no prefix argument. Its numeric value is 1, but numerous commands make a distinction between `nil` and the integer 1.
- An integer, which stands for itself.
- A list of one element, which is an integer. This form of prefix argument results from one or a succession of `C-u`s with no digits. The numeric value is the integer in the list, but some commands make a distinction between such a list and an integer alone.
- The symbol `-`. This indicates that `M--` or `C-u -` was typed, without following digits. The equivalent numeric value is `-1`, but some commands make a distinction between the integer `-1` and the symbol `-`.

We illustrate these possibilities by calling the following function with various prefixes:

```
(defun display-prefix (arg)
  "Display the value of the raw prefix arg."
  (interactive "P")
  (message "%s" arg))
```

Here are the results of calling `display-prefix` with various raw prefix arguments:

```
M-x display-prefix    → nil
C-u      M-x display-prefix    → (4)
C-u C-u M-x display-prefix    → (16)
C-u 3    M-x display-prefix    → 3
M-3      M-x display-prefix    → 3      ; (Same as C-u 3.)
C-u -    M-x display-prefix    → -
```

```
M--      M-x display-prefix  ⊂ -      ; (Same as C-u -.)
```

```
C-u - 7 M-x display-prefix  ⊂ -7
```

```
M-- 7  M-x display-prefix  ⊂ -7      ; (Same as C-u -7.)
```

Emacs uses two variables to store the prefix argument: `prefix-arg` and `current-prefix-arg`. Commands such as `universal-argument` that set up prefix arguments for other commands store them in `prefix-arg`. In contrast, `current-prefix-arg` conveys the prefix argument to the current command, so setting it has no effect on the prefix arguments for future commands.

Normally, commands specify which representation to use for the prefix argument, either numeric or raw, in the `interactive` specification. (See Section 22.2.1 [Using Interactive], page 424.) Alternatively, functions may look at the value of the prefix argument directly in the variable `current-prefix-arg`, but this is less clean.

`prefix-numeric-value arg`

[Function]

This function returns the numeric meaning of a valid raw prefix argument value, `arg`. The argument may be a symbol, a number, or a list. If it is `nil`, the value 1 is returned; if it is `-`, the value `-1` is returned; if it is a number, that number is returned; if it is a list, the `CAR` of that list (which should be a number) is returned.

`current-prefix-arg`

[Variable]

This variable holds the raw prefix argument for the *current* command. Commands may examine it directly, but the usual method for accessing it is with (`interactive "P"`).

`prefix-arg`

[Variable]

The value of this variable is the raw prefix argument for the *next* editing command. Commands such as `universal-argument` that specify prefix arguments for the following command work by setting this variable.

`last-prefix-arg`

[Variable]

The raw prefix argument value used by the previous command.

The following commands exist to set up prefix arguments for the following command. Do not call them for any other reason.

`universal-argument`

[Command]

This command reads input and specifies a prefix argument for the following command. Don't call this command yourself unless you know what you are doing.

`digit-argument arg`

[Command]

This command adds to the prefix argument for the following command. The argument `arg` is the raw prefix argument as it was before this command; it is used to compute the updated prefix argument. Don't call this command yourself unless you know what you are doing.

`negative-argument arg`

[Command]

This command adds to the numeric argument for the next command. The argument `arg` is the raw prefix argument as it was before this command; its value is negated

to form the new prefix argument. Don't call this command yourself unless you know what you are doing.

22.13 Recursive Editing

The Emacs command loop is entered automatically when Emacs starts up. This top-level invocation of the command loop never exits; it keeps running as long as Emacs does. Lisp programs can also invoke the command loop. Since this makes more than one activation of the command loop, we call it *recursive editing*. A recursive editing level has the effect of suspending whatever command invoked it and permitting the user to do arbitrary editing before resuming that command.

The commands available during recursive editing are the same ones available in the top-level editing loop and defined in the keymaps. Only a few special commands exit the recursive editing level; the others return to the recursive editing level when they finish. (The special commands for exiting are always available, but they do nothing when recursive editing is not in progress.)

All command loops, including recursive ones, set up all-purpose error handlers so that an error in a command run from the command loop will not exit the loop.

Minibuffer input is a special kind of recursive editing. It has a few special wrinkles, such as enabling display of the minibuffer and the minibuffer window, but fewer than you might suppose. Certain keys behave differently in the minibuffer, but that is only because of the minibuffer's local map; if you switch windows, you get the usual Emacs commands.

To invoke a recursive editing level, call the function `recursive-edit`. This function contains the command loop; it also contains a call to `catch` with tag `exit`, which makes it possible to exit the recursive editing level by throwing to `exit` (see Section 11.7.1 [Catch and Throw], page 177). Throwing a `t` value causes `recursive-edit` to quit, so that control returns to the command loop one level up. This is called *aborting*, and is done by `C-]` (`abort-recursive-edit`). Similarly, you can throw a string value to make `recursive-edit` signal an error, printing this string as the message. If you throw a function, `recursive-edit` will call it without arguments before returning. Throwing any other value, will make `recursive-edit` return normally to the function that called it. The command `C-M-c` (`exit-recursive-edit`) does this.

Most applications should not use recursive editing, except as part of using the minibuffer. Usually it is more convenient for the user if you change the major mode of the current buffer temporarily to a special major mode, which should have a command to go back to the previous mode. (The `e` command in Rmail uses this technique.) Or, if you wish to give the user different text to edit recursively, create and select a new buffer in a special mode. In this mode, define a command to complete the processing and go back to the previous buffer. (The `m` command in Rmail does this.)

Recursive edits are useful in debugging. You can insert a call to `debug` into a function definition as a sort of breakpoint, so that you can look around when the function gets there. `debug` invokes a recursive edit but also provides the other features of the debugger.

Recursive editing levels are also used when you type `C-r` in `query-replace` or use `C-x q` (`kbd-macro-query`).

recursive-edit

[Command]

This function invokes the editor command loop. It is called automatically by the initialization of Emacs, to let the user begin editing. When called from a Lisp program, it enters a recursive editing level.

If the current buffer is not the same as the selected window's buffer, **recursive-edit** saves and restores the current buffer. Otherwise, if you switch buffers, the buffer you switched to is current after **recursive-edit** returns.

In the following example, the function **simple-rec** first advances point one word, then enters a recursive edit, printing out a message in the echo area. The user can then do any editing desired, and then type *C-M-c* to exit and continue executing **simple-rec**.

```
(defun simple-rec ()
  (forward-word 1)
  (message "Recursive edit in progress")
  (recursive-edit)
  (forward-word 1))
  ⇒ simple-rec
(simple-rec)
  ⇒ nil
```

exit-recursive-edit

[Command]

This function exits from the innermost recursive edit (including minibuffer input). Its definition is effectively (**throw 'exit nil**).

abort-recursive-edit

[Command]

This function aborts the command that requested the innermost recursive edit (including minibuffer input), by signaling **quit** after exiting the recursive edit. Its definition is effectively (**throw 'exit t**). See Section 22.11 [Quitting], page 471.

top-level

[Command]

This function exits all recursive editing levels; it does not return a value, as it jumps completely out of any computation directly back to the main command loop.

recursion-depth

[Function]

This function returns the current depth of recursive edits. When no recursive edit is active, it returns 0.

22.14 Disabling Commands

Disabling a command marks the command as requiring user confirmation before it can be executed. Disabling is used for commands which might be confusing to beginning users, to prevent them from using the commands by accident.

The low-level mechanism for disabling a command is to put a non-**nil** **disabled** property on the Lisp symbol for the command. These properties are normally set up by the user's init file (see Section 42.1.2 [Init File], page 1258) with Lisp expressions such as this:

```
(put 'upcase-region 'disabled t)
```

For a few commands, these properties are present by default (you can remove them in your init file if you wish).

If the value of the `disabled` property is a string, the message saying the command is disabled includes that string. For example:

```
(put 'delete-region 'disabled
     "Text deleted this way cannot be yanked back!\n")
```

See Section “Disabling” in *The GNU Emacs Manual*, for the details on what happens when a disabled command is invoked interactively. Disabling a command has no effect on calling it as a function from Lisp programs.

The value of the `disabled` property can also be a list where the first element is the symbol `query`. In that case, the user will be queried whether to execute the command. The second element in the list should be `nil` or `non-nil` to say whether to use `y-or-n-p` or `yes-or-no-p`, respectively, and the third element is the question to use. The `command-query` convenience function should be used to enable querying for a command.

enable-command *command* [Command]

Allow *command* (a symbol) to be executed without special confirmation from now on, and alter the user’s init file (see Section 42.1.2 [Init File], page 1258) so that this will apply to future sessions.

disable-command *command* [Command]

Require special confirmation to execute *command* from now on, and alter the user’s init file so that this will apply to future sessions.

disabled-command-function [Variable]

The value of this variable should be a function. When the user invokes a disabled command interactively, this function is called instead of the disabled command. It can use `this-command-keys` to determine what the user typed to run the command, and thus find the command itself.

The value may also be `nil`. Then all commands work normally, even disabled ones.

By default, the value is a function that asks the user whether to proceed.

22.15 Command History

The command loop keeps a history of the complex commands that have been executed, to make it convenient to repeat these commands. A *complex command* is one for which the interactive argument reading uses the minibuffer. This includes any `M-x` command, any `M-:` command, and any command whose `interactive` specification reads an argument from the minibuffer. Explicit use of the minibuffer during the execution of the command itself does not cause the command to be considered complex.

command-history [Variable]

This variable’s value is a list of recent complex commands, each represented as a form to evaluate. It continues to accumulate all complex commands for the duration of the editing session, but when it reaches the maximum size (see Section 21.4 [Minibuffer History], page 392), the oldest elements are deleted as new ones are added.

```

command-history
⇒ ((switch-to-buffer "chistory.texi")
  (describe-key "^X^[" )
  (visit-tags-table "~/emacs/src/")
  (find-tag "repeat-complex-command"))

```

This history list is actually a special case of minibuffer history (see Section 21.4 [Minibuffer History], page 392), with one special twist: the elements are expressions rather than strings.

There are a number of commands devoted to the editing and recall of previous commands. The commands `repeat-complex-command`, and `list-command-history` are described in the user manual (see Section “Repetition” in *The GNU Emacs Manual*). Within the minibuffer, the usual minibuffer history commands are available.

22.16 Keyboard Macros

A *keyboard macro* is a canned sequence of input events that can be considered a command and made the definition of a key. The Lisp representation of a keyboard macro is a string or vector containing the events. Don’t confuse keyboard macros with Lisp macros (see Chapter 14 [Macros], page 268).

execute-kbd-macro *kbdmacro* &**optional** *count* *loopfunc* [Function]

This function executes *kbdmacro* as a sequence of events. If *kbdmacro* is a string or vector, then the events in it are executed exactly as if they had been input by the user. The sequence is *not* expected to be a single key sequence; normally a keyboard macro definition consists of several key sequences concatenated.

If *kbdmacro* is a symbol, then its function definition is used in place of *kbdmacro*. If that is another symbol, this process repeats. Eventually the result should be a string or vector. If the result is not a symbol, string, or vector, an error is signaled.

The argument *count* is a repeat count; *kbdmacro* is executed that many times. If *count* is omitted or `nil`, *kbdmacro* is executed once. If it is 0, *kbdmacro* is executed over and over until it encounters an error or a failing search.

If *loopfunc* is non-`nil`, it is a function that is called, without arguments, prior to each iteration of the macro. If *loopfunc* returns `nil`, then this stops execution of the macro.

See Section 22.8.2 [Reading One Event], page 462, for an example of using `execute-kbd-macro`.

executing-kbd-macro [Variable]

This variable contains the string or vector that defines the keyboard macro that is currently executing. It is `nil` if no macro is currently executing. A command can test this variable so as to behave differently when run from an executing macro. Do not set this variable yourself.

defining-kbd-macro [Variable]

This variable is non-`nil` if and only if a keyboard macro is being defined. A command can test this variable so as to behave differently while a macro is being defined. The value is `append` while appending to the definition of an existing macro. The commands `start-kbd-macro`, `kmacro-start-macro` and `end-kbd-macro` set this variable—do not set it yourself.

The variable is always local to the current terminal and cannot be buffer-local. See Section 30.2 [Multiple Terminals], page 787.

last-kbd-macro

[Variable]

This variable is the definition of the most recently defined keyboard macro. Its value is a string or vector, or `nil`.

The variable is always local to the current terminal and cannot be buffer-local. See Section 30.2 [Multiple Terminals], page 787.

kbd-macro-termination-hook

[Variable]

This normal hook is run when a keyboard macro terminates, regardless of what caused it to terminate (reaching the macro end or an error which ended the macro prematurely).

23 Keymaps

The command bindings of input events are recorded in data structures called *keymaps*. Each entry in a keymap associates (or *binds*) an individual event type, either to another keymap or to a command. When an event type is bound to a keymap, that keymap is used to look up the next input event; this continues until a command is found. The whole process is called *key lookup*.

23.1 Key Sequences

A *key sequence*, or *key* for short, is a sequence of one or more input events that form a unit. Input events include characters, function keys, mouse actions, or system events external to Emacs, such as `iconify-frame` (see Section 22.7 [Input Events], page 440). The Emacs Lisp representation for a key sequence is a string or vector. Unless otherwise stated, any Emacs Lisp function that accepts a key sequence as an argument can handle both representations.

In the string representation, alphanumeric characters ordinarily stand for themselves; for example, "`a`" represents `a` and "`2`" represents `2`. Control character events are prefixed by the substring "`\C-`", and meta characters by "`\M-`"; for example, "`\Cx-x`" represents the key `C-x`. In addition, the TAB, RET, ESC, and DEL events are represented by "`\t`", "`\r`", "`\e`", and "`\d`" respectively. The string representation of a complete key sequence is the concatenation of the string representations of the constituent events; thus, "`\Cx-x1`" represents the key sequence `C-x 1`.

Key sequences containing function keys, mouse button events, system events, or non-ASCII characters such as `C-=` or `H-a` cannot be represented as strings; they have to be represented as vectors.

In the vector representation, each element of the vector represents an input event, in its Lisp form. See Section 22.7 [Input Events], page 440. For example, the vector `[?\Cx-x ?1]` represents the key sequence `C-x 1`.

For examples of key sequences written in string and vector representations, Section “Init Rebinding” in *The GNU Emacs Manual*.

`kbd keyseq-text`

[Function]

This function converts the text *keyseq-text* (a string constant) into a key sequence (a string or vector constant). The contents of *keyseq-text* should use the same syntax as in the buffer invoked by the `C-x C-k RET` (`kmacro-edit-macro`) command; in particular, you must surround function key names with ‘`<...>`’. See Section “Edit Keyboard Macro” in *The GNU Emacs Manual*.

```
(kbd "C-x") ⇒ "\Cx-x"
(kbd "C-x C-f") ⇒ "\Cx-x\C-f"
(kbd "C-x 4 C-f") ⇒ "\Cx-x4\C-f"
(kbd "X") ⇒ "X"
(kbd "RET") ⇒ "\M-\r"
(kbd "C-c SPC") ⇒ "\Cc "
(kbd "<f1> SPC") ⇒ [f1 32]
(kbd "C-M-<down>") ⇒ [C-M-down]
```

The `kbd` function is very permissive, and will try to return something sensible even if the syntax used isn't completely conforming. To check whether the syntax is actually valid, use the `key-valid-p` function.

23.2 Keymap Basics

A keymap is a Lisp data structure that specifies *key bindings* for various key sequences.

A single keymap directly specifies definitions for individual events. When a key sequence consists of a single event, its binding in a keymap is the keymap's definition for that event. The binding of a longer key sequence is found by an iterative process: first find the definition of the first event (which must itself be a keymap); then find the second event's definition in that keymap, and so on until all the events in the key sequence have been processed.

If the binding of a key sequence is a keymap, we call the key sequence a *prefix key*. Otherwise, we call it a *complete key* (because no more events can be added to it). If the binding is `nil`, we call the key *undefined*. Examples of prefix keys are `C-c`, `C-x`, and `C-x 4`. Examples of defined complete keys are `X`, `RET`, and `C-x 4 C-f`. Examples of undefined complete keys are `C-x C-g`, and `C-c 3`. See Section 23.6 [Prefix Keys], page 488, for more details.

The rule for finding the binding of a key sequence assumes that the intermediate bindings (found for the events before the last) are all keymaps; if this is not so, the sequence of events does not form a unit—it is not really one key sequence. In other words, removing one or more events from the end of any valid key sequence must always yield a prefix key. For example, `C-f C-n` is not a key sequence; `C-f` is not a prefix key, so a longer sequence starting with `C-f` cannot be a key sequence.

The set of possible multi-event key sequences depends on the bindings for prefix keys; therefore, it can be different for different keymaps, and can change when bindings are changed. However, a one-event sequence is always a key sequence, because it does not depend on any prefix keys for its well-formedness.

At any time, several primary keymaps are *active*—that is, in use for finding key bindings. These are the *global map*, which is shared by all buffers; the *local keymap*, which is usually associated with a specific major mode; and zero or more *minor mode keymaps*, which belong to currently enabled minor modes. (Not all minor modes have keymaps.) The local keymap bindings shadow (i.e., take precedence over) the corresponding global bindings. The minor mode keymaps shadow both local and global keymaps. See Section 23.7 [Active Keymaps], page 489, for details.

23.3 Format of Keymaps

Each keymap is a list whose `CAR` is the symbol `keymap`. The remaining elements of the list define the key bindings of the keymap. A symbol whose function definition is a keymap is also a keymap. Use the function `keymapp` (see below) to test whether an object is a keymap.

Several kinds of elements may appear in a keymap, after the symbol `keymap` that begins it:

`(type . binding)`

This specifies one binding, for events of type `type`. Each ordinary binding applies to events of a particular event `type`, which is always a character or a symbol. See

Section 22.7.14 [Classifying Events], page 455. In this kind of binding, *binding* is a command.

(type item-name . binding)

This specifies a binding which is also a simple menu item that displays as *item-name* in the menu. See Section 23.18.1.1 [Simple Menu Items], page 510.

(type item-name help-string . binding)

This is a simple menu item with help string *help-string*.

(type menu-item . details)

This specifies a binding which is also an extended menu item. This allows use of other features. See Section 23.18.1.2 [Extended Menu Items], page 511.

(t . binding)

This specifies a *default key binding*; any event not bound by other elements of the keymap is given *binding* as its binding. Default bindings allow a keymap to bind all possible event types without having to enumerate all of them. A keymap that has a default binding completely masks any lower-precedence keymap, except for events explicitly bound to `nil` (see below).

char-table

If an element of a keymap is a char-table, it counts as holding bindings for all character events with no modifier bits (see [modifier bits], page 14): the element whose index is *c* is the binding for the character *c*. This is a compact way to record lots of bindings. A keymap with such a char-table is called a *full keymap*. Other keymaps are called *sparse keymaps*.

vector

This kind of element is similar to a char-table: the element whose index is *c* is the binding for the character *c*. Since the range of characters that can be bound this way is limited by the vector size, and vector creation allocates space for all character codes from 0 up, this format should not be used except for creating menu keymaps (see Section 23.18 [Menu Keymaps], page 510), where the bindings themselves don't matter.

string

Aside from elements that specify bindings for keys, a keymap can also have a string as an element. This is called the *overall prompt string* and makes it possible to use the keymap as a menu. See Section 23.18.1 [Defining Menus], page 510.

(keymap ...)

If an element of a keymap is itself a keymap, it counts as if this inner keymap were inlined in the outer keymap. This is used for multiple-inheritance, such as in `make-composed-keymap`.

When the binding is `nil`, it doesn't constitute a definition but it does take precedence over a default binding or a binding in the parent keymap. On the other hand, a binding of `nil` does *not* override lower-precedence keymaps; thus, if the local map gives a binding of `nil`, Emacs uses the binding from the global map.

Keymaps do not directly record bindings for the meta characters. Instead, meta characters are regarded for purposes of key lookup as sequences of two characters, the first of which is `ESC` (or whatever is currently the value of `meta-prefix-char`). Thus, the key `M-a` is

internally represented as `ESC a`, and its global binding is found at the slot for `a` in `esc-map` (see Section 23.6 [Prefix Keys], page 488).

This conversion applies only to characters, not to function keys or other input events; thus, `M-end` has nothing to do with `ESC end`.

Here as an example is the local keymap for Lisp mode, a sparse keymap. It defines bindings for `DEL`, `C-c C-z`, `C-M-q`, and `C-M-x` (the actual value also contains a menu binding, which is omitted here for the sake of brevity).

```

lisp-mode-map
⇒
(keymap
 (3 keymap
   (26 . run-lisp))
 (27 keymap
   (24 . lisp-send-defun))
   ;;; This part is inherited from lisp-mode-shared-map.
(keymap
   (127 . backward-delete-char-untabify)
 (27 keymap
   (17 . indent-sexp)))

```

`keymapp object` [Function]

This function returns `t` if `object` is a keymap, `nil` otherwise. More precisely, this function tests for a list whose CAR is `keymap`, or for a symbol whose function definition satisfies `keymapp`.

```

(keymapp '(keymap))
⇒ t
(fset 'foo '(keymap))
(keymapp 'foo)
⇒ t
(keymapp (current-global-map))
⇒ t

```

23.4 Creating Keymaps

Here we describe the functions for creating keymaps.

`make-sparse-keymap &optional prompt` [Function]

This function creates and returns a new sparse keymap with no entries. (A sparse keymap is the kind of keymap you usually want.) The new keymap does not contain a char-table, unlike `make-keymap`, and does not bind any events.

```

(make-sparse-keymap)
⇒ (keymap)

```

If you specify *prompt*, that becomes the overall prompt string for the keymap. You should specify this only for menu keymaps (see Section 23.18.1 [Defining Menus], page 510). A keymap with an overall prompt string will always present a mouse menu or a keyboard menu if it is active for looking up the next input event. Don't specify an overall prompt string for the main map of a major or minor mode, because that would cause the command loop to present a keyboard menu every time.

make-keymap &optional *prompt* [Function]

This function creates and returns a new full keymap. That keymap contains a char-table (see Section 6.6 [Char-Tables], page 119) with slots for all characters without modifiers. The new keymap initially binds all these characters to `nil`, and does not bind any other kind of event. The argument *prompt* specifies a prompt string, as in `make-sparse-keymap`.

```
(make-keymap)
  ⇒ (keymap #^ [nil nil keymap nil nil nil ...])
```

A full keymap is more efficient than a sparse keymap when it holds lots of bindings; for just a few, the sparse keymap is better.

define-keymap &key *options...* &rest *pairs...* [Function]

You can create a keymap with the functions described above, and then use `keymap-set` (see Section 23.12 [Changing Key Bindings], page 497) to specify key bindings in that map. When writing modes, however, you frequently have to bind a large number of keys at once, and using `keymap-set` on them all can be tedious and error-prone. Instead you can use `define-keymap`, which creates a keymap and binds a number of keys. Here's a very basic example:

```
(define-keymap
  "n" #'forward-line
  "f" #'previous-line
  "C-c C-c" #'quit-window)
```

This function creates a new sparse keymap, defines the keystrokes in *pairs*, and returns the new keymap. It signals an error if there are duplicate key bindings in *pairs*.

pairs is a list of alternating key bindings and key definitions, as accepted by `keymap-set`. In addition, the key can be the special symbol `:menu`, in which case the definition should be a menu definition as accepted by `easy-menu-define` (see Section 23.18.8 [Easy Menu], page 521). Here's a brief example of this usage:

```
(define-keymap :full t
  "g" #'eww-reload
  :menu '("Eww"
          ["Exit" quit-window t]
          ["Reload" eww-reload t]))
```

A number of keywords can be used before the key/definition pairs to change features of the new keymap. If any of the feature keywords is missing from the `define-keymap` call, the default value for that feature is `nil`. Here's a list of the available feature keywords:

:full	If non- <i>nil</i> , create a char-table keymap (as from <code>make-keymap</code>) instead of a sparse keymap (as from <code>make-sparse-keymap</code> (see Section 23.4 [Creating Keymaps], page 483)). A sparse keymap is the default.
:parent	If non- <i>nil</i> , the value should be a keymap to use as the parent (see Section 23.5 [Inheritance and Keymaps], page 487).
:keymap	If non- <i>nil</i> , the value should be a keymap. Instead of creating a new keymap, the specified keymap is modified instead.
:suppress	If non- <i>nil</i> , the keymap will be suppressed with <code>suppress-keymap</code> (see Section 23.12 [Changing Key Bindings], page 497). By default, digits and the minus sign are exempt from suppressing, but if the value is <code>nodigits</code> , this suppresses digits and minus-sign like it does with other characters.
:name	If non- <i>nil</i> , the value should be a string to use as the menu for the keymap if you use it as a menu with <code>x-popup-menu</code> (see Section 30.17 [Pop-Up Menus], page 837).
:prefix	If non- <i>nil</i> , the value should be a symbol to be used as a prefix command (see Section 23.6 [Prefix Keys], page 488). If this is the case, this symbol is returned by <code>define-keymap</code> instead of the map itself.

`defvar-keymap name &key options... &rest pairs...` [Macro]

By far, the most common thing to do with a keymap is to bind it to a variable. This is what virtually all modes do—a mode called `foo` almost always has a variable called `foo-mode-map`.

This macro defines *name* as a variable, passes *options* and *pairs* to `define-keymap`, and uses the result as the default value for the variable. It signals an error if there are duplicate key bindings in *pairs*.

options is like the keywords in `define-keymap`, but there's an additional `:doc` keyword that provides the doc string for the defined variable.

Here's an example:

```
(defvar-keymap eww-textarea-map
  :parent text-mode-map
  :doc "Keymap for the eww text area."
  "RET" #'forward-line
  "TAB" #'shr-next-link)
```

Each command in the keymap can be marked as ‘repeatable’, i.e. usable in `repeat-mode`, by putting a `repeat-map` property on it, e.g.

```
(put 'undo 'repeat-map 'undo-repeat-map)
```

where the value of the property is the map to be used by `repeat-mode`.

To avoid repetitive invocations of `put`, `defvar-keymap` also has a `:repeat` keyword, which can be used to specify which commands in the keymap are usable by `repeat-mode`. The following values are available:

- t This means all the commands in the keymap are repeatable, and is the most common usage.

```
(:enter (commands ...)) :exit (commands ...))
```

This specifies that the commands in the `:enter` list enter `repeat-mode`, and the commands in the `:exit` list exit `repeat mode`.

If the `:enter` list is empty, then all commands in the map enter `repeat-mode`. Specifying one or more commands in this list is useful if there is a command which doesn't exist in the map being defined, but which should have the `repeat-map` property.

If the `:exit` list is empty then no commands in the map exit `repeat-mode`. Specifying one or more commands in this list is useful if the keymap being defined contains a command that should not have the `repeat-map` property.

In order to make e.g. `u` repeat the `undo` command, the following two stanzas are equivalent:

```
(defvar-keymap undo-repeat-map
  "u" #'undo)
(put 'undo 'repeat-map 'undo-repeat-map)
```

and

```
(defvar-keymap undo-repeat-map
  :repeat t
  "u" #'undo)
```

The latter is preferred when there are many commands in the map, all of which should be repeatable.

`copy-keymap keymap`

[Function]

This function returns a copy of `keymap`. This is almost never needed. If you want a keymap that's like another yet with a few changes, you should use map inheritance rather than copying. I.e., something like:

```
(let ((map (make-sparse-keymap)))
  (set-keymap-parent map <theirmap>)
  (keymap-set map ...)
  ...)
```

When performing `copy-keymap`, any keymaps that appear directly as bindings in `keymap` are also copied recursively, and so on to any number of levels. However, recursive copying does not take place when the definition of a character is a symbol whose function definition is a keymap; the same symbol appears in the new copy.

```
(setq map (copy-keymap (current-local-map)))
⇒ (keymap
  ; (This implements meta characters.)
  (27 keymap
    (83 . center-paragraph)
    (115 . center-line))
  (9 . tab-to-tab-stop))

(eq map (current-local-map))
⇒ nil
```

```
(equal map (current-local-map))
⇒ t
```

23.5 Inheritance and Keymaps

A keymap can inherit the bindings of another keymap, which we call the *parent keymap*. Such a keymap looks like this:

```
(keymap elements... . parent-keymap)
```

The effect is that this keymap inherits all the bindings of *parent-keymap*, whatever they may be at the time a key is looked up, but can add to them or override them with *elements*.

If you change the bindings in *parent-keymap* using `keymap-set` or other key-binding functions, these changed bindings are visible in the inheriting keymap, unless shadowed by the bindings made by *elements*. The converse is not true: if you use `keymap-set` to change bindings in the inheriting keymap, these changes are recorded in *elements*, but have no effect on *parent-keymap*.

The proper way to construct a keymap with a parent is to use `set-keymap-parent`; if you have code that directly constructs a keymap with a parent, please convert the program to use `set-keymap-parent` instead.

keymap-parent *keymap* [Function]

This returns the parent keymap of *keymap*. If *keymap* has no parent, `keymap-parent` returns `nil`.

set-keymap-parent *keymap parent* [Function]

This sets the parent keymap of *keymap* to *parent*, and returns *parent*. If *parent* is `nil`, this function gives *keymap* no parent at all.

If *keymap* has submaps (bindings for prefix keys), they too receive new parent keymaps that reflect what *parent* specifies for those prefix keys.

Here is an example showing how to make a keymap that inherits from `text-mode-map`:

```
(let ((map (make-sparse-keymap)))
  (set-keymap-parent map text-mode-map)
  map)
```

A non-sparse keymap can have a parent too, but this is not very useful. A non-sparse keymap always specifies something as the binding for every numeric character code without modifier bits, even if it is `nil`, so these character's bindings are never inherited from the parent keymap.

Sometimes you want to make a keymap that inherits from more than one map. You can use the function `make-composed-keymap` for this.

make-composed-keymap *maps &optional parent* [Function]

This function returns a new keymap composed of the existing keymap(s) *maps*, and optionally inheriting from a parent keymap *parent*. *maps* can be a single keymap or a list of more than one. When looking up a key in the resulting new map, Emacs searches in each of the *maps* in turn, and then in *parent*, stopping at the first match. A `nil` binding in any one of *maps* overrides any binding in *parent*, but it does not override any non-`nil` binding in any other of the *maps*.

For example, here is how Emacs sets the parent of `help-mode-map`, such that it inherits from both `button-buffer-map` and `special-mode-map`:

```
(defvar-keymap help-mode-map
  :parent (make-composed-keymap button-buffer-map
                                 special-mode-map)
  ...)
```

23.6 Prefix Keys

A *prefix key* is a key sequence whose binding is a keymap. The keymap defines what to do with key sequences that extend the prefix key. For example, `C-x` is a prefix key, and it uses a keymap that is also stored in the variable `ctl-x-map`. This keymap defines bindings for key sequences starting with `C-x`.

Some of the standard Emacs prefix keys use keymaps that are also found in Lisp variables:

- `esc-map` is the global keymap for the ESC prefix key. Thus, the global definitions of all meta characters are actually found here. This map is also the function definition of `ESC-prefix`.
- `help-map` is the global keymap for the `C-h` prefix key.
- `mode-specific-map` is the global keymap for the prefix key `C-c`. This map is actually global, not mode-specific, but its name provides useful information about `C-c` in the output of `C-h b (display-bindings)`, since the main use of this prefix key is for mode-specific bindings.
- `ctl-x-map` is the global keymap used for the `C-x` prefix key. This map is found via the function cell of the symbol `Control-X-prefix`.
- `mule-keymap` is the global keymap used for the `C-x RET` prefix key.
- `ctl-x-4-map` is the global keymap used for the `C-x 4` prefix key.
- `ctl-x-5-map` is the global keymap used for the `C-x 5` prefix key.
- `2C-mode-map` is the global keymap used for the `C-x 6` prefix key.
- `tab-prefix-map` is the global keymap used for the `C-x t` prefix key.
- `vc-prefix-map` is the global keymap used for the `C-x v` prefix key.
- `goto-map` is the global keymap used for the `M-g` prefix key.
- `search-map` is the global keymap used for the `M-s` prefix key.
- The other Emacs prefix keys are `C-x @`, `C-x a i`, `C-x ESC` and `ESC ESC`. They use keymaps that have no special names.

The keymap binding of a prefix key is used for looking up the event that follows the prefix key. (It may instead be a symbol whose function definition is a keymap. The effect is the same, but the symbol serves as a name for the prefix key.) Thus, the binding of `C-x` is the symbol `Control-X-prefix`, whose function cell holds the keymap for `C-x` commands. (The same keymap is also the value of `ctl-x-map`.)

Prefix key definitions can appear in any active keymap. The definitions of `C-c`, `C-x`, `C-h` and `ESC` as prefix keys appear in the global map, so these prefix keys are always available. Major and minor modes can redefine a key as a prefix by putting a prefix key definition for it in the local map or the minor mode's map. See Section 23.7 [Active Keymaps], page 489.

If a key is defined as a prefix in more than one active map, then its various definitions are in effect merged: the commands defined in the minor mode keymaps come first, followed by those in the local map's prefix definition, and then by those from the global map.

In the following example, we make *C-p* a prefix key in the local keymap, in such a way that *C-p* is identical to *C-x*. Then the binding for *C-p C-f* is the function `find-file`, just like *C-x C-f*. By contrast, the key sequence *C-p 9* is not found in any active keymap.

```
(use-local-map (make-sparse-keymap))
  ⇒ nil
(keymap-local-set "C-p" ctl-x-map)
  ⇒ (keymap #^[[nil nil keymap ...
(keymap-lookup nil "C-p C-f")
  ⇒ find-file
(keymap-lookup nil "C-p 9")
  ⇒ nil
```

define-prefix-command *symbol* &**optional** *mapvar prompt* [Function]

This function prepares *symbol* for use as a prefix key's binding: it creates a sparse keymap and stores it as *symbol*'s function definition. Subsequently binding a key sequence to *symbol* will make that key sequence into a prefix key. The return value is *symbol*.

This function also sets *symbol* as a variable, with the keymap as its value. But if *mapvar* is non-*nil*, it sets *mapvar* as a variable instead.

If *prompt* is non-*nil*, that becomes the overall prompt string for the keymap. The prompt string should be given for menu keymaps (see Section 23.18.1 [Defining Menus], page 510).

23.7 Active Keymaps

Emacs contains many keymaps, but at any time only a few keymaps are *active*. When Emacs receives user input, it translates the input event (see Section 23.15 [Translation Keymaps], page 504), and looks for a key binding in the active keymaps.

Usually, the active keymaps are: (i) the keymap specified by the `keymap` property, (ii) the keymaps of enabled minor modes, (iii) the current buffer's local keymap, and (iv) the global keymap, in that order. Emacs searches for each input key sequence in all these keymaps.

Of these usual keymaps, the highest-precedence one is specified by the `keymap` text or overlay property at point, if any. (For a mouse input event, Emacs uses the event position instead of point; see the next section for details.)

Next in precedence are keymaps specified by enabled minor modes. These keymaps, if any, are specified by the variables `emulation-mode-map-alists`, `minor-mode-overriding-map-alist`, and `minor-mode-map-alist`. See Section 23.9 [Controlling Active Maps], page 491.

Next in precedence is the buffer's *local keymap*, containing key bindings specific to the buffer. The minibuffer also has a local keymap (see Section 21.1 [Intro to Minibuffers], page 385). If there is a `local-map` text or overlay property at point, that specifies the local keymap to use, in place of the buffer's default local keymap.

The local keymap is normally set by the buffer's major mode, and every buffer with the same major mode shares the same local keymap. Hence, if you call `keymap-local-set` (see

Section 23.16 [Key Binding Commands], page 506) to change the local keymap in one buffer, that also affects the local keymaps in other buffers with the same major mode.

Finally, the *global keymap* contains key bindings that are defined regardless of the current buffer, such as *C-f*. It is always active, and is bound to the variable `global-map`.

Apart from the above usual keymaps, Emacs provides special ways for programs to make other keymaps active. Firstly, the variable `overriding-local-map` specifies a keymap that replaces the usual active keymaps, except for the global keymap. Secondly, the terminal-local variable `overriding-terminal-local-map` specifies a keymap that takes precedence over *all* other keymaps (including `overriding-local-map`); this is normally used for modal/transient key bindings (the function `set-transient-map` provides a convenient interface for this). See Section 23.9 [Controlling Active Maps], page 491, for details.

Making keymaps active is not the only way to use them. Keymaps are also used in other ways, such as for translating events within `read-key-sequence`. See Section 23.15 [Translation Keymaps], page 504.

See Appendix G [Standard Keymaps], page 1395, for a list of some standard keymaps.

`current-active-maps` &optional *olp position*

[Function]

This returns the list of active keymaps that would be used by the command loop in the current circumstances to look up a key sequence. Normally it ignores `overriding-local-map` and `overriding-terminal-local-map`, but if *olp* is non-nil then it pays attention to them. *position* can optionally be either an event position as returned by `event-start` or a buffer position, and may change the keymaps as described for `keymap-lookup` (see Section 23.11 [Functions for Key Lookup], page 495).

23.8 Searching the Active Keymaps

Here is a pseudo-Lisp summary of how Emacs searches the active keymaps:

```
(or (if overriding-terminal-local-map
        (find-in overriding-terminal-local-map))
    (if overriding-local-map
        (find-in overriding-local-map)
        (or (find-in (get-char-property (point) 'keymap))
            (find-in-any emulation-mode-map-alists)
            (find-in-any minor-mode-overriding-map-alist)
            (find-in-any minor-mode-map-alist)
            (if (get-char-property (point) 'local-map)
                (find-in (get-char-property (point) 'local-map))
                (find-in (current-local-map))))
        (find-in (current-global-map))))
```

Here, `find-in` and `find-in-any` are pseudo functions that search in one keymap and in an alist of keymaps, respectively. Note that the `set-transient-map` function works by setting `overriding-terminal-local-map` (see Section 23.9 [Controlling Active Maps], page 491).

In the above pseudo-code, if a key sequence starts with a mouse event (see Section 22.7.3 [Mouse Events], page 442), that event's position is used instead of point, and the event's buffer is used instead of the current buffer. In particular, this affects how the keymap

and `local-map` properties are looked up. If a mouse event occurs on a string embedded with a `display`, `before-string`, or `after-string` property (see Section 33.19.4 [Special Properties], page 924), and the string has a non-`nil` `keymap` or `local-map` property, that overrides the corresponding property in the underlying buffer text (i.e., the property specified by the underlying text is ignored).

When a key binding is found in one of the active keymaps, and that binding is a command, the search is over—the command is executed. However, if the binding is a symbol with a value or a string, Emacs replaces the input key sequences with the variable’s value or the string, and restarts the search of the active keymaps. See Section 23.10 [Key Lookup], page 494.

The command which is finally found might also be remapped. See Section 23.14 [Remapping Commands], page 503.

23.9 Controlling the Active Keymaps

`global-map`

[Variable]

This variable contains the default global keymap that maps Emacs keyboard input to commands. The global keymap is normally this keymap. The default global keymap is a full keymap that binds `self-insert-command` to all of the printing characters.

It is normal practice to change the bindings in the global keymap, but you should not assign this variable any value other than the keymap it starts out with.

`current-global-map`

[Function]

This function returns the current global keymap. This is the same as the value of `global-map` unless you change one or the other. The return value is a reference, not a copy; if you use `keymap-set` or other functions on it you will alter global bindings.

```
(current-global-map)
⇒ (keymap [set-mark-command beginning-of-line ...
           delete-backward-char])
```

`current-local-map`

[Function]

This function returns the current buffer’s local keymap, or `nil` if it has none. In the following example, the keymap for the `*scratch*` buffer (using Lisp Interaction mode) is a sparse keymap in which the entry for `ESC`, ASCII code 27, is another sparse keymap.

```
(current-local-map)
⇒ (keymap
    (10 . eval-print-last-sexp)
    (9 . lisp-indent-line)
    (127 . backward-delete-char-untabify)
    (27 keymap
        (24 . eval-defun)
        (17 . indent-sexp)))
```

`current-local-map` returns a reference to the local keymap, not a copy of it; if you use `keymap-set` or other functions on it you will alter local bindings.

current-minor-mode-maps [Function]

This function returns a list of the keymaps of currently enabled minor modes.

use-global-map keymap [Function]

This function makes *keymap* the new current global keymap. It returns `nil`.

It is very unusual to change the global keymap.

use-local-map keymap [Function]

This function makes *keymap* the new local keymap of the current buffer. If *keymap* is `nil`, then the buffer has no local keymap. `use-local-map` returns `nil`. Most major mode commands use this function.

minor-mode-map-alist [Variable]

This variable is an alist describing keymaps that may or may not be active according to the values of certain variables. Its elements look like this:

`(variable . keymap)`

The keymap *keymap* is active whenever *variable* has a non-`nil` value. Typically *variable* is the variable that enables or disables a minor mode. See Section 24.3.2 [Keymaps and Minor Modes], page 546.

Note that elements of `minor-mode-map-alist` do not have the same structure as elements of `minor-mode-alist`. The map must be the CDR of the element; a list with the map as the second element will not do. The CDR can be either a keymap (a list) or a symbol whose function definition is a keymap.

When more than one minor mode keymap is active, the earlier one in `minor-mode-map-alist` takes priority. But you should design minor modes so that they don't interfere with each other. If you do this properly, the order will not matter.

See Section 24.3.2 [Keymaps and Minor Modes], page 546, for more information about minor modes. See also `minor-mode-key-binding` (see Section 23.11 [Functions for Key Lookup], page 495).

minor-mode-overriding-map-alist [Variable]

This variable allows major modes to override the key bindings for particular minor modes. The elements of this alist look like the elements of `minor-mode-map-alist`: `(variable . keymap)`.

If a variable appears as an element of `minor-mode-overriding-map-alist`, the map specified by that element totally replaces any map specified for the same variable in `minor-mode-map-alist`.

`minor-mode-overriding-map-alist` is automatically buffer-local in all buffers.

overriding-local-map [Variable]

If non-`nil`, this variable holds a keymap to use instead of the buffer's local keymap, any text property or overlay keymaps, and any minor mode keymaps. This keymap, if specified, overrides all other maps that would have been active, except for the current global map.

overriding-terminal-local-map

[Variable]

If non-*nil*, this variable holds a keymap to use instead of `overriding-local-map`, the buffer's local keymap, text property or overlay keymaps, and all the minor mode keymaps.

This variable is always local to the current terminal and cannot be buffer-local. See Section 30.2 [Multiple Terminals], page 787. It is used to implement incremental search mode.

overriding-local-map-menu-flag

[Variable]

If this variable is non-*nil*, the value of `overriding-local-map` or `overriding-terminal-local-map` can affect the display of the menu bar. The default value is *nil*, so those map variables have no effect on the menu bar.

Note that these two map variables do affect the execution of key sequences entered using the menu bar, even if they do not affect the menu bar display. So if a menu bar key sequence comes in, you should clear the variables before looking up and executing that key sequence. Modes that use the variables would typically do this anyway; normally they respond to events that they do not handle by “unread” them and exiting.

special-event-map

[Variable]

This variable holds a keymap for special events. If an event type has a binding in this keymap, then it is special, and the binding for the event is run directly by `read-event`. See Section 22.9 [Special Events], page 470.

emulation-mode-map-alists

[Variable]

This variable holds a list of keymap alists to use for emulation modes. It is intended for modes or packages using multiple minor-mode keymaps. Each element is a keymap alist which has the same format and meaning as `minor-mode-map-alist`, or a symbol with a variable binding which is such an alist. The active keymaps in each alist are used before `minor-mode-map-alist` and `minor-mode-overriding-map-alist`.

set-transient-map keymap &optional keep-pred on-exit

[Function]

This function adds *keymap* as a *transient* keymap, which takes precedence over other keymaps for one (or more) subsequent keys.

Normally, *keymap* is used just once, to look up the very next key. If the optional argument *keep-pred* is *t*, the map stays active as long as the user types keys defined in *keymap*; when the user types a key that is not in *keymap*, the transient keymap is deactivated and normal key lookup continues for that key.

The *keep-pred* argument can also be a function. In that case, the function is called with no arguments, prior to running each command, while *keymap* is active; it should return *non-nil* if *keymap* should stay active.

The optional argument *on-exit*, if *non-nil*, specifies a function that is called, with no arguments, after *keymap* is deactivated.

The optional argument *message* specifies the message to display after activating the transient map. If *message* is a string, it is the format string for the message, and any ‘%k’ specifier in that string is replaced with the list of keys from the transient map.

Any other non-`nil` value of `message` stands for the default message format ‘Repeat with %k’.

If the optional argument `timeout` is non-`nil`, it should be a number that specifies how many seconds of idle time to wait before deactivating `keymap`. The value of the variable `set-transient-map-timeout`, if non-`nil`, overrides the value of this argument.

This function works by adding and removing `keymap` from the variable `overriding-terminal-local-map`, which takes precedence over all other active keymaps (see Section 23.8 [Searching Keymaps], page 490).

23.10 Key Lookup

Key lookup is the process of finding the binding of a key sequence from a given keymap. The execution or use of the binding is not part of key lookup.

Key lookup uses just the event type of each event in the key sequence; the rest of the event is ignored. In fact, a key sequence used for key lookup may designate a mouse event with just its types (a symbol) instead of the entire event (a list). See Section 22.7 [Input Events], page 440. Such a key sequence is insufficient for `command-execute` to run, but it is sufficient for looking up or rebinding a key.

When the key sequence consists of multiple events, key lookup processes the events sequentially: the binding of the first event is found, and must be a keymap; then the second event’s binding is found in that keymap, and so on until all the events in the key sequence are used up. (The binding thus found for the last event may or may not be a keymap.) Thus, the process of key lookup is defined in terms of a simpler process for looking up a single event in a keymap. How that is done depends on the type of object associated with the event in that keymap.

Let’s use the term *keymap entry* to describe the value found by looking up an event type in a keymap. (This doesn’t include the item string and other extra elements in a keymap element for a menu item, because `keymap-lookup` and other key lookup functions don’t include them in the returned value.) While any Lisp object may be stored in a keymap as a keymap entry, not all make sense for key lookup. Here is a table of the meaningful types of keymap entries:

<code>nil</code>	<code>nil</code> means that the events used so far in the lookup form an undefined key. When a keymap fails to mention an event type at all, and has no default binding, that is equivalent to a binding of <code>nil</code> for that event type.
<code>command</code>	The events used so far in the lookup form a complete key, and <code>command</code> is its binding. See Section 13.1 [What Is a Function], page 230.
<code>array</code>	The array (either a string or a vector) is a keyboard macro. The events used so far in the lookup form a complete key, and the array is its binding. See Section 22.16 [Keyboard Macros], page 478, for more information.
<code>keymap</code>	The events used so far in the lookup form a prefix key. The next event of the key sequence is looked up in <code>keymap</code> .
<code>list</code>	The meaning of a list depends on what it contains: <ul style="list-style-type: none">• If the CAR of <code>list</code> is the symbol <code>keymap</code>, then the list is a keymap, and is treated as a keymap (see above).

- If the CAR of *list* is `lambda`, then the list is a lambda expression. This is presumed to be a function, and is treated as such (see above). In order to execute properly as a key binding, this function must be a command—it must have an `interactive` specification. See Section 22.2 [Defining Commands], page 424.

symbol The function definition of *symbol* is used in place of *symbol*. If that too is a symbol, then this process is repeated, any number of times. Ultimately this should lead to an object that is a keymap, a command, or a keyboard macro.

Note that keymaps and keyboard macros (strings and vectors) are not valid functions, so a symbol with a keymap, string, or vector as its function definition is invalid as a function. It is, however, valid as a key binding. If the definition is a keyboard macro, then the symbol is also valid as an argument to `command-execute` (see Section 22.3 [Interactive Call], page 432).

The symbol `undefined` is worth special mention: it means to treat the key as undefined. Strictly speaking, the key is defined, and its binding is the command `undefined`; but that command does the same thing that is done automatically for an undefined key: it rings the bell (by calling `ding`) but does not signal an error.

`undefined` is used in local keymaps to override a global key binding and make the key undefined locally. A local binding of `nil` would fail to do this because it would not override the global binding.

anything else

If any other type of object is found, the events used so far in the lookup form a complete key, and the object is its binding, but the binding is not executable as a command.

In short, a keymap entry may be a keymap, a command, a keyboard macro, a symbol that leads to one of them, or `nil`.

23.11 Functions for Key Lookup

Here are the functions and variables pertaining to key lookup.

keymap-lookup *keymap* *key* &*optional* *accept-defaults* *no-remap* [Function]
position

This function returns the definition of *key* in *keymap*. All the other functions described in this chapter that look up keys use `keymap-lookup`. Here are examples:

```
(keymap-lookup (current-global-map) "C-x C-f")
  ⇒ find-file
(keymap-lookup (current-global-map) "C-x C-f 1 2 3 4 5")
  ⇒ 2
```

If the string or vector *key* is not a valid key sequence according to the prefix keys specified in *keymap*, it must be too long and have extra events at the end that do not fit into a single key sequence. Then the value is a number, the number of events at the front of *key* that compose a complete key.

If *accept-defaults* is non-*nil*, then `keymap-lookup` considers default bindings as well as bindings for the specific events in *key*. Otherwise, `keymap-lookup` reports only bindings for the specific sequence *key*, ignoring default bindings except when you explicitly ask about them. (To do this, supply *t* as an element of *key*; see Section 23.3 [Format of Keymaps], page 481.)

If *key* contains a meta character (not a function key), that character is implicitly replaced by a two-character sequence: the value of `meta-prefix-char`, followed by the corresponding non-meta character. Thus, the first example below is handled by conversion into the second example.

```
(keymap-lookup (current-global-map) "M-f")
  ⇒ forward-word
(keymap-lookup (current-global-map) "ESC f")
  ⇒ forward-word
```

The *keymap* argument can be *nil*, meaning to look up *key* in the current keymaps (as returned by `current-active-maps`, see Section 23.7 [Active Keymaps], page 489); or it can be a keymap or a list of keymaps, meaning to look up *key* only in the specified keymaps.

Unlike `read-key-sequence`, this function does not modify the specified events in ways that discard information (see Section 22.8.1 [Key Sequence Input], page 461). In particular, it does not convert letters to lower case and it does not change drag events to clicks.

Like the normal command loop, `keymap-lookup` will remap the command resulting from looking up *key* by looking up the command in the current keymaps. However, if the optional third argument *no-remap* is non-*nil*, `keymap-lookup` returns the command without remapping.

If the optional argument *position* is non-*nil*, it specifies a mouse position as returned by `event-start` and `event-end`, and the lookup occurs in the keymaps associated with that position, instead of in *keymap*. *position* can also be a number or a marker, in which case it is interpreted as a buffer position, and the function uses the keymap properties at that position instead of at point.

undefined

[Command]

Used in keymaps to undefine keys. It calls `ding`, but does not cause an error.

keymap-local-lookup key &optional accept-defaults

[Function]

This function returns the binding for *key* in the current local keymap, or *nil* if it is undefined there.

The argument *accept-defaults* controls checking for default bindings, as in `keymap-lookup` (above).

keymap-global-lookup key &optional accept-defaults

[Function]

This function returns the binding for command *key* in the current global keymap, or *nil* if it is undefined there.

The argument *accept-defaults* controls checking for default bindings, as in `keymap-lookup` (above).

minor-mode-key-binding key &optional accept-defaults [Function]

This function returns a list of all the active minor mode bindings of *key*. More precisely, it returns an alist of pairs (*modename . binding*), where *modename* is the variable that enables the minor mode, and *binding* is *key*'s binding in that mode. If *key* has no minor-mode bindings, the value is *nil*.

If the first binding found is not a prefix definition (a keymap or a symbol defined as a keymap), all subsequent bindings from other minor modes are omitted, since they would be completely shadowed. Similarly, the list omits non-prefix bindings that follow prefix bindings.

The argument *accept-defaults* controls checking for default bindings, as in `keymap-lookup` (above).

meta-prefix-char [User Option]

This variable is the meta-prefix character code. It is used for translating a meta character to a two-character sequence so it can be looked up in a keymap. For useful results, the value should be a prefix event (see Section 23.6 [Prefix Keys], page 488). The default value is 27, which is the ASCII code for ESC.

As long as the value of `meta-prefix-char` remains 27, key lookup translates *M-b* into `ESC b`, which is normally defined as the `backward-word` command. However, if you were to set `meta-prefix-char` to 24, the code for *C-x*, then Emacs will translate *M-b* into *C-x b*, whose standard binding is the `switch-to-buffer` command. (Don't actually do this!) Here is an illustration of what would happen:

```

meta-prefix-char           ; The default value.
                         ⇒ 27
(key-binding "\M-b")
                         ⇒ backward-word
?\C-x                      ; The print representation
                         ⇒ 24                      ; of a character.
(setq meta-prefix-char 24)
                         ⇒ 24
(key-binding "\M-b")
                         ⇒ switch-to-buffer        ; Now, typing M-b is
                                         ; like typing C-x b.
(setq meta-prefix-char 27)      ; Avoid confusion!
                         ⇒ 27                      ; Restore the default value!
```

This translation of one event into two happens only for characters, not for other kinds of input events. Thus, *M-F1*, a function key, is not converted into `ESC F1`.

23.12 Changing Key Bindings

The way to rebind a key is to change its entry in a keymap. If you change a binding in the global keymap, the change is effective in all buffers (though it has no direct effect in buffers that shadow the global binding with a local one). If you change the current buffer's local map, that usually affects all buffers using the same major mode. The `keymap-global-set` and `keymap-local-set` functions are convenient interfaces for these operations (see Section 23.16 [Key Binding Commands], page 506). You can also use `keymap-set`, a more general function; then you must explicitly specify the map to change.

When choosing the key sequences for Lisp programs to rebind, please follow the Emacs conventions for use of various keys (see Section D.2 [Key Binding Conventions], page 1334).

The functions below signal an error if *keymap* is not a keymap, or if *key* is not a valid key.

key is a string representing a single key or a series of key strokes, and must satisfy `key-valid-p`. Key strokes are separated by a single space character.

Each key stroke is either a single character, or the name of an event, surrounded by angle brackets. In addition, any key stroke may be preceded by one or more modifier keys. Finally, a limited number of characters have a special shorthand syntax. Here's some example key sequences:

f The key *f*.

S o m A three key sequence of the keys *S*, *o* and *m*.

C-c o A two key sequence of the keys *c* with the control modifier and then the key *o*

H-<left> The key named *left* with the hyper modifier.

M-RET The *return* key with a meta modifier.

C-M-<space>

The *space* key with both the control and meta modifiers.

The only keys that have a special shorthand syntax are *NUL*, *RET*, *TAB*, *LFD*, *ESC*, *SPC* and *DEL*.

The modifiers have to be specified in alphabetical order: ‘*A-C-H-M-S-s*’, which is ‘*Alt-Control-Hyper-Meta-Shift-super*’.

`keymap-set keymap key binding`

[Function]

This function sets the binding for *key* in *keymap*. (If *key* is more than one event long, the change is actually made in another keymap reached from *keymap*.) The argument *binding* can be any Lisp object, but only certain types are meaningful. (For a list of meaningful types, see Section 23.10 [Key Lookup], page 494.) The value returned by `keymap-set` is *binding*.

If *key* is *<t>*, this sets the default binding in *keymap*. When an event has no binding of its own, the Emacs command loop uses the keymap’s default binding, if there is one.

Every prefix of *key* must be a prefix key (i.e., bound to a keymap) or undefined; otherwise an error is signaled. If some prefix of *key* is undefined, then `keymap-set` defines it as a prefix key so that the rest of *key* can be defined as specified.

If there was previously no binding for *key* in *keymap*, the new binding is added at the beginning of *keymap*. The order of bindings in a keymap makes no difference for keyboard input, but it does matter for menu keymaps (see Section 23.18 [Menu Keymaps], page 510).

`keymap-unset keymap key &optional remove`

[Function]

This function is the inverse of `keymap-set`, it unsets the binding for *key* in *keymap*, which is the same as setting the binding to `nil`. In order to instead remove the binding completely, specify *remove* as `non-nil`. This only makes a difference if *keymap* has a parent keymap: if you just unset a key in a child map, it will still shadow the same key in the parent keymap; using *remove* instead will allow the key in the parent keymap to be used.

Note: using `keymap-unset` with `remove non-nil` is intended for users to put in their init file; Emacs packages should avoid using it if possible, since they have complete control over their own keymaps anyway, and they should not be altering other packages' keymaps.

This example creates a sparse keymap and makes a number of bindings in it:

```
(setq map (make-sparse-keymap))
  ⇒ (keymap)
(keymap-set map "C-f" 'forward-char)
  ⇒ forward-char
map
  ⇒ (keymap (6 . forward-char))

;; Build sparse submap for C-x and bind f in that.
(keymap-set map "C-x f" 'forward-word)
  ⇒ forward-word
map
  ⇒ (keymap
      (24 keymap ; C-x
          (102 . forward-word)) ; f
      (6 . forward-char)) ; C-f

;; Bind C-p to the ctl-x-map.
(keymap-set map "C-p" ctl-x-map)
;; ctl-x-map
  ⇒ [nil ... find-file ... backward-kill-sentence]

;; Bind C-f to foo in the ctl-x-map.
(keymap-set map "C-p C-f" 'foo)
  ⇒ 'foo
map
  ⇒ (keymap ; Note foo in ctl-x-map.
      (16 keymap [nil ... foo ... backward-kill-sentence])
      (24 keymap
          (102 . forward-word))
      (6 . forward-char))
```

Note that storing a new binding for `C-p C-f` actually works by changing an entry in `ctl-x-map`, and this has the effect of changing the bindings of both `C-p C-f` and `C-x C-f` in the default global map.

`keymap-set` is the general work horse for defining a key in a keymap. When writing modes, however, you frequently have to bind a large number of keys at once, and using `keymap-set` on them all can be tedious and error-prone. Instead you can use `define-keymap`, which creates a keymap and binds a number of keys. See Section 23.4 [Creating Keymaps], page 483, for details.

The function `substitute-key-definition` scans a keymap for keys that have a certain binding and rebinds them with a different binding. Another feature which is cleaner and can often produce the same results is to remap one command into another (see Section 23.14 [Remapping Commands], page 503).

<code>substitute-key-definition olddef newdef keymap &optional oldmap</code>	[Function]
--	------------

This function replaces `olddef` with `newdef` for any keys in `keymap` that were bound to `olddef`. In other words, `olddef` is replaced with `newdef` wherever it appears. The function returns `nil`.

For example, this redefines *C-x C-f*, if you do it in an Emacs with standard bindings:

```
(substitute-key-definition
  'find-file 'find-file-read-only (current-global-map))
```

If *oldmap* is non-*nil*, that changes the behavior of **substitute-key-definition**: the bindings in *oldmap* determine which keys to rebind. The rebinding still happen in **keymap**, not in *oldmap*. Thus, you can change one map under the control of the bindings in another. For example,

```
(substitute-key-definition
  'delete-backward-char 'my-funny-delete
  my-map global-map)
```

puts the special deletion command in **my-map** for whichever keys are globally bound to the standard deletion command.

Here is an example showing a keymap before and after substitution:

```
(setq map (list 'keymap
                 (cons ?1 olddef-1)
                 (cons ?2 olddef-2)
                 (cons ?3 olddef-1)))
  ⇒ (keymap (49 . olddef-1) (50 . olddef-2) (51 . olddef-1))

  (substitute-key-definition 'olddef-1 'newdef map)
  ⇒ nil
  map
  ⇒ (keymap (49 . newdef) (50 . olddef-2) (51 . newdef))
```

suppress-keymap *keymap* &**optional** *nodigits*

[Function]

This function changes the contents of the full keymap *keymap* by remapping **self-insert-command** to the command **undefined** (see Section 23.14 [Remapping Commands], page 503). This has the effect of undefining all printing characters, thus making ordinary insertion of text impossible. **suppress-keymap** returns **nil**.

If *nodigits* is **nil**, then **suppress-keymap** defines digits to run **digit-argument**, and **-** to run **negative-argument**. Otherwise it makes them undefined like the rest of the printing characters.

The **suppress-keymap** function does not make it impossible to modify a buffer, as it does not suppress commands such as **yank** and **quoted-insert**. To prevent any modification of a buffer, make it read-only (see Section 28.7 [Read Only Buffers], page 680).

Since this function modifies *keymap*, you would normally use it on a newly created keymap. Operating on an existing keymap that is used for some other purpose is likely to cause trouble; for example, suppressing **global-map** would make it impossible to use most of Emacs.

This function can be used to initialize the local keymap of a major mode for which insertion of text is not desirable. But usually such a mode should be derived from **special-mode** (see Section 24.2.5 [Basic Major Modes], page 536); then its keymap will automatically inherit from **special-mode-map**, which is already suppressed. Here is how **special-mode-map** is defined:

```
(defvar special-mode-map
  (let ((map (make-sparse-keymap)))
    (suppress-keymap map)
    (keymap-set map "q" 'quit-window)
    ...
  map))
```

23.13 Low-Level Key Binding

Historically, Emacs has supported a number of different syntaxes for defining keys. The documented way to bind a key today is to use the syntax supported by `key-valid-p`, which is what all the functions like `keymap-set` and `keymap-lookup` supports. This section documents the old-style syntax and interface functions; they should not be used in new code.

`define-key` (and other low-level functions that are used to rebind keys) understand a number of different syntaxes for the keys.

A vector containing lists of keys.

You can use a list containing modifier names plus one base event (a character or function key name). For example, `[(control ?a) (meta b)]` is equivalent to `C-a M-b` and `[(hyper control left)]` is equivalent to `C-H-left`.

A string of characters with modifiers

Internally, key sequences are often represented as strings using the special escape sequences for shift, control and meta modifiers (see Section 2.4.8 [String Type], page 20), but this representation can also be used by users when rebinding keys. A string like "`\M-x`" is read as containing a single `M-x`, "`\C-f`" is read as containing a single `C-f`, and "`\M-\C-x`" and "`\C-\M-x`" are both read as containing a single `C-M-x`.

A vector of characters and key symbols

This is the other internal representation of key sequences. It supports a fuller range of modifiers than the string representation, and also support function keys. An example is '`[?\C-\H-x home]`', which represents the `C-H-x home` key sequence. See Section 2.4.3 [Character Type], page 11.

define-key keymap key binding &optional remove [Function]

This function is like `keymap-set` (see Section 23.12 [Changing Key Bindings], page 497, but understands only the legacy key syntaxes.

In addition, this function also has a `remove` argument. If it is non-`nil`, the definition will be removed. This is almost the same as setting the definition to `nil`, but makes a difference if the `keymap` has a parent, and `key` is shadowing the same binding in the parent. With `remove`, subsequent lookups will return the binding in the parent, whereas with a `nil` definition the lookups will return `nil`.

Here are other legacy key definition functions and commands, with the equivalent modern function to use instead in new code.

global-set-key key binding [Command]

This function sets the binding of `key` in the current global map to `binding`. Use `keymap-global-set` instead.

global-unset-key *key* [Command]

This function removes the binding of *key* from the current global map. Use **keymap-global-unset** instead.

local-set-key *key binding* [Command]

This function sets the binding of *key* in the current local keymap to *binding*. Use **keymap-local-set** instead.

local-unset-key *key* [Command]

This function removes the binding of *key* from the current local map. Use **keymap-local-unset** instead.

substitute-key-definition *olddef newdef keymap &optional oldmap* [Function]

This function replaces *olddef* with *newdef* for any keys in *keymap* that were bound to *olddef*. In other words, *olddef* is replaced with *newdef* wherever it appears. The function returns **nil**. Use **keymap-substitute** instead.

define-key-after *map key binding &optional after* [Function]

Define a binding in *map* for *key*, with value *binding*, just like **define-key**, but position the binding in *map* after the binding for the event *after*. The argument *key* should be of length one—a vector or string with just one element. But *after* should be a single event type—a symbol or a character, not a sequence. The new binding goes after the binding for *after*. If *after* is **t** or is omitted, then the new binding goes last, at the end of the keymap. However, new bindings are added before any inherited keymap. Use **keymap-set-after** instead of this function.

keyboard-translate *from to* [Function]

This function modifies **keyboard-translate-table** to translate character code *from* into character code *to*. It creates the keyboard translate table if necessary. Use **key-translate** instead.

key-binding *key &optional accept-defaults no-remap position* [Function]

This function returns the binding for *key* according to the current active keymaps. The result is **nil** if *key* is undefined in the keymaps. The argument *accept-defaults* controls checking for default bindings, as in **lookup-key** (see Section 23.11 [Functions for Key Lookup], page 495). If *no-remap* is non-**nil**, **key-binding** ignores command remappings (see Section 23.14 [Remapping Commands], page 503) and returns the binding directly specified for *key*. The optional argument *position* should be either a buffer position or an event position like the value of **event-start**; it tells the function to consult the maps determined based on that *position*.

Emacs signals an error if *key* is not a string or a vector.

Use **keymap-lookup** instead of this function.

lookup-key *keymap key &optional accept-defaults* [Function]

This function returns the definition of *key* in *keymap*. If the string or vector *key* is not a valid key sequence according to the prefix keys specified in *keymap*, it must be too long and have extra events at the end that do not fit into a single key sequence.

Then the value is a number, the number of events at the front of key that compose a complete key.

If `accept-defaults` is non-`nil`, then `lookup-key` considers default bindings as well as bindings for the specific events in `key`. Otherwise, `lookup-key` reports only bindings for the specific sequence `key`, ignoring default bindings except when you explicitly ask about them.

Use `keymap-lookup` instead of this function.

local-key-binding `key &optional accept-defaults` [Function]

This function returns the binding for `key` in the current local keymap, or `nil` if it is undefined there.

The argument `accept-defaults` controls checking for default bindings, as in `lookup-key` (above).

global-key-binding `key &optional accept-defaults` [Function]

This function returns the binding for command `key` in the current global keymap, or `nil` if it is undefined there.

The argument `accept-defaults` controls checking for default bindings, as in `lookup-key` (above).

event-convert-list `list` [Function]

This function converts a list of modifier names and a basic event type to an event type which specifies all of them. The basic event type must be the last element of the list. For example,

```
(event-convert-list '(control ?a))
⇒ 1
(event-convert-list '(control meta ?a))
⇒ -134217727
(event-convert-list '(control super f1))
⇒ C-s-f1
```

23.14 Remapping Commands

A special kind of key binding can be used to *remap* one command to another, without having to refer to the key sequence(s) bound to the original command. To use this feature, make a key binding for a key sequence that starts with the dummy event `remap`, followed by the command name you want to remap; for the binding, specify the new definition (usually a command name, but possibly any other valid definition for a key binding).

For example, suppose My mode provides a special command `my-kill-line`, which should be invoked instead of `kill-line`. To establish this, its mode keymap should contain the following remapping:

```
(keymap-set my-mode-map "<remap> <kill-line>" 'my-kill-line)
```

Then, whenever `my-mode-map` is active, if the user types `C-k` (the default global key sequence for `kill-line`) Emacs will instead run `my-kill-line`.

Note that remapping only takes place through active keymaps; for example, putting a remapping in a prefix keymap like `ctl-x-map` typically has no effect, as such keymaps are

not themselves active. In addition, remapping only works through a single level; in the following example,

```
(keymap-set my-mode-map "<remap> <kill-line>" 'my-kill-line)
(keymap-set my-mode-map "<remap> <my-kill-line>" 'my-other-kill-line)
```

`kill-line` is *not* remapped to `my-other-kill-line`. Instead, if an ordinary key binding specifies `kill-line`, it is remapped to `my-kill-line`; if an ordinary binding specifies `my-kill-line`, it is remapped to `my-other-kill-line`.

To undo the remapping of a command, remap it to `nil`; e.g.,

```
(keymap-set my-mode-map "<remap> <kill-line>" nil)
```

command-remapping *command* &**optional** *position* **keymaps** [Function]

This function returns the remapping for *command* (a symbol), given the current active keymaps. If *command* is not remapped (which is the usual situation), or not a symbol, the function returns `nil`. *position* can optionally specify a buffer position or an event position to determine the keymaps to use, as in **key-binding**.

If the optional argument **keymaps** is non-`nil`, it specifies a list of keymaps to search in. This argument is ignored if *position* is non-`nil`.

23.15 Keymaps for Translating Sequences of Events

When the **read-key-sequence** function reads a key sequence (see Section 22.8.1 [Key Sequence Input], page 461), it uses *translation keymaps* to translate certain event sequences into others. The translation keymaps are **input-decode-map**, **local-function-key-map**, and **key-translation-map** (in order of priority).

Translation keymaps have the same structure as other keymaps, but are used differently: they specify translations to make while reading key sequences, rather than bindings for complete key sequences. As each key sequence is read, it is checked against each translation keymap. If one of the translation keymaps binds *k* to a vector *v*, then whenever *k* appears as a sub-sequence *anywhere* in a key sequence, that sub-sequence is replaced with the events in *v*.

For example, VT100 terminals send `ESC O P` when the keypad key PF1 is pressed. On such terminals, Emacs must translate that sequence of events into a single event `pf1`. This is done by binding `ESC O P` to `[pf1]` in **input-decode-map**. Thus, when you type `C-c PF1` on the terminal, the terminal emits the character sequence `C-c ESC O P`, and **read-key-sequence** translates this back into `C-c PF1` and returns it as the vector `[?\C-c pf1]`.

Translation keymaps take effect only after Emacs has decoded the keyboard input (via the input coding system specified by **keyboard-coding-system**). See Section 34.10.8 [Terminal I/O Encoding], page 990.

input-decode-map [Variable]

This variable holds a keymap that describes the character sequences sent by function keys on an ordinary character terminal.

The value of **input-decode-map** is usually set up automatically according to the terminal's Terminfo or Termcap entry, but sometimes those need help from terminal-specific Lisp files. Emacs comes with terminal-specific files for many common terminals; their main purpose is to make entries in **input-decode-map** beyond those that can be deduced from Termcap and Terminfo. See Section 42.1.3 [Terminal-Specific], page 1260.

local-function-key-map

[Variable]

This variable holds a keymap similar to `input-decode-map` except that it describes key sequences which should be translated to alternative interpretations that are usually preferred. It applies after `input-decode-map` and before `key-translation-map`.

Entries in `local-function-key-map` are ignored if they conflict with bindings made in the minor mode, local, or global keymaps. I.e., the remapping only applies if the original key sequence would otherwise not have any binding.

`local-function-key-map` inherits from `function-key-map`. The latter should only be altered if you want the binding to apply in all terminals, so using the former is almost always preferred.

key-translation-map

[Variable]

This variable is another keymap used just like `input-decode-map` to translate input events into other events. It differs from `input-decode-map` in that it goes to work after `local-function-key-map` is finished rather than before; it receives the results of translation by `local-function-key-map`.

Just like `input-decode-map`, but unlike `local-function-key-map`, this keymap is applied regardless of whether the input key-sequence has a normal binding. Note however that actual key bindings can have an effect on `key-translation-map`, even though they are overridden by it. Indeed, actual key bindings override `local-function-key-map` and thus may alter the key sequence that `key-translation-map` receives. Clearly, it is better to avoid this type of situation.

The intent of `key-translation-map` is for users to map one character set to another, including ordinary characters normally bound to `self-insert-command`.

You can use `input-decode-map`, `local-function-key-map`, and `key-translation-map` for more than simple aliases, by using a function, instead of a key sequence, as the translation of a key. Then this function is called to compute the translation of that key.

The key translation function receives one argument, which is the prompt that was specified in `read-key-sequence`—or `nil` if the key sequence is being read by the editor command loop. In most cases you can ignore the prompt value.

If the function reads input itself, it can have the effect of altering the event that follows. For example, here's how to define `C-c h` to turn the character that follows into a Hyper character:

```
(defun hyperify (prompt)
  (let ((e (read-event)))
    (vector (if (numberp e)
                 (logior (ash 1 24) e)
                 (if (memq 'hyper (event-modifiers e))
                     e
                     (add-event-modifier "H-" e)))))

  (defun add-event-modifier (string e)
    (let ((symbol (if (symbolp e) e (car e))))
      (setq symbol (intern (concat string
                                     (symbol-name symbol)))))
      (if (symbolp e)
          symbol
          (cons symbol (cdr e)))))

  (keymap-set local-function-key-map "C-c h" 'hyperify))
```

23.15.1 Interaction with normal keymaps

The end of a key sequence is detected when that key sequence either is bound to a command, or when Emacs determines that no additional event can lead to a sequence that is bound to a command.

This means that, while `input-decode-map` and `key-translation-map` apply regardless of whether the original key sequence would have a binding, the presence of such a binding can still prevent translation from taking place. For example, let us return to our VT100 example above and add a binding for `C-c ESC` to the global map; now when the user hits `C-c PF1` Emacs will fail to decode `C-c ESC O P` into `C-c PF1` because it will stop reading keys right after `C-c ESC`, leaving `O P` for later. This is in case the user really hit `C-c ESC`, in which case Emacs should not sit there waiting for the next key to decide whether the user really pressed `ESC` or `PF1`.

For that reason, it is better to avoid binding commands to key sequences where the end of the key sequence is a prefix of a key translation. The main such problematic suffixes/prefixes are `ESC`, `M-O` (which is really `ESC O`) and `M-L` (which is really `ESC L`).

23.16 Commands for Binding Keys

This section describes some convenient interactive interfaces for changing key bindings. They work by calling `keymap-set` (see Section 23.12 [Changing Key Bindings], page 497). In interactive use, these commands prompt for the argument `key` and expect the user to type a valid key sequence; they also prompt for the `binding` of the key sequence, and expect the name of a command (i.e., a symbol that satisfies `commandp`, see Section 22.3 [Interactive Call], page 432). When called from Lisp, these commands expect `key` to be a string that satisfies `key-valid-p` (see Section 23.1 [Key Sequences], page 480), and `binding` to be any Lisp object that is meaningful in a keymap (see Section 23.10 [Key Lookup], page 494).

People often use `keymap-global-set` in their init files (see Section 42.1.2 [Init File], page 1258) for simple customization. For example,

```
(keymap-global-set "C-x C-\\" 'next-line)
```

redefines *C-x C-* to move down a line.

```
(keymap-global-set "M-" 'mouse-set-point)
```

redefines the first (leftmost) mouse button, entered with the Meta key, to set point where you click.

Be careful when using non-ASCII text characters in Lisp specifications of keys to bind. If these are read as multibyte text, as they usually will be in a Lisp file (see Section 16.4 [Loading Non-ASCII], page 304), you must type the keys as multibyte too. For instance, if you use this:

```
(keymap-global-set "ö" 'my-function) ; bind ö-umlaut
```

and your language environment is multibyte Latin-1, these commands actually bind the multibyte character with code 246, not the byte code 246 (*M-v*) sent by a Latin-1 terminal. In order to use this binding, you need to teach Emacs how to decode the keyboard by using an appropriate input method (see Section “Input Methods” in *The GNU Emacs Manual*).

keymap-global-set *key binding* [Command]

This function sets the binding of *key* in the current global map to *binding*.

```
(keymap-global-set key binding)
≡
(keymap-set (current-global-map) key binding)
```

keymap-global-unset *key* [Command]

This function removes the binding of *key* from the current global map.

One use of this function is in preparation for defining a longer key that uses *key* as a prefix—which would not be allowed if *key* has a non-prefix binding. For example:

```
(keymap-global-unset "C-1")
⇒ nil
(keymap-global-set "C-1 C-1" 'redraw-display)
⇒ nil
```

keymap-local-set *key binding* [Command]

This function sets the binding of *key* in the current local keymap to *binding*.

```
(keymap-local-set key binding)
≡
(keymap-set (current-local-map) key binding)
```

keymap-local-unset *key* [Command]

This function removes the binding of *key* from the current local map.

23.17 Scanning Keymaps

This section describes functions used to scan all the current keymaps for the sake of printing help information. To display the bindings in a particular keymap, you can use the `describe-keymap` command (see Section “Other Help Commands” in *The GNU Emacs Manual*)

accessible-keymaps *keymap* &*optional prefix* [Function]

This function returns a list of all the keymaps that can be reached (via zero or more prefix keys) from *keymap*. The value is an association list with elements of the form `(key . map)`, where *key* is a prefix key whose definition in *keymap* is *map*.

The elements of the alist are ordered so that the key increases in length. The first element is always `([] . keymap)`, because the specified keymap is accessible from itself with a prefix of no events.

If *prefix* is given, it should be a prefix key sequence; then `accessible-keymaps` includes only the submaps whose prefixes start with *prefix*. These elements look just as they do in the value of `(accessible-keymaps)`; the only difference is that some elements are omitted.

In the example below, the returned alist indicates that the key ESC, which is displayed as ‘`[’, is a prefix key whose definition is the sparse keymap `(keymap (83 . center-paragraph) (115 . foo))`.

```
(accessible-keymaps (current-local-map))
⇒(([] keymap
  (27 keymap ; Note this keymap for ESC is repeated below.
    (83 . center-paragraph)
    (115 . center-line))
  (9 . tab-to-tab-stop))

  ("^[" keymap
    (83 . center-paragraph)
    (115 . foo)))
```

In the following example, *C-h* is a prefix key that uses a sparse keymap starting with `(keymap (118 . describe-variable) ...)`. Another prefix, *C-x 4*, uses a keymap which is also the value of the variable `ctl-x-4-map`. The event `mode-line` is one of several dummy events used as prefixes for mouse actions in special parts of a window.

```
(accessible-keymaps (current-global-map))
⇒ (([] keymap [set-mark-command beginning-of-line ...
  delete-backward-char])
  ("^H" keymap (118 . describe-variable) ...
  (8 . help-for-help))
  ("^X" keymap [x-flush-mouse-queue ...
  backward-kill-sentence])
  ("^[" keymap [mark-sexp backward-sexp ...
  backward-kill-word])
  ("^X4" keymap (15 . display-buffer) ...)
  ([mode-line] keymap
  (S-mouse-2 . mouse-split-window-horizontally) ...))
```

These are not all the keymaps you would see in actuality.

map-keymap *function keymap* [Function]

The function `map-keymap` calls *function* once for each binding in *keymap*. It passes two arguments, the event type and the value of the binding. If *keymap* has a parent, the parent’s bindings are included as well. This works recursively: if the parent has itself a parent, then the grandparent’s bindings are also included and so on.

This function is the cleanest way to examine all the bindings in a keymap.

where-is-internal *command &optional keymap firstonly noindirect no-remap* [Function]

This function is a subroutine used by the `where-is` command (see Section “Help” in *The GNU Emacs Manual*). It returns a list of all key sequences (of any length) that are bound to *command* in a set of keymaps.

The argument *command* can be any object; it is compared with all keymap entries using `eq`.

If *keymap* is `nil`, then the maps used are the current active keymaps, disregarding `overriding-local-map` (that is, pretending its value is `nil`). If *keymap* is a keymap, then the maps searched are *keymap* and the global keymap. If *keymap* is a list of keymaps, only those keymaps are searched.

Usually it's best to use `overriding-local-map` as the expression for *keymap*. Then `where-is-internal` searches precisely the keymaps that are active. To search only the global map, pass the value `(keymap)` (an empty keymap) as *keymap*.

If *firstonly* is `non-ascii`, then the value is a single vector representing the first key sequence found, rather than a list of all possible key sequences. If *firstonly* is `t`, then the value is the first key sequence, except that key sequences consisting entirely of ASCII characters (or meta variants of ASCII characters) are preferred to all other key sequences and that the return value can never be a menu binding.

If *noindirect* is `non-nil`, `where-is-internal` doesn't look inside menu-items to find their commands. This makes it possible to search for a menu-item itself.

The fifth argument, *no-remap*, determines how this function treats command remappings (see Section 23.14 [Remapping Commands], page 503). There are two cases of interest:

If a command *other-command* is remapped to *command*:

If *no-remap* is `nil`, find the bindings for *other-command* and treat them as though they are also bindings for *command*. If *no-remap* is `non-nil`, include the vector `[remap other-command]` in the list of possible key sequences, instead of finding those bindings.

If *command* is remapped to *other-command*:

If *no-remap* is `nil`, return the bindings for *other-command* rather than *command*. If *no-remap* is `non-nil`, return the bindings for *command*, ignoring the fact that it is remapped.

If a command maps to a key binding like `[some-event]`, and *some-event* has a symbol plist containing a `non-nil non-key-event` property, then that binding is ignored by `where-is-internal`.

`describe-bindings &optional prefix buffer-or-name` [Command]

This function creates a listing of all current key bindings, and displays it in a buffer named `*Help*`. The text is grouped by modes—minor modes first, then the major mode, then global bindings.

If *prefix* is `non-nil`, it should be a prefix key; then the listing includes only keys that start with *prefix*.

When several characters with consecutive ASCII codes have the same definition, they are shown together, as '`firstchar..lastchar`'. In this instance, you need to know the ASCII codes to understand which characters this means. For example, in the default global map, the characters '`SPC .. ~`' are described by a single line. `SPC` is ASCII 32, `~` is ASCII 126, and the characters between them include all the normal printing characters, (e.g., letters, digits, punctuation, etc.); all these characters are bound to `self-insert-command`.

If `buffer-or-name` is non-`nil`, it should be a buffer or a buffer name. Then `describe-bindings` lists that buffer's bindings, instead of the current buffer's.

23.18 Menu Keymaps

A keymap can operate as a menu as well as defining bindings for keyboard keys and mouse buttons. Menus are usually actuated with the mouse, but they can function with the keyboard also. If a menu keymap is active for the next input event, that activates the keyboard menu feature.

23.18.1 Defining Menus

A keymap acts as a menu if it has an *overall prompt string*, which is a string that appears as an element of the keymap. (See Section 23.3 [Format of Keymaps], page 481.) The string should describe the purpose of the menu's commands. Emacs displays the overall prompt string as the menu title in some cases, depending on the toolkit (if any) used for displaying menus.¹ Keyboard menus also display the overall prompt string.

The easiest way to construct a keymap with a prompt string is to specify the string as an argument when you call `make-keymap`, `make-sparse-keymap` (see Section 23.4 [Creating Keymaps], page 483), or `define-prefix-command` (see [Definition of define-prefix-command], page 489). If you do not want the keymap to operate as a menu, don't specify a prompt string for it.

keymap-prompt `keymap` [Function]

This function returns the overall prompt string of `keymap`, or `nil` if it has none.

The menu's items are the bindings in the keymap. Each binding associates an event type to a definition, but the event types have no significance for the menu appearance. (Usually we use pseudo-events, symbols that the keyboard cannot generate, as the event types for menu item bindings.) The menu is generated entirely from the bindings that correspond in the keymap to these events.

The order of items in the menu is the same as the order of bindings in the keymap. Since `define-key` puts new bindings at the front, you should define the menu items starting at the bottom of the menu and moving to the top, if you care about the order. When you add an item to an existing menu, you can specify its position in the menu using `keymap-set-after` (see Section 23.18.7 [Modifying Menus], page 521).

23.18.1.1 Simple Menu Items

The simpler (and original) way to define a menu item is to bind some event type (it doesn't matter what event type) to a binding like this:

`(item-string . real-binding)`

The CAR, `item-string`, is the string to be displayed in the menu. It should be short—preferably one to three words. It should describe the action of the command it corresponds to. Note that not all graphical toolkits can display non-ASCII text in menus (it will work for keyboard menus and will work to a large extent with the GTK+ toolkit).

¹ It is required for menus which do not use a toolkit, e.g., on a text terminal.

You can also supply a second string, called the help string, as follows:

```
(item-string help . real-binding)
```

help specifies a help-echo string to display while the mouse is on that item in the same way as `help-echo` text properties (see [Help display], page 931).

As far as `define-key` is concerned, *item-string* and *help-string* are part of the event's binding. However, `lookup-key` returns just *real-binding*, and only *real-binding* is used for executing the key.

If *real-binding* is `nil`, then *item-string* appears in the menu but cannot be selected.

If *real-binding* is a symbol and has a non-`nil` `menu-enable` property, that property is an expression that controls whether the menu item is enabled. Every time the keymap is used to display a menu, Emacs evaluates the expression, and it enables the menu item only if the expression's value is non-`nil`. When a menu item is disabled, it is displayed in a fuzzy fashion, and cannot be selected.

The menu bar does not recalculate which items are enabled every time you look at a menu. This is because the X toolkit requires the whole tree of menus in advance. To force recalculation of the menu bar, call `force-mode-line-update` (see Section 24.4 [Mode Line Format], page 550).

23.18.1.2 Extended Menu Items

An extended-format menu item is a more flexible and also cleaner alternative to the simple format. You define an event type with a binding that's a list starting with the symbol `menu-item`. For a non-selectable string, the binding looks like this:

```
(menu-item item-name)
```

A string starting with two or more dashes specifies a separator line; see Section 23.18.1.3 [Menu Separators], page 513.

To define a real menu item which can be selected, the extended format binding looks like this:

```
(menu-item item-name real-binding
  . item-property-list)
```

Here, *item-name* is an expression which evaluates to the menu item string. Thus, the string need not be a constant.

The third element, *real-binding*, can be the command to execute (in which case you get a normal menu item). It can also be a keymap, which will result in a submenu, and *item-name* is used as the submenu name. Finally, it can be `nil`, in which case you will get a non-selectable menu item. This is mostly useful when creating separator lines and the like.

The tail of the list, *item-property-list*, has the form of a property list (see Section 5.9 [Property Lists], page 99) which contains other information.

Here is a table of the properties that are supported:

`:enable` *form*

The result of evaluating *form* determines whether the item is enabled (non-`nil` means yes). If the item is not enabled, you can't really click on it.

:visible form

The result of evaluating *form* determines whether the item should actually appear in the menu (non-*nil* means yes). If the item does not appear, then the menu is displayed as if this item were not defined at all.

:help help

The value of this property, *help*, specifies a help-echo string to display while the mouse is on that item. This is displayed in the same way as **help-echo** text properties (see [Help display], page 931). Note that this must be a constant string, unlike the **help-echo** property for text and overlays.

:button (type . selected)

This property provides a way to define radio buttons and toggle buttons. The CAR, *type*, says which: it should be **:toggle** or **:radio**. The CDR, *selected*, should be a form; the result of evaluating it says whether this button is currently selected.

A *toggle* is a menu item which is labeled as either on or off according to the value of *selected*. The command itself should toggle *selected*, setting it to *t* if it is *nil*, and to *nil* if it is *t*. Here is how the menu item to toggle the **debug-on-error** flag is defined:

```
(menu-item "Debug on Error" toggle-debug-on-error
          :button (:toggle
                    . (and (boundp 'debug-on-error)
                           debug-on-error)))
```

This works because **toggle-debug-on-error** is defined as a command which toggles the variable **debug-on-error**.

Radio buttons are a group of menu items, in which at any time one and only one is selected. There should be a variable whose value says which one is selected at any time. The *selected* form for each radio button in the group should check whether the variable has the right value for selecting that button. Clicking on the button should set the variable so that the button you clicked on becomes selected.

:key-sequence key-sequence

This property specifies which key sequence to display as keyboard equivalent. Before Emacs displays *key-sequence* in the menu, it verifies that *key-sequence* is really equivalent to this menu item, so it only has an effect if you specify a correct key sequence. Specifying *nil* for *key-sequence* is equivalent to the **:key-sequence** attribute being absent.

:keys string

This property specifies that *string* is the string to display as the keyboard equivalent for this menu item. You can use the ‘\\[...’ documentation construct in *string*.

This property can also be a function (which will be called with no arguments). This function should return a string. This function will be called every time the menu is computed, so using a function that takes a lot of time to compute is not a good idea, and it should expect to be called from any context.

:filter filter-fn

This property provides a way to compute the menu item dynamically. The property value *filter-fn* should be a function of one argument; when it is called, its argument will be *real-binding*. The function should return the binding to use instead.

Emacs can call this function at any time that it does redisplay or operates on menu data structures, so you should write it so it can safely be called at any time.

23.18.1.3 Menu Separators

A menu separator is a kind of menu item that doesn't display any text—instead, it divides the menu into subparts with a horizontal line. A separator looks like this in the menu keymap:

`(menu-item separator-type)`

where *separator-type* is a string starting with two or more dashes.

In the simplest case, *separator-type* consists of only dashes. That specifies the default kind of separator. (For compatibility, "" and – also count as separators.)

Certain other values of *separator-type* specify a different style of separator. Here is a table of them:

`--no-line"`

`--space"`

An extra vertical space, with no actual line.

`--single-line"`

A single line in the menu's foreground color.

`--double-line"`

A double line in the menu's foreground color.

`--single-dashed-line"`

A single dashed line in the menu's foreground color.

`--double-dashed-line"`

A double dashed line in the menu's foreground color.

`--shadow-etched-in"`

A single line with a 3D sunken appearance. This is the default, used for separators consisting of dashes only.

`--shadow-etched-out"`

A single line with a 3D raised appearance.

`--shadow-etched-in-dash"`

A single dashed line with a 3D sunken appearance.

`--shadow-etched-out-dash"`

A single dashed line with a 3D raised appearance.

`--shadow-double-etched-in"`

Two lines with a 3D sunken appearance.

```
--shadow-double-etched-out"
    Two lines with a 3D raised appearance.

--shadow-double-etched-in-dash"
    Two dashed lines with a 3D sunken appearance.

--shadow-double-etched-out-dash"
    Two dashed lines with a 3D raised appearance.
```

You can also give these names in another style, adding a colon after the double-dash and replacing each single dash with capitalization of the following word. Thus, "`--:singleLine`", is equivalent to "`--single-line`".

You can use a longer form to specify keywords such as `:enable` and `:visible` for a menu separator:

```
(menu-item separator-type nil . item-property-list)
```

For example:

```
(menu-item "--" nil :visible (boundp 'foo))
```

Some systems and display toolkits don't really handle all of these separator types. If you use a type that isn't supported, the menu displays a similar kind of separator that is supported.

23.18.1.4 Alias Menu Items

Sometimes it is useful to make menu items that use the same command but with different enable conditions. The best way to do this in Emacs now is with extended menu items; before that feature existed, it could be done by defining alias commands and using them in menu items. Here's an example that makes two aliases for `read-only-mode` and gives them different enable conditions:

```
(defalias 'make-read-only 'read-only-mode)
(put 'make-read-only 'menu-enable '(not buffer-read-only))
(defalias 'make-writable 'read-only-mode)
(put 'make-writable 'menu-enable 'buffer-read-only)
```

When using aliases in menus, often it is useful to display the equivalent key bindings for the real command name, not the aliases (which typically don't have any key bindings except for the menu itself). To request this, give the alias symbol a non-nil `menu-alias` property. Thus,

```
(put 'make-read-only 'menu-alias t)
(put 'make-writable 'menu-alias t)
```

causes menu items for `make-read-only` and `make-writable` to show the keyboard bindings for `read-only-mode`.

23.18.2 Menus and the Mouse

The usual way to make a menu keymap produce a menu is to make it the definition of a prefix key. (A Lisp program can explicitly pop up a menu and receive the user's choice—see Section 30.17 [Pop-Up Menus], page 837.)

If the prefix key ends with a mouse event, Emacs handles the menu keymap by popping up a visible menu, so that the user can select a choice with the mouse. When the user clicks

on a menu item, the event generated is whatever character or symbol has the binding that brought about that menu item. (A menu item may generate a series of events if the menu has multiple levels or comes from the menu bar.)

It's often best to use a button-down event to trigger the menu. Then the user can select a menu item by releasing the button.

If the menu keymap contains a binding to a nested keymap, the nested keymap specifies a *submenu*. There will be a menu item, labeled by the nested keymap's item string, and clicking on this item automatically pops up the specified submenu. As a special exception, if the menu keymap contains a single nested keymap and no other menu items, the menu shows the contents of the nested keymap directly, not as a submenu.

However, if Emacs is compiled without X toolkit support, or on text terminals, submenus are not supported. Each nested keymap is shown as a menu item, but clicking on it does not automatically pop up the submenu. If you wish to imitate the effect of submenus, you can do that by giving a nested keymap an item string which starts with ‘@’. This causes Emacs to display the nested keymap using a separate *menu pane*; the rest of the item string after the ‘@’ is the pane label. If Emacs is compiled without X toolkit support, or if a menu is displayed on a text terminal, menu panes are not used; in that case, a ‘@’ at the beginning of an item string is omitted when the menu label is displayed, and has no other effect.

23.18.3 Menus and the Keyboard

When a prefix key ending with a keyboard event (a character or function key) has a definition that is a menu keymap, the keymap operates as a keyboard menu; the user specifies the next event by choosing a menu item with the keyboard.

Emacs displays the keyboard menu with the map's overall prompt string, followed by the alternatives (the item strings of the map's bindings), in the echo area. If the bindings don't all fit at once, the user can type SPC to see the next line of alternatives. Successive uses of SPC eventually get to the end of the menu and then cycle around to the beginning. (The variable `menu-prompt-more-char` specifies which character is used for this; SPC is the default.)

When the user has found the desired alternative from the menu, he or she should type the corresponding character—the one whose binding is that alternative.

`menu-prompt-more-char` [Variable]

This variable specifies the character to use to ask to see the next line of a menu. Its initial value is 32, the code for SPC.

23.18.4 Menu Example

Here is a complete example of defining a menu keymap. It is the definition of the ‘Replace’ submenu in the ‘Edit’ menu in the menu bar, and it uses the extended menu item format (see Section 23.18.1.2 [Extended Menu Items], page 511). First we create the keymap, and give it a name:

```
(defvar menu-bar-replace-menu (make-sparse-keymap "Replace"))
```

Next we define the menu items:

```
(define-key menu-bar-replace-menu [tags-repl-continue]
  '(menu-item "Continue Replace" multifile-continue
    :help "Continue last tags replace operation"))
```

```
(define-key menu-bar-replace-menu [tags-repl]
  '(menu-item "Replace in tagged files" tags-query-replace
    :help "Interactively replace a regexp in all tagged files"))
(define-key menu-bar-replace-menu [separator-replace-tags]
  '(menu-item "--"))
;; ...
```

Note the symbols which the bindings are made for; these appear inside square brackets, in the key sequence being defined. In some cases, this symbol is the same as the command name; sometimes it is different. These symbols are treated as function keys, but they are not real function keys on the keyboard. They do not affect the functioning of the menu itself, but they are echoed in the echo area when the user selects from the menu, and they appear in the output of `where-is` and `apropos`.

The menu in this example is intended for use with the mouse. If a menu is intended for use with the keyboard, that is, if it is bound to a key sequence ending with a keyboard event, then the menu items should be bound to characters or real function keys, that can be typed with the keyboard.

The binding whose definition is ("--") is a separator line. Like a real menu item, the separator has a key symbol, in this case `separator-replace-tags`. If one menu has two separators, they must have two different key symbols.

Here is how we make this menu appear as an item in the parent menu:

```
(define-key menu-bar-edit-menu [replace]
  (list 'menu-item "Replace" menu-bar-replace-menu))
```

Note that this incorporates the submenu keymap, which is the value of the variable `menu-bar-replace-menu`, rather than the symbol `menu-bar-replace-menu` itself. Using that symbol in the parent menu item would be meaningless because `menu-bar-replace-menu` is not a command.

If you wanted to attach the same replace menu to a mouse click, you can do it this way:

```
(define-key global-map [C-S-down-mouse-1]
  menu-bar-replace-menu)
```

23.18.5 The Menu Bar

Emacs usually shows a *menu bar* at the top of each frame. See Section “Menu Bars” in *The GNU Emacs Manual*. Menu bar items are subcommands of the fake function key `MENU-BAR`, as defined in the active keymaps.

To add an item to the menu bar, invent a fake function key of your own (let’s call it `key`), and make a binding for the key sequence `[menu-bar key]`. Most often, the binding is a menu keymap, so that pressing a button on the menu bar item leads to another menu.

When more than one active keymap defines the same function key for the menu bar, the item appears just once. If the user clicks on that menu bar item, it brings up a single, combined menu containing all the subcommands of that item—the global subcommands, the local subcommands, and the minor mode subcommands.

The variable `overriding-local-map` is normally ignored when determining the menu bar contents. That is, the menu bar is computed from the keymaps that would be active if `overriding-local-map` were `nil`. See Section 23.7 [Active Keymaps], page 489.

Here's an example of setting up a menu bar item:

```
; ; Make a menu keymap (with a prompt string)
; ; and make it the menu bar item's definition.
(define-key global-map [menu-bar words]
  (cons "Words" (make-sparse-keymap "Words")))

; ; Define specific subcommands in this menu.
(define-key global-map
  [menu-bar words forward]
  '("Forward word" . forward-word))
(define-key global-map
  [menu-bar words backward]
  '("Backward word" . backward-word))
```

A local keymap can cancel a menu bar item made by the global keymap by rebinding the same fake function key with `undefined` as the binding. For example, this is how Dired suppresses the 'Edit' menu bar item:

```
(define-key dired-mode-map [menu-bar edit] 'undefined)
```

Here, `edit` is the symbol produced by a fake function key, it is used by the global map for the 'Edit' menu bar item. The main reason to suppress a global menu bar item is to regain space for mode-specific items.

menu-bar-final-items

[Variable]

Normally the menu bar shows global items followed by items defined by the local maps.

This variable holds a list of fake function keys for items to display at the end of the menu bar rather than in normal sequence. The default value is `(help-menu)`; thus, the 'Help' menu item normally appears at the end of the menu bar, following local menu items.

menu-bar-update-hook

[Variable]

This normal hook is run by redisplay to update the menu bar contents, before redisplaying the menu bar. You can use it to update menus whose contents should vary. Since this hook is run frequently, we advise you to ensure that the functions it calls do not take much time in the usual case.

Next to every menu bar item, Emacs displays a key binding that runs the same command (if such a key binding exists). This serves as a convenient hint for users who do not know the key binding. If a command has multiple bindings, Emacs normally displays the first one it finds. You can specify one particular key binding by assigning an `:advertised-binding` symbol property to the command. See Section 25.3 [Keys in Documentation], page 598.

23.18.6 Tool bars

A *tool bar* is a row of clickable icons at the top of a frame, just below the menu bar. See Section "Tool Bars" in *The GNU Emacs Manual*. Emacs normally shows a tool bar on graphical displays.

On each frame, the frame parameter `tool-bar-lines` controls how many lines' worth of height to reserve for the tool bar. A zero value suppresses the tool bar. If the value

is nonzero, and `auto-resize-tool-bars` is non-`nil`, the tool bar expands and contracts automatically as needed to hold the specified contents. If the value is `grow-only`, the tool bar expands automatically, but does not contract automatically.

The tool bar contents are controlled by a menu keymap attached to a fake function key called `TOOL-BAR` (much like the way the menu bar is controlled). So you define a tool bar item using `define-key`, like this:

```
(define-key global-map [tool-bar key] item)
```

where `key` is a fake function key to distinguish this item from other items, and `item` is a menu item key binding (see Section 23.18.1.2 [Extended Menu Items], page 511), which says how to display this item and how it behaves.

The usual menu keymap item properties, `:visible`, `:enable`, `:button`, and `:filter`, are useful in tool bar bindings and have their normal meanings. The *real-binding* in the item must be a command, not a keymap; in other words, it does not work to define a tool bar icon as a prefix key.

The `:help` property specifies a help-echo string to display while the mouse is on that item. This is displayed in the same way as `help-echo` text properties (see [Help display], page 931).

In addition, you should use the `:image` property; this is how you specify the image to display in the tool bar:

`:image image`

`image` is either a single image specification (see Section 41.17 [Images], page 1206) or a vector of four image specifications. If you use a vector of four, one of them is used, depending on circumstances:

- item 0 Used when the item is enabled and selected.
- item 1 Used when the item is enabled and deselected.
- item 2 Used when the item is disabled and selected.
- item 3 Used when the item is disabled and deselected.

The GTK+ and NS versions of Emacs ignores items 1 to 3, because disabled and/or deselected images are autocomputed from item 0.

If `image` is a single image specification, Emacs draws the tool bar button in disabled state by applying an edge-detection algorithm to the image.

The `:rtl` property specifies an alternative image to use for right-to-left languages. Only the GTK+ version of Emacs supports this at present.

Some toolkits display both an image and a text in the toolbar. If you want to force using only the image, use a `:vert-only non-nil` property.

Like the menu bar, the tool bar can display separators (see Section 23.18.1.3 [Menu Separators], page 513). Tool bar separators are vertical rather than horizontal, though, and only a single style is supported. They are represented in the tool bar keymap by (`menu-item "--"`) entries; properties like `:visible` are not supported for tool bar separators. Separators are rendered natively in GTK+ and Nextstep tool bars; in the other cases, they are rendered using an image of a vertical line.

The default tool bar is defined so that items specific to editing do not appear for major modes whose command symbol has a `mode-class` property of `special` (see Section 24.2.1 [Major Mode Conventions], page 528). Major modes may add items to the global bar by binding `[tool-bar foo]` in their local map. It makes sense for some major modes to replace the default tool bar items completely, since not many can be accommodated conveniently, and the default bindings make this easy by using an indirection through `tool-bar-map`.

tool-bar-map [Variable]

By default, the global map binds `[tool-bar]` as follows:

```
(keymap-global-set "<tool-bar>"  
  `(menu-item ,(purecopy "tool bar") ignore  
    :filter tool-bar-make-keymap))
```

The function `tool-bar-make-keymap`, in turn, derives the actual tool bar map dynamically from the value of the variable `tool-bar-map`. Hence, you should normally adjust the default (global) tool bar by changing that map. Some major modes, such as Info mode, completely replace the global tool bar by making `tool-bar-map` buffer-local and setting it to a different keymap.

There are two convenience functions for defining tool bar items, as follows.

tool-bar-add-item icon def key &rest props [Function]

This function adds an item to the tool bar by modifying `tool-bar-map`. The image to use is defined by `icon`, which is the base name of an XPM, XBM or PBM image file to be located by `find-image`. Given a value "`"exit"`", say, `exit.xpm`, `exit.pbm` and `exit.xbm` would be searched for in that order on a color display. On a monochrome display, the search order is '`.pbm`', '`.xbm`' and '`.xpm`'. The binding to use is the command `def`, and `key` is the fake function key symbol in the prefix keymap. The remaining arguments `props` are additional property list elements to add to the menu item specification.

To define items in some local map, bind `tool-bar-map` with `let` around calls of this function:

```
(defvar foo-tool-bar-map  
  (let ((tool-bar-map (make-sparse-keymap)))  
    (tool-bar-add-item ...)  
    ...  
    tool-bar-map))
```

tool-bar-add-item-from-menu command icon &optional map &rest props [Function]

This function is a convenience for defining tool bar items which are consistent with existing menu bar bindings. The binding of `command` is looked up in the menu bar in `map` (default `global-map`) and modified to add an image specification for `icon`, which is found in the same way as by `tool-bar-add-item`. The resulting binding is then placed in `tool-bar-map`, so use this function only for global tool bar items.

`map` must contain an appropriate keymap bound to `[menu-bar]`. The remaining arguments `props` are additional property list elements to add to the menu item specification.

tool-bar-local-item-from-menu *command icon in-map &optional from-map &rest props* [Function]

This function is used for making non-global tool bar items. Use it like **tool-bar-add-item-from-menu** except that *in-map* specifies the local map to make the definition in. The argument *from-map* is like the *map* argument of **tool-bar-add-item-from-menu**.

auto-resize-tool-bars [Variable]

If this variable is non-*nil*, the tool bar automatically resizes to show all defined tool bar items—but not larger than a quarter of the frame's height.

If the value is *grow-only*, the tool bar expands automatically, but does not contract automatically. To contract the tool bar, the user has to redraw the frame by entering *C-l*.

If Emacs is built with GTK+ or Nextstep, the tool bar can only show one line, so this variable has no effect.

auto-raise-tool-bar-buttons [Variable]

If this variable is non-*nil*, tool bar items display in raised form when the mouse moves over them.

tool-bar-button-margin [Variable]

This variable specifies an extra margin to add around tool bar items. The value is an integer, a number of pixels. The default is 4.

tool-bar-button-relief [Variable]

This variable specifies the shadow width for tool bar items. The value is an integer, a number of pixels. The default is 1.

tool-bar-border [Variable]

This variable specifies the height of the border drawn below the tool bar area. An integer specifies height as a number of pixels. If the value is one of **internal-border-width** (the default) or **border-width**, the tool bar border height corresponds to the corresponding frame parameter.

You can define a special meaning for clicking on a tool bar item with the shift, control, meta, etc., modifiers. You do this by setting up additional items that relate to the original item through the fake function keys. Specifically, the additional items should use the modified versions of the same fake function key used to name the original item.

Thus, if the original item was defined this way,

```
(define-key global-map [tool-bar shell]
  '(menu-item "Shell" shell
    :image (image :type xpm :file "shell.xpm")))
```

then here is how you can define clicking on the same tool bar image with the shift modifier:

```
(define-key global-map [tool-bar S-shell] 'some-command)
```

See Section 22.7.2 [Function Keys], page 441, for more information about how to add modifiers to function keys.

If you have functions that change whether a tool bar item is enabled or not, this status is not necessarily updated visually immediately. To force recalculation of the tool bar, call **force-mode-line-update** (see Section 24.4 [Mode Line Format], page 550).

23.18.7 Modifying Menus

When you insert a new item in an existing menu, you probably want to put it in a particular place among the menu's existing items. If you use `define-key` to add the item, it normally goes at the front of the menu. To put it elsewhere in the menu, use `keymap-set-after`:

`keymap-set-after map key binding &optional after` [Function]

Define a binding in *map* for *key*, with value *binding*, just like `keymap-set` (see Section 23.12 [Changing Key Bindings], page 497), but position the binding in *map* after the binding for the event *after*. The argument *key* should represent a single menu item or key, and should satisfy `key-valid-p` (see Section 23.1 [Key Sequences], page 480). *after* should be a single event type—a symbol or a character, not a sequence. The new binding goes after the binding for *after*. If *after* is `t` or is omitted, then the new binding goes last, at the end of the keymap. However, new bindings are added before any inherited keymap.

Here is an example:

```
(keymap-set-after my-menu "<drink>"  
  ('("Drink" . drink-command) 'eat))
```

makes a binding for the fake function key DRINK and puts it right after the binding for EAT.

Here is how to insert an item called ‘Work’ in the ‘Signals’ menu of Shell mode, after the item break:

```
(keymap-set-after shell-mode-map "<menu-bar> <signals> <work>"  
  ('("Work" . work-command) 'break))
```

23.18.8 Easy Menu

The following macro provides a convenient way to define pop-up menus and/or menu bar menus.

`easy-menu-define symbol maps doc menu` [Macro]

This macro defines a pop-up menu and/or menu bar submenu, whose contents are given by *menu*.

If *symbol* is non-`nil`, it should be a symbol; then this macro defines *symbol* as a function for popping up the menu (see Section 30.17 [Pop-Up Menus], page 837), with *doc* as its documentation string. *symbol* should not be quoted.

Regardless of the value of *symbol*, if *maps* is a keymap, the menu is added to that keymap, as a top-level menu for the menu bar (see Section 23.18.5 [Menu Bar], page 516). It can also be a list of keymaps, in which case the menu is added separately to each of those keymaps.

The first element of *menu* must be a string, which serves as the menu label. It may be followed by any number of the following keyword-argument pairs:

`:filter function`

function must be a function which, if called with one argument—the list of the other menu items—returns the actual items to be displayed in the menu.

:visible include
include is an expression; if it evaluates to `nil`, the menu is made invisible.
:included is an alias for **:visible**.

:active enable
enable is an expression; if it evaluates to `nil`, the menu is not selectable.
:enable is an alias for **:active**.

The remaining elements in *menu* are menu items.

A menu item can be a vector of three elements, `[name callback enable]`. *name* is the menu item name (a string). *callback* is a command to run, or an expression to evaluate, when the item is chosen. *enable* is an expression; if it evaluates to `nil`, the item is disabled for selection.

Alternatively, a menu item may have the form:

`[name callback [keyword arg]...]`

where *name* and *callback* have the same meanings as above, and each optional *keyword* and *arg* pair should be one of the following:

:keys keys
keys is a string to display as keyboard equivalent to the menu item. This is normally not needed, as keyboard equivalents are computed automatically. *keys* is expanded with `substitute-command-keys` before it is displayed (see Section 25.3 [Keys in Documentation], page 598).

:key-sequence keys
keys is a hint indicating which key sequence to display as keyboard equivalent, in case the command is bound to several key sequences. It has no effect if *keys* is not bound to same command as this menu item.

:active enable
enable is an expression; if it evaluates to `nil`, the item is made unselectable.
:enable is an alias for **:active**.

:visible include
include is an expression; if it evaluates to `nil`, the item is made invisible.
:included is an alias for **:visible**.

:label form
form is an expression that is evaluated to obtain a value which serves as the menu item's label (the default is *name*).

:suffix form
form is an expression that is dynamically evaluated and whose value is concatenated with the menu entry's label.

:style style
style is a symbol describing the type of menu item; it should be `toggle` (a checkbox), or `radio` (a radio button), or anything else (meaning an ordinary menu item).

:selected selected
selected is an expression; the checkbox or radio button is selected whenever the expression's value is non-`nil`.

```
:help help
```

help is a string describing the menu item.

Alternatively, a menu item can be a string. Then that string appears in the menu as unselectable text. A string consisting of dashes is displayed as a separator (see Section 23.18.1.3 [Menu Separators], page 513).

Alternatively, a menu item can be a list with the same format as *menu*. This is a submenu.

Here is an example of using `easy-menu-define` to define a menu similar to the one defined in the example in Section 23.18.5 [Menu Bar], page 516:

```
(easy-menu-define words-menu global-map
  "Menu for word navigation commands."
  '("Words"
    ["Forward word" forward-word]
    ["Backward word" backward-word]))
```

24 Major and Minor Modes

A *mode* is a set of definitions that customize Emacs behavior in useful ways. There are two varieties of modes: *minor modes*, which provide features that users can turn on and off while editing; and *major modes*, which are used for editing or interacting with a particular kind of text. Each buffer has exactly one *major mode* at a time.

This chapter describes how to write both major and minor modes, how to indicate them in the mode line, and how they run hooks supplied by the user. For related topics such as keymaps and syntax tables, see Chapter 23 [Keymaps], page 480, and Chapter 36 [Syntax Tables], page 1022.

24.1 Hooks

A *hook* is a variable where you can store a function or functions (see Section 13.1 [What Is a Function], page 230) to be called on a particular occasion by an existing program. Emacs provides hooks for the sake of customization. Most often, hooks are set up in the init file (see Section 42.1.2 [Init File], page 1258), but Lisp programs can set them also. See Appendix H [Standard Hooks], page 1398, for a list of some standard hook variables.

Most of the hooks in Emacs are *normal hooks*. These variables contain lists of functions to be called with no arguments. By convention, whenever the hook name ends in ‘`-hook`’, that tells you it is normal. We try to make all hooks normal, as much as possible, so that you can use them in a uniform way.

Every major mode command is supposed to run a normal hook called the *mode hook* as one of the last steps of initialization. This makes it easy for a user to customize the behavior of the mode, by overriding the buffer-local variable assignments already made by the mode. Most minor mode functions also run a mode hook at the end. But hooks are used in other contexts too. For example, the hook `suspend-hook` runs just before Emacs suspends itself (see Section 42.2.2 [Suspending Emacs], page 1263).

If the hook variable’s name does not end with ‘`-hook`’, that indicates it is probably an *abnormal hook*. These differ from normal hooks in two ways: they can be called with one or more arguments, and their return values can be used in some way. The hook’s documentation says how the functions are called and how their return values are used. Any functions added to an abnormal hook must follow the hook’s calling convention. By convention, abnormal hook names end in ‘`-functions`’.

If the name of the variable ends in ‘`-predicate`’ or ‘`-function`’ (singular) then its value must be a function, not a list of functions. As with abnormal hooks, the expected arguments and meaning of the return value vary across such *single function hooks*. The details are explained in each variable’s docstring.

Since hooks (both multi and single function) are variables, their values can be modified with `setq` or temporarily with `let`. However, it is often useful to add or remove a particular function from a hook while preserving any other functions it might have. For multi function hooks, the recommended way of doing this is with `add-hook` and `remove-hook` (see Section 24.1.2 [Setting Hooks], page 525). Most normal hook variables are initially void; `add-hook` knows how to deal with this. You can add hooks either globally or buffer-locally with `add-hook`. For hooks which hold only a single function, `add-hook` is not appropriate, but you can use `add-function` (see Section 13.12 [Advising Functions], page 252) to combine

new functions with the hook. Note that some single function hooks may be `nil` which `add-function` cannot deal with, so you must check for that before calling `add-function`.

24.1.1 Running Hooks

In this section, we document the `run-hooks` function, which is used to run a normal hook. We also document the functions for running various kinds of abnormal hooks.

`run-hooks &rest hookvars`

[Function]

This function takes one or more normal hook variable names as arguments, and runs each hook in turn. Each argument should be a symbol that is a normal hook variable. These arguments are processed in the order specified.

If a hook variable has a non-`nil` value, that value should be a list of functions. `run-hooks` calls all the functions, one by one, with no arguments.

The hook variable's value can also be a single function—either a lambda expression or a symbol with a function definition—which `run-hooks` calls. But this usage is obsolete.

If the hook variable is buffer-local, the buffer-local variable will be used instead of the global variable. However, if the buffer-local variable contains the element `t`, the global hook variable will be run as well.

`run-hook-with-args hook &rest args`

[Function]

This function runs an abnormal hook by calling all the hook functions in `hook`, passing each one the arguments `args`.

`run-hook-with-args-until-failure hook &rest args`

[Function]

This function runs an abnormal hook by calling each hook function in turn, stopping if one of them fails by returning `nil`. Each hook function is passed the arguments `args`. If this function stops because one of the hook functions fails, it returns `nil`; otherwise it returns a non-`nil` value.

`run-hook-with-args-until-success hook &rest args`

[Function]

This function runs an abnormal hook by calling each hook function, stopping if one of them succeeds by returning a non-`nil` value. Each hook function is passed the arguments `args`. If this function stops because one of the hook functions returns a non-`nil` value, it returns that value; otherwise it returns `nil`.

24.1.2 Setting Hooks

Here's an example that adds a function to a mode hook to turn on Auto Fill mode when in Lisp Interaction mode:

```
(add-hook 'lisp-interaction-mode-hook 'auto-fill-mode)
```

The value of a hook variable should be a list of functions. You can manipulate that list using the normal Lisp facilities, but the modular way is to use the functions `add-hook` and `remove-hook`, defined below. They take care to handle some unusual situations and avoid problems.

It works to put a `lambda`-expression function on a hook, but we recommend avoiding this because it can lead to confusion. If you add the same `lambda`-expression a second time but write it slightly differently, you will get two equivalent but distinct functions on the hook. If you then remove one of them, the other will still be on it.

add-hook hook function &optional depth local [Function]

This function is the handy way to add function *function* to hook variable *hook*. You can use it for abnormal hooks as well as for normal hooks. *function* can be any Lisp function that can accept the proper number of arguments for *hook*. For example,

```
(add-hook 'text-mode-hook 'my-text-hook-function)
```

adds *my-text-hook-function* to the hook called *text-mode-hook*.

If *function* is already present in *hook* (comparing using `equal`), then `add-hook` does not add it a second time.

If *function* has a non-*nil* property `permanent-local-hook`, then `kill-all-local-variables` (or changing major modes) won't delete it from the hook variable's local value.

For a normal hook, hook functions should be designed so that the order in which they are executed does not matter. Any dependence on the order is asking for trouble. However, the order is predictable: normally, *function* goes at the front of the hook list, so it is executed first (barring another `add-hook` call).

In some cases, it is important to control the relative ordering of functions on the hook. The optional argument *depth* lets you indicate where the function should be inserted in the list: it should then be a number between -100 and 100 where the higher the value, the closer to the end of the list the function should go. The *depth* defaults to 0 and for backward compatibility when *depth* is a non-*nil* symbol it is interpreted as a depth of 90. Furthermore, when *depth* is strictly greater than 0 the function is added *after* rather than before functions of the same depth. One should never use a depth of 100 (or -100), because one can never be sure that no other function will ever need to come before (or after) us.

`add-hook` can handle the cases where *hook* is void or its value is a single function; it sets or changes the value to a list of functions.

If *local* is non-*nil*, that says to add *function* to the buffer-local hook list instead of to the global hook list. This makes the hook buffer-local and adds `t` to the buffer-local value. The latter acts as a flag to run the hook functions in the default value as well as in the local value.

remove-hook hook function &optional local [Function]

This function removes *function* from the hook variable *hook*. It compares *function* with elements of *hook* using `equal`, so it works for both symbols and lambda expressions.

If *local* is non-*nil*, that says to remove *function* from the buffer-local hook list instead of from the global hook list.

24.2 Major Modes

Major modes specialize Emacs for editing or interacting with particular kinds of text. Each buffer has exactly one major mode at a time. Every major mode is associated with a *major mode command*, whose name should end in '`-mode`'. This command takes care of switching to that mode in the current buffer, by setting various buffer-local variables such as a local keymap. See Section 24.2.1 [Major Mode Conventions], page 528. Note that unlike minor modes there is no way to "turn off" a major mode, instead the buffer must be switched to a

different one. However, you can temporarily *suspend* a major mode and later *restore* the suspended mode, see below.

The least specialized major mode is called *Fundamental mode*, which has no mode-specific definitions or variable settings.

fundamental-mode

[Command]

This is the major mode command for Fundamental mode. Unlike other mode commands, it does *not* run any mode hooks (see Section 24.2.1 [Major Mode Conventions], page 528), since you are not supposed to customize this mode.

major-mode-suspend

[Function]

This function works like `fundamental-mode`, in that it kills all buffer-local variables, but it also records the major mode in effect, so that it could subsequently be restored. This function and `major-mode-restore` (described next) are useful when you need to put a buffer under some specialized mode other than the one Emacs chooses for it automatically (see Section 24.2.2 [Auto Major Mode], page 531), but would also like to be able to switch back to the original mode later.

major-mode-restore &optional avoided-modes

[Function]

This function restores the major mode recorded by `major-mode-suspend`. If no major mode was recorded, this function calls `normal-mode` (see Section 24.2.2 [Auto Major Mode], page 531), but tries to force it not to choose any modes in `avoided-modes`, if that argument is non-`nil`.

clean-mode

[Function]

Changing the major mode clears out most local variables, but it doesn't remove all artifacts in the buffer (like text properties and overlays). It's rare to change a buffer from one major mode to another (except from `fundamental-mode` to everything else), so this is usually not a concern. It can sometimes be convenient (mostly when debugging a problem in a buffer) to do a "full reset" of the buffer, and that's what the `clean-mode` major mode offers. It will kill all local variables (even the permanently local ones), and also removes all overlays and text properties.

The easiest way to write a major mode is to use the macro `define-derived-mode`, which sets up the new mode as a variant of an existing major mode. See Section 24.2.4 [Derived Modes], page 534. We recommend using `define-derived-mode` even if the new mode is not an obvious derivative of another mode, as it automatically enforces many coding conventions for you. See Section 24.2.5 [Basic Major Modes], page 536, for common modes to derive from.

The standard GNU Emacs Lisp directory tree contains the code for several major modes, in files such as `text-mode.el`, `texinfo.el`, `lisp-mode.el`, and `rmail.el`. You can study these libraries to see how modes are written.

major-mode

[User Option]

The buffer-local value of this variable holds the symbol for the current major mode. Its default value holds the default major mode for new buffers. The standard default value is `fundamental-mode`.

If the default value is `nil`, then whenever Emacs creates a new buffer via a command such as `C-x b` (`switch-to-buffer`), the new buffer is put in the major mode of the

previously current buffer. As an exception, if the major mode of the previous buffer has a `mode-class` symbol property with value `special`, the new buffer is put in Fundamental mode (see Section 24.2.1 [Major Mode Conventions], page 528).

24.2.1 Major Mode Conventions

The code for every major mode should follow various coding conventions, including conventions for local keymap and syntax table initialization, function and variable names, and hooks.

If you use the `define-derived-mode` macro, it will take care of many of these conventions automatically. See Section 24.2.4 [Derived Modes], page 534. Note also that Fundamental mode is an exception to many of these conventions, because it represents the default state of Emacs.

The following list of conventions is only partial. Each major mode should aim for consistency in general with other Emacs major modes, as this makes Emacs as a whole more coherent. It is impossible to list here all the possible points where this issue might come up; if the Emacs developers point out an area where your major mode deviates from the usual conventions, please make it compatible.

- Define a major mode command whose name ends in ‘`-mode`’. When called with no arguments, this command should switch to the new mode in the current buffer by setting up the keymap, syntax table, and buffer-local variables in an existing buffer. It should not change the buffer’s contents.
- Write a documentation string for this command that describes the special commands available in this mode. See Section 24.2.3 [Mode Help], page 534.

The documentation string may include the special documentation substrings, ‘`\[command]`’, ‘`\{keymap}`’, and ‘`\<keymap>`’, which allow the help display to adapt automatically to the user’s own key bindings. See Section 25.3 [Keys in Documentation], page 598.

- The major mode command should start by calling `kill-all-local-variables`. This runs the normal hook `change-major-mode-hook`, then gets rid of the buffer-local variables of the major mode previously in effect. See Section 12.11.2 [Creating Buffer-Local], page 208.
- The major mode command should set the variable `major-mode` to the major mode command symbol. This is how `describe-mode` discovers which documentation to print.
- The major mode command should set the variable `mode-name` to the “pretty” name of the mode, usually a string (but see Section 24.4.2 [Mode Line Data], page 551, for other possible forms). The name of the mode appears in the mode line.
- Calling the major mode command twice in direct succession should not fail and should do the same thing as calling the command only once. In other words, the major mode command should be idempotent.
- Since all global names are in the same name space, all the global variables, constants, and functions that are part of the mode should have names that start with the major mode name (or with an abbreviation of it if the name is long). See Section D.1 [Coding Conventions], page 1331.
- In a major mode for editing some kind of structured text, such as a programming language, indentation of text according to structure is probably useful. So the mode

should set `indent-line-function` to a suitable function, and probably customize other variables for indentation. See Section 24.7 [Auto-Indentation], page 581.

- The major mode should usually have its own keymap, which is used as the local keymap in all buffers in that mode. The major mode command should call `use-local-map` to install this local map. See Section 23.7 [Active Keymaps], page 489, for more information.

This keymap should be stored permanently in a global variable named `modename-mode-map`. Normally the library that defines the mode sets this variable.

See Section 12.6 [Tips for Defining], page 196, for advice about how to write the code to set up the mode's keymap variable.

- The key sequences bound in a major mode keymap should usually start with `C-c`, followed by a control character, a digit, or `{`, `}`, `<`, `>`, `:` or `;`. The other punctuation characters are reserved for minor modes, and ordinary letters are reserved for users.

A major mode can also rebind the keys `M-n`, `M-p` and `M-s`. The bindings for `M-n` and `M-p` should normally be some kind of moving forward and backward, but this does not necessarily mean cursor motion.

It is legitimate for a major mode to rebind a standard key sequence if it provides a command that does the same job in a way better suited to the text this mode is used for. For example, a major mode for editing a programming language might redefine `C-M-a` to move to the beginning of a function in a way that works better for that language. The recommended way of tailoring `C-M-a` to the needs of a major mode is to set `beginning-of-defun-function` (see Section 31.2.6 [List Motion], page 861) to invoke the function specific to the mode.

It is also legitimate for a major mode to rebind a standard key sequence whose standard meaning is rarely useful in that mode. For instance, minibuffer modes rebind `M-r`, whose standard meaning is rarely of any use in the minibuffer. Major modes such as Dired or Rmail that do not allow self-insertion of text can reasonably redefine letters and other printing characters as special commands.

- Major modes for editing text should not define `RET` to do anything other than insert a newline. However, it is ok for specialized modes for text that users don't directly edit, such as Dired and Info modes, to redefine `RET` to do something entirely different.
- Major modes should not alter options that are primarily a matter of user preference, such as whether Auto-Fill mode is enabled. Leave this to each user to decide. However, a major mode should customize other variables so that Auto-Fill mode will work usefully *if* the user decides to use it.
- The mode may have its own syntax table or may share one with other related modes. If it has its own syntax table, it should store this in a variable named `modename-mode-syntax-table`. See Chapter 36 [Syntax Tables], page 1022.
- If the mode handles a language that has a syntax for comments, it should set the variables that define the comment syntax. See Section “Options Controlling Comments” in *The GNU Emacs Manual*.
- The mode may have its own abbrev table or may share one with other related modes. If it has its own abbrev table, it should store this in a variable named `modename-mode-abbrev-table`. If the major mode command defines any abbrevs itself, it should pass `t`

for the *system-flag* argument to `define-abbrev`. See Section 38.2 [Defining Abbrevs], page 1067.

- The mode should specify how to do highlighting for Font Lock mode, by setting up a buffer-local value for the variable `font-lock-defaults` (see Section 24.6 [Font Lock Mode], page 563).
 - Each face that the mode defines should, if possible, inherit from an existing Emacs face. See Section 41.12.8 [Basic Faces], page 1178, and Section 24.6.7 [Faces for Font Lock], page 573.
 - Consider adding a mode-specific menu to the menu bar. This should preferably include the most important menu-specific settings and commands that will allow users discovering the main features quickly and efficiently.
 - Consider adding mode-specific context menus for the mode, to be used if and when users activate the `context-menu-mode` (see Section “Menu Mouse Clicks” in *The Emacs Manual*). To this end, define a mode-specific function which builds one or more menus depending on the location of the `mouse-3` click in the buffer, and then add that function to the buffer-local value of `context-menu-functions`.
 - The mode should specify how Imenu should find the definitions or sections of a buffer, by setting up a buffer-local value for the variable `imenu-generic-expression`, for the two variables `imenu-prev-index-position-function` and `imenu-extract-index-name-function`, or for the variable `imenu-create-index-function` (see Section 24.5 [Imenu], page 561).
 - The mode can tell ElDoc mode how to retrieve different types of documentation for whatever is at point, by adding one or more buffer-local entries to the special hook `eldoc-documentation-functions`.
 - The mode can specify how to complete various keywords by adding one or more buffer-local entries to the special hook `completion-at-point-functions`. See Section 21.6.8 [Completion in Buffers], page 411.
 - To make a buffer-local binding for an Emacs customization variable, use `make-local-variable` in the major mode command, not `make-variable-buffer-local`. The latter function would make the variable local to every buffer in which it is subsequently set, which would affect buffers that do not use this mode. It is undesirable for a mode to have such global effects. See Section 12.11 [Buffer-Local Variables], page 207.
- With rare exceptions, the only reasonable way to use `make-variable-buffer-local` in a Lisp package is for a variable which is used only within that package. Using it on a variable used by other packages would interfere with them.
- Each major mode should have a normal *mode hook* named `modename-mode-hook`. The very last thing the major mode command should do is to call `run-mode-hooks`. This runs the normal hook `change-major-mode-after-body-hook`, the mode hook, the function `hack-local-variables` (when the buffer is visiting a file), and then the normal hook `after-change-major-mode-hook`. See Section 24.2.6 [Mode Hooks], page 537.
 - The major mode command may start by calling some other major mode command (called the *parent mode*) and then alter some of its settings. A mode that does this is called a *derived mode*. The recommended way to define one is to use the `define-derived-mode` macro, but this is not required. Such a mode should call the parent mode command inside a `delay-mode-hooks` form. (Using `define-derived-mode` does this

automatically.) See Section 24.2.4 [Derived Modes], page 534, and Section 24.2.6 [Mode Hooks], page 537.

- If something special should be done if the user switches a buffer from this mode to any other major mode, this mode can set up a buffer-local value for `change-major-mode-hook` (see Section 12.11.2 [Creating Buffer-Local], page 208).
- If this mode is appropriate only for specially-prepared text produced by the mode itself (rather than by the user typing at the keyboard or by an external file), then the major mode command symbol should have a property named `mode-class` with value `special`, put on as follows:

```
(put 'funny-mode 'mode-class 'special)
```

This tells Emacs that new buffers created while the current buffer is in Funny mode should not be put in Funny mode, even though the default value of `major-mode` is `nil`. By default, the value of `nil` for `major-mode` means to use the current buffer's major mode when creating new buffers (see Section 24.2.2 [Auto Major Mode], page 531), but with such `special` modes, Fundamental mode is used instead. Modes such as `Dired`, `Rmail`, and `Buffer List` use this feature.

The function `view-buffer` does not enable View mode in buffers whose mode-class is special, because such modes usually provide their own View-like bindings.

The `define-derived-mode` macro automatically marks the derived mode as special if the parent mode is special. Special mode is a convenient parent for such modes to inherit from; See Section 24.2.5 [Basic Major Modes], page 536.

- If you want to make the new mode the default for files with certain recognizable names, add an element to `auto-mode-alist` to select the mode for those file names (see Section 24.2.2 [Auto Major Mode], page 531). If you define the mode command to autoload, you should add this element in the same file that calls `autoload`. If you use an autoload cookie for the mode command, you can also use an autoload cookie for the form that adds the element (see [autoload cookie], page 305). If you do not autoload the mode command, it is sufficient to add the element in the file that contains the mode definition.
- The top-level forms in the file defining the mode should be written so that they may be evaluated more than once without adverse consequences. For instance, use `defvar` or `defcustom` to set mode-related variables, so that they are not reinitialized if they already have a value (see Section 12.5 [Defining Variables], page 194).

24.2.2 How Emacs Chooses a Major Mode

When Emacs visits a file, it automatically selects a major mode for the buffer based on information in the file name or in the file itself. It also processes local variables specified in the file text.

`normal-mode &optional find-file`

[Command]

This function establishes the proper major mode and buffer-local variable bindings for the current buffer. It calls `set-auto-mode` (see below). As of Emacs 26.1, it no longer runs `hack-local-variables`, this now being done in `run-mode-hooks` at the initialization of major modes (see Section 24.2.6 [Mode Hooks], page 537).

If the `find-file` argument to `normal-mode` is non-`nil`, `normal-mode` assumes that the `find-file` function is calling it. In this case, it may process local variables in the

‘***-*-***’ line or at the end of the file. The variable `enable-local-variables` controls whether to do so. See Section “Local Variables in Files” in *The GNU Emacs Manual*, for the syntax of the local variables section of a file.

If you run `normal-mode` interactively, the argument `find-file` is normally `nil`. In this case, `normal-mode` unconditionally processes any file local variables.

The function calls `set-auto-mode` to choose and set a major mode. If this does not specify a mode, the buffer stays in the major mode determined by the default value of `major-mode` (see below).

`normal-mode` uses `condition-case` around the call to the major mode command, so errors are caught and reported as a ‘File mode specification error’, followed by the original error message.

`set-auto-mode &optional keep-mode-if-same`

[Function]

This function selects and sets the major mode that is appropriate for the current buffer. It bases its decision (in order of precedence) on the ‘***-*-***’ line, on any ‘mode:’ local variable near the end of a file, on the ‘#!’ line (using `interpreter-mode-alist`), on the text at the beginning of the buffer (using `magic-mode-alist`), and finally on the visited file name (using `auto-mode-alist`). See Section “How Major Modes are Chosen” in *The GNU Emacs Manual*. If `enable-local-variables` is `nil`, `set-auto-mode` does not check the ‘***-*-***’ line, or near the end of the file, for any mode tag.

There are some file types where it is not appropriate to scan the file contents for a mode specifier. For example, a tar archive may happen to contain, near the end of the file, a member file that has a local variables section specifying a mode for that particular file. This should not be applied to the containing tar file. Similarly, a tiff image file might just happen to contain a first line that seems to match the ‘***-*-***’ pattern. For these reasons, both these file extensions are members of the list `inhibit-local-variables-regexp`s. Add patterns to this list to prevent Emacs searching them for local variables of any kind (not just mode specifiers).

If `keep-mode-if-same` is non-`nil`, this function does not call the mode command if the buffer is already in the proper major mode. For instance, `set-visited-file-name` sets this to `t` to avoid killing buffer local variables that the user may have set.

`set-buffer-major-mode buffer`

[Function]

This function sets the major mode of `buffer` to the default value of `major-mode`; if that is `nil`, it uses the current buffer’s major mode (if that is suitable). As an exception, if `buffer`’s name is `*scratch*`, it sets the mode to `initial-major-mode`.

The low-level primitives for creating buffers do not use this function, but medium-level commands such as `switch-to-buffer` and `find-file-noselect` use it whenever they create buffers.

`initial-major-mode`

[User Option]

The value of this variable determines the major mode of the initial `*scratch*` buffer. The value should be a symbol that is a major mode command. The default value is `lisp-interaction-mode`.

interpreter-mode-alist

[Variable]

This variable specifies major modes to use for scripts that specify a command interpreter in a ‘#!’ line. Its value is an alist with elements of the form `(regexp . mode)`; this says to use mode *mode* if the file specifies an interpreter which matches `\`\`regexp\```. For example, one of the default elements is `("python[0-9.]*" . python-mode)`.

magic-mode-alist

[Variable]

This variable’s value is an alist with elements of the form `(regexp . function)`, where *regexp* is a regular expression and *function* is a function or `nil`. After visiting a file, `set-auto-mode` calls *function* if the text at the beginning of the buffer matches *regexp* and *function* is non-`nil`; if *function* is `nil`, `auto-mode-alist` gets to decide the mode.

magic-fallback-mode-alist

[Variable]

This works like `magic-mode-alist`, except that it is handled only if `auto-mode-alist` does not specify a mode for this file.

auto-mode-alist

[Variable]

This variable contains an association list of file name patterns (regular expressions) and corresponding major mode commands. Usually, the file name patterns test for suffixes, such as ‘.el’ and ‘.c’, but this need not be the case. An ordinary element of the alist looks like `(regexp . mode-function)`.

For example,

```
(("\`/tmp/fol/" . text-mode)
 ("\\.texinfo\\'" . texinfo-mode)
 ("\\.texi\\'" . texinfo-mode)
 ("\\.el\\'" . emacs-lisp-mode)
 ("\\.c\\'" . c-mode)
 ("\\.h\\'" . c-mode)
 ...)
```

When you visit a file whose expanded file name (see Section 26.9.4 [File Name Expansion], page 639), with version numbers and backup suffixes removed using `file-name-sans-versions` (see Section 26.9.1 [File Name Components], page 634), matches a *regexp*, `set-auto-mode` calls the corresponding *mode-function*. This feature enables Emacs to select the proper major mode for most files.

If an element of `auto-mode-alist` has the form `(regexp function t)`, then after calling *function*, Emacs searches `auto-mode-alist` again for a match against the portion of the file name that did not match before. This feature is useful for uncompression packages: an entry of the form `("\\.gz\\'" function t)` can uncompress the file and then put the uncompressed file in the proper mode according to the name sans ‘.gz’.

If `auto-mode-alist` has more than one element whose *regexp* matches the file name, Emacs will use the first match.

Here is an example of how to prepend several pattern pairs to `auto-mode-alist`. (You might use this sort of expression in your init file.)

```
(setq auto-mode-alist
      (append
        ;; File name (within directory) starts with a dot.
        ('(/\\". [^/]*/\\" . fundamental-mode)
         ;; File name has no dot.
         ('/[^\\".]/*\\" . fundamental-mode)
         ;; File name ends in '.'.
         ('\\".C\\" . c++-mode))
        auto-mode-alist))
```

24.2.3 Getting Help about a Major Mode

The `describe-mode` function provides information about major modes. It is normally bound to `C-h m`. It uses the value of the variable `major-mode` (see Section 24.2 [Major Modes], page 526), which is why every major mode command needs to set that variable.

`describe-mode &optional buffer`

[Command]

This command displays the documentation of the current buffer's major mode and minor modes. It uses the `documentation` function to retrieve the documentation strings of the major and minor mode commands (see Section 25.2 [Accessing Documentation], page 596).

If called from Lisp with a non-`nil` `buffer` argument, this function displays the documentation for that buffer's major and minor modes, rather than those of the current buffer.

24.2.4 Defining Derived Modes

The recommended way to define a new major mode is to derive it from an existing one using `define-derived-mode`. If there is no closely related mode, you should inherit from either `text-mode`, `special-mode`, or `prog-mode`. See Section 24.2.5 [Basic Major Modes], page 536. If none of these are suitable, you can inherit from `fundamental-mode` (see Section 24.2 [Major Modes], page 526).

`define-derived-mode variant parent name docstring keyword-args... body...`

This macro defines `variant` as a major mode command, using `name` as the string form of the mode name. `variant` and `parent` should be unquoted symbols.

The new command `variant` is defined to call the function `parent`, then override certain aspects of that parent mode:

- The new mode has its own sparse keymap, named `variant-map`. `define-derived-mode` makes the parent mode's keymap the parent of the new map, unless `variant-map` is already set and already has a parent.
- The new mode has its own syntax table, kept in the variable `variant-syntax-table`, unless you override this using the `:syntax-table` keyword (see below). `define-derived-mode` makes the parent mode's syntax-table the parent of `variant-syntax-table`, unless the latter is already set and already has a parent different from the standard syntax table.
- The new mode has its own abbrev table, kept in the variable `variant-abbrev-table`, unless you override this using the `:abbrev-table` keyword (see below).

- The new mode has its own mode hook, `variant-hook`. It runs this hook, after running the hooks of its ancestor modes, with `run-mode-hooks`, as the last thing it does, apart from running any `:after-hook` form it may have. See Section 24.2.6 [Mode Hooks], page 537.

In addition, you can specify how to override other aspects of `parent` with `body`. The command `variant` evaluates the forms in `body` after setting up all its usual overrides, just before running the mode hooks.

If `parent` has a non-`nil` `mode-class` symbol property, then `define-derived-mode` sets the `mode-class` property of `variant` to the same value. This ensures, for example, that if `parent` is a special mode, then `variant` is also a special mode (see Section 24.2.1 [Major Mode Conventions], page 528).

You can also specify `nil` for `parent`. This gives the new mode no parent. Then `define-derived-mode` behaves as described above, but, of course, omits all actions connected with `parent`.

The argument `docstring` specifies the documentation string for the new mode. `define-derived-mode` adds some general information about the mode's hook, followed by the mode's keymap, at the end of this documentation string. If you omit `docstring`, `define-derived-mode` generates a documentation string.

The `keyword-args` are pairs of keywords and values. The values, except for `:after-hook`'s, are evaluated. The following keywords are currently supported:

:syntax-table

You can use this to explicitly specify a syntax table for the new mode. If you specify a `nil` value, the new mode uses the same syntax table as `parent`, or the standard syntax table if `parent` is `nil`. (Note that this does *not* follow the convention used for non-keyword arguments that a `nil` value is equivalent with not specifying the argument.)

:abbrev-table

You can use this to explicitly specify an abbrev table for the new mode. If you specify a `nil` value, the new mode uses the same abbrev table as `parent`, or `fundamental-mode-abbrev-table` if `parent` is `nil`. (Again, a `nil` value is *not* equivalent to not specifying this keyword.)

:interactive

Modes are interactive commands by default. If you specify a `nil` value, the mode defined here won't be interactive. This is useful for modes that are never meant to be activated by users manually, but are only supposed to be used in some specially-formatted buffer.

:group

If this is specified, the value should be the customization group for this mode. (Not all major modes have one.) The command `customize-mode` uses this. `define-derived-mode` does *not* automatically define the specified customization group.

:after-hook

This optional keyword specifies a single Lisp form to evaluate as the final act of the mode function, after the mode hooks have been run. It should

not be quoted. Since the form might be evaluated after the mode function has terminated, it should not access any element of the mode function’s local state. An `:after-hook` form is useful for setting up aspects of the mode which depend on the user’s settings, which in turn may have been changed in a mode hook.

Here is a hypothetical example:

```
(defvar-keymap hypertext-mode-map
  "<down-mouse-3>" #'do-hyper-link)

(define-derived-mode hypertext-mode
  text-mode "Hypertext"
  "Major mode for hypertext."
  (setq-local case-fold-search nil))
```

Do not write an `interactive` spec in the definition; `define-derived-mode` does that automatically.

`derived-mode-p &rest modes`

[Function]

This function returns non-`nil` if the current major mode is derived from any of the major modes given by the symbols *modes*.

24.2.5 Basic Major Modes

Apart from Fundamental mode, there are three major modes that other major modes commonly derive from: Text mode, Prog mode, and Special mode. While Text mode is useful in its own right (e.g., for editing files ending in `.txt`), Prog mode and Special mode exist mainly to let other modes derive from them.

As far as possible, new major modes should be derived, either directly or indirectly, from one of these three modes. One reason is that this allows users to customize a single mode hook (e.g., `prog-mode-hook`) for an entire family of relevant modes (e.g., all programming language modes).

`text-mode`

[Command]

Text mode is a major mode for editing human languages. It defines the ‘‘’ and ‘\’ characters as having punctuation syntax (see Section 36.2.1 [Syntax Class Table], page 1023), and binds `M-TAB` to `ispell-complete-word` (see Section “Spelling” in *The GNU Emacs Manual*).

An example of a major mode derived from Text mode is HTML mode. See Section “SGML and HTML Modes” in *The GNU Emacs Manual*.

`prog-mode`

[Command]

Prog mode is a basic major mode for buffers containing programming language source code. Most of the programming language major modes built into Emacs are derived from it.

Prog mode binds `parse-sexp-ignore-comments` to `t` (see Section 36.6.1 [Motion via Parsing], page 1031) and `bidi-paragraph-direction` to `left-to-right` (see Section 41.27 [Bidirectional Display], page 1250).

special-mode

[Command]

Special mode is a basic major mode for buffers containing text that is produced specially by Emacs, rather than directly from a file. Major modes derived from Special mode are given a `mode-class` property of `special` (see Section 24.2.1 [Major Mode Conventions], page 528).

Special mode sets the buffer to read-only. Its keymap defines several common bindings, including `q` for `quit-window` and `g` for `revert-buffer` (see Section 27.3 [Reverting], page 667).

An example of a major mode derived from Special mode is Buffer Menu mode, which is used by the `*Buffer List*` buffer. See Section “Listing Existing Buffers” in *The GNU Emacs Manual*.

In addition, modes for buffers of tabulated data can inherit from Tabulated List mode, which is in turn derived from Special mode. See Section 24.2.7 [Tabulated List Mode], page 538.

24.2.6 Mode Hooks

Every major mode command should finish by running the mode-independent normal hook `change-major-mode-after-body-hook`, its mode hook, and the normal hook `after-change-major-mode-hook`. It does this by calling `run-mode-hooks`. If the major mode is a derived mode, that is if it calls another major mode (the parent mode) in its body, it should do this inside `delay-mode-hooks` so that the parent won’t run these hooks itself. Instead, the derived mode’s call to `run-mode-hooks` runs the parent’s mode hook too. See Section 24.2.1 [Major Mode Conventions], page 528.

Emacs versions before Emacs 22 did not have `delay-mode-hooks`. Versions before 24 did not have `change-major-mode-after-body-hook`. When user-implemented major modes do not use `run-mode-hooks` and have not been updated to use these newer features, they won’t entirely follow these conventions: they may run the parent’s mode hook too early, or fail to run `after-change-major-mode-hook`. If you encounter such a major mode, please correct it to follow these conventions.

When you define a major mode using `define-derived-mode`, it automatically makes sure these conventions are followed. If you define a major mode “by hand”, not using `define-derived-mode`, use the following functions to handle these conventions automatically.

run-mode-hooks &rest hookvars

[Function]

Major modes should run their mode hook using this function. It is similar to `run-hooks` (see Section 24.1 [Hooks], page 524), but it also runs `change-major-mode-after-body-hook`, `hack-local-variables` (when the buffer is visiting a file) (see Section 12.12 [File Local Variables], page 213), and `after-change-major-mode-hook`. The last thing it does is to evaluate any `:after-hook` forms declared by parent modes (see Section 24.2.4 [Derived Modes], page 534).

When this function is called during the execution of a `delay-mode-hooks` form, it does not run the hooks or `hack-local-variables` or evaluate the forms immediately. Instead, it arranges for the next call to `run-mode-hooks` to run them.

delay-mode-hooks *body...* [Macro]

When one major mode command calls another, it should do so inside of **delay-mode-hooks**.

This macro executes *body*, but tells all **run-mode-hooks** calls during the execution of *body* to delay running their hooks. The hooks will actually run during the next call to **run-mode-hooks** after the end of the **delay-mode-hooks** construct.

change-major-mode-after-body-hook [Variable]

This is a normal hook run by **run-mode-hooks**. It is run before the mode hooks.

after-change-major-mode-hook [Variable]

This is a normal hook run by **run-mode-hooks**. It is run at the very end of every properly-written major mode command.

24.2.7 Tabulated List mode

Tabulated List mode is a major mode for displaying tabulated data, i.e., data consisting of entries, each entry occupying one row of text with its contents divided into columns. Tabulated List mode provides facilities for pretty-printing rows and columns, and sorting the rows according to the values in each column. It is derived from Special mode (see Section 24.2.5 [Basic Major Modes], page 536).

Tabulated List mode is geared towards displaying text using monospaced fonts, using a single font and text size. If you want to display a table using variable pitch fonts or images, **make-vtable** can be used instead. **vtable** also support having more than a single table in a buffer, or having a buffer that contains both a table and additional text in it. See Section “Introduction” in **vtable**, for more information.

Tabulated List mode is intended to be used as a parent mode by a more specialized major mode. Examples include Process Menu mode (see Section 40.6 [Process Information], page 1092) and Package Menu mode (see Section “Package Menu” in *The GNU Emacs Manual*).

Such a derived mode should use **define-derived-mode** in the usual way, specifying **tabulated-list-mode** as the second argument (see Section 24.2.4 [Derived Modes], page 534). The body of the **define-derived-mode** form should specify the format of the tabulated data, by assigning values to the variables documented below; optionally, it can then call the function **tabulated-list-init-header**, which will populate a header with the names of the columns.

The derived mode should also define a *listing command*. This, not the mode command, is what the user calls (e.g., *M-x list-processes*). The listing command should create or switch to a buffer, turn on the derived mode, specify the tabulated data, and finally call **tabulated-list-print** to populate the buffer.

tabulated-list-gui-sort-indicator-asc [User Option]

This variable specifies the character to be used on GUI frames as an indication that the column is sorted in the ascending order.

Whenever you change the sort direction in Tabulated List buffers, this indicator toggles between ascending (“asc”) and descending (“desc”).

tabulated-list-gui-sort-indicator-desc [User Option]

Like `tabulated-list-gui-sort-indicator-asc`, but used when the column is sorted in the descending order.

tabulated-list-tty-sort-indicator-asc [User Option]

Like `tabulated-list-gui-sort-indicator-asc`, but used for text-mode frames.

tabulated-list-tty-sort-indicator-desc [User Option]

Like `tabulated-list-tty-sort-indicator-asc`, but used when the column is sorted in the descending order.

tabulated-list-format [Variable]

This buffer-local variable specifies the format of the Tabulated List data. Its value should be a vector. Each element of the vector represents a data column, and should be a list (`name width sort . props`), where

- `name` is the column's name (a string).
- `width` is the width to reserve for the column (an integer). This is meaningless for the last column, which runs to the end of each line.
- `sort` specifies how to sort entries by the column. If `nil`, the column cannot be used for sorting. If `t`, the column is sorted by comparing string values. Otherwise, this should be a predicate function for `sort` (see Section 5.6.3 [Rearrangement], page 90), which accepts two arguments with the same form as the elements of `tabulated-list-entries` (see below).
- `props` is a plist (see Section 5.9 [Property Lists], page 99) of additional column properties. If the value of the property `:right-align` is non-`nil` then the column should be right-aligned. And the property `:pad-right` specifies the number of additional padding spaces to the right of the column (by default 1 if omitted).

tabulated-list-entries [Variable]

This buffer-local variable specifies the entries displayed in the Tabulated List buffer. Its value should be either a list, or a function.

If the value is a list, each list element corresponds to one entry, and should have the form (`id contents`), where

- `id` is either `nil`, or a Lisp object that identifies the entry. If the latter, the cursor stays on the same entry when re-sorting entries. Comparison is done with `equal`.
- `contents` is a vector with the same number of elements as `tabulated-list-format`. Each vector element is either a string, which is inserted into the buffer as-is; an image descriptor, which is used to insert an image (see Section 41.17.2 [Image Descriptors], page 1207); or a list (`label . properties`), which means to insert a text button by calling `insert-text-button` with `label` and `properties` as arguments (see Section 41.20.3 [Making Buttons], page 1233).

There should be no newlines in any of these strings.

Otherwise, the value should be a function which returns a list of the above form when called with no arguments.

tabulated-list-revert-hook

[Variable]

This normal hook is run prior to reverting a Tabulated List buffer. A derived mode can add a function to this hook to recompute `tabulated-list-entries`.

tabulated-list-printer

[Variable]

The value of this variable is the function called to insert an entry at point, including its terminating newline. The function should accept two arguments, `id` and `contents`, having the same meanings as in `tabulated-list-entries`. The default value is a function which inserts an entry in a straightforward way; a mode which uses Tabulated List mode in a more complex way can specify another function.

tabulated-list-sort-key

[Variable]

The value of this variable specifies the current sort key for the Tabulated List buffer. If it is `nil`, no sorting is done. Otherwise, it should have the form `(name . flip)`, where `name` is a string matching one of the column names in `tabulated-list-format`, and `flip`, if non-`nil`, means to invert the sort order.

tabulated-list-init-header

[Function]

This function computes and sets `header-line-format` for the Tabulated List buffer (see Section 24.4.7 [Header Lines], page 559), and assigns a keymap to the header line to allow sorting entries by clicking on column headers.

Modes derived from Tabulated List mode should call this after setting the above variables (in particular, only after setting `tabulated-list-format`).

tabulated-list-print &optional remember-pos update

[Function]

This function populates the current buffer with entries. It should be called by the listing command. It erases the buffer, sorts the entries specified by `tabulated-list-entries` according to `tabulated-list-sort-key`, then calls the function specified by `tabulated-list-printer` to insert each entry.

If the optional argument `remember-pos` is non-`nil`, this function looks for the `id` element on the current line, if any, and tries to move to that entry after all the entries are (re)inserted.

If the optional argument `update` is non-`nil`, this function will only erase or add entries that have changed since the last print. This is several times faster if most entries haven't changed since the last time this function was called. The only difference in outcome is that tags placed via `tabulated-list-put-tag` will not be removed from entries that haven't changed (normally all tags are removed).

tabulated-list-delete-entry

[Function]

This function deletes the entry at point.

It returns a list `(id cols)`, where `id` is the ID of the deleted entry and `cols` is a vector of its column descriptors. It moves point to the beginning of the current line. It returns `nil` if there is no entry at point.

Note that this function only changes the buffer contents; it does not alter `tabulated-list-entries`.

tabulated-list-get-id &optional pos [Function]

This `defsubst` returns the ID object from `tabulated-list-entries` (if that is a list) or from the list returned by `tabulated-list-entries` (if it is a function). If omitted or `nil`, `pos` defaults to point.

tabulated-list-get-entry &optional pos [Function]

This `defsubst` returns the entry object from `tabulated-list-entries` (if that is a list) or from the list returned by `tabulated-list-entries` (if it is a function). This will be a vector for the ID at `pos`. If there is no entry at `pos`, then the function returns `nil`.

tabulated-list-header-overlay-p &optional POS [Function]

This `defsubst` returns non-`nil` if there is a fake header at `pos`. A fake header is used if `tabulated-list-use-header-line` is `nil` to put the column names at the beginning of the buffer. If omitted or `nil`, `pos` defaults to `point-min`.

tabulated-list-put-tag tag &optional advance [Function]

This function puts `tag` in the padding area of the current line. The padding area can be empty space at the beginning of the line, the width of which is governed by `tabulated-list-padding`. `tag` should be a string, with a length less than or equal to `tabulated-list-padding`. If `advance` is non-`nil`, this function advances point by one line.

tabulated-list-clear-all-tags [Function]

This function clears all tags from the padding area in the current buffer.

tabulated-list-set-col col desc &optional change-entry-data [Function]

This function changes the tabulated list entry at point, setting `col` to `desc`. `col` is the column number to change, or the name of the column to change. `desc` is the new column descriptor, which is inserted via `tabulated-list-print-col`.

If `change-entry-data` is non-`nil`, this function modifies the underlying data (usually the column descriptor in the list `tabulated-list-entries`) by setting the column descriptor of the vector to `desc`.

24.2.8 Generic Modes

Generic modes are simple major modes with basic support for comment syntax and Font Lock mode. To define a generic mode, use the macro `define-generic-mode`. See the file `generic-x.el` for some examples of the use of `define-generic-mode`.

define-generic-mode mode comment-list keyword-list font-lock-list [Macro]
auto-mode-list function-list &optional docstring

This macro defines a generic mode command named `mode` (a symbol, not quoted). The optional argument `docstring` is the documentation for the mode command. If you do not supply it, `define-generic-mode` generates one by default.

The argument `comment-list` is a list in which each element is either a character, a string of one or two characters, or a cons cell. A character or a string is set up in the mode's syntax table as a comment starter. If the entry is a cons cell, the CAR is set up as a comment starter and the CDR as a comment ender. (Use `nil` for the latter if you

want comments to end at the end of the line.) Note that the syntax table mechanism has limitations about what comment starters and enders are actually possible. See Chapter 36 [Syntax Tables], page 1022.

The argument *keyword-list* is a list of keywords to highlight with `font-lock-keyword-face`. Each keyword should be a string. Meanwhile, `font-lock-list` is a list of additional expressions to highlight. Each element of this list should have the same form as an element of `font-lock-keywords`. See Section 24.6.2 [Search-based Fontification], page 565.

The argument *auto-mode-list* is a list of regular expressions to add to the variable `auto-mode-alist`. They are added by the execution of the `define-generic-mode` form, not by expanding the macro call.

Finally, *function-list* is a list of functions for the mode command to call for additional setup. It calls these functions just before it runs the mode hook variable `mode-hook`.

24.2.9 Major Mode Examples

Text mode is perhaps the simplest mode besides Fundamental mode. Here are excerpts from `text-mode.el` that illustrate many of the conventions listed above:

```
;; Create the syntax table for this mode.
(defvar text-mode-syntax-table
  (let ((st (make-syntax-table)))
    (modify-syntax-entry ?\" ". " st)
    (modify-syntax-entry ?\\ ". " st)
    ;; Add 'p' so M-c on 'hello' leads to 'Hello', not 'hello'.
    (modify-syntax-entry ?' "w p" st)
    ...
    st)
  "Syntax table used while in `text-mode'.")

;; Create the keymap for this mode.
(defvar-keymap text-mode-map
  :doc "Keymap for `text-mode'.
Many other modes, such as `mail-mode' and `outline-mode', inherit all
the commands defined in this map."
  "C-M-i" #'ispell-complete-word)
```

Here is how the actual mode command is defined now:

```
(define-derived-mode text-mode nil "Text"
  "Major mode for editing text written for humans to read.
In this mode, paragraphs are delimited only by blank or white lines.
You can thus get the full benefit of adaptive filling
  (see the variable `adaptive-fill-mode').
\\{text-mode-map}
Turning on Text mode runs the normal hook `text-mode-hook'.
  (setq-local text-mode-variant t)
  (setq-local require-final-newline mode-require-final-newline))
```

The three Lisp modes (Lisp mode, Emacs Lisp mode, and Lisp Interaction mode) have more features than Text mode and the code is correspondingly more complicated. Here are excerpts from `lisp-mode.el` that illustrate how these modes are written.

Here is how the Lisp mode syntax and abbrev tables are defined:

```
; ; Create mode-specific table variables.
(define-abbrev-table 'lisp-mode-abbrev-table ()
  "Abbrev table for Lisp mode.")

(defvar lisp-mode-syntax-table
  (let ((table (make-syntax-table lisp--mode-syntax-table)))
    (modify-syntax-entry ?[ "_   " table)
    (modify-syntax-entry ?\] "_   " table)
    (modify-syntax-entry ?# "' 14" table)
    (modify-syntax-entry ?| "\\" 23bn" table)
    table)
  "Syntax table used in `lisp-mode'.")
```

The three modes for Lisp share much of their code. For instance, Lisp mode and Emacs Lisp mode inherit from Lisp Data mode and Lisp Interaction Mode inherits from Emacs Lisp mode.

Amongst other things, Lisp Data mode sets up the `comment-start` variable to handle Lisp comments:

```
(setq-local comment-start ";")  
...
```

Each of the different Lisp modes has a slightly different keymap. For example, Lisp mode binds `C-c C-z` to `run-lisp`, but the other Lisp modes do not. However, all Lisp modes have some commands in common. The following code sets up the common commands:

```
(defvar-keymap lisp-mode-shared-map
  :parent prog-mode-map
  :doc "Keypad for commands shared by all sorts of Lisp modes."
  "C-M-q" #'indent-sexp
  "DEL" #'backward-delete-char-untabify)
```

And here is the code to set up the keymap for Lisp mode:

```
(defvar-keymap lisp-mode-map
  :doc "Keymap for ordinary Lisp mode.
All commands in `lisp-mode-shared-map' are inherited by this map."
  :parent lisp-mode-shared-map
  "C-M-x" #'lisp-eval-defun
  "C-c C-z" #'run-lisp)
```

Finally, here is the major mode command for Lisp mode:

24.3 Minor Modes

A *minor mode* provides optional features that users may enable or disable independently of the choice of major mode. Minor modes can be enabled individually or in combination.

Most minor modes implement features that are independent of the major mode, and can thus be used with most major modes. For example, Auto Fill mode works with any major mode that permits text insertion. A few minor modes, however, are specific to a particular major mode. For example, Diff Auto Refine mode is a minor mode that is intended to be used only with Diff mode.

Ideally, a minor mode should have its desired effect regardless of the other minor modes in effect. It should be possible to activate and deactivate minor modes in any order.

local-minor-modes

[Variable]

This buffer-local variable lists the currently enabled minor modes in the current buffer, and is a list of symbols.

global-minor-modes

[Variable]

This variable lists the currently enabled global minor modes, and is a list of symbols.

minor-mode-list

[Variable]

The value of this variable is a list of all minor mode commands.

24.3.1 Conventions for Writing Minor Modes

There are conventions for writing minor modes just as there are for major modes (see Section 24.2 [Major Modes], page 526). These conventions are described below. The easiest way to follow them is to use the macro `define-minor-mode`. See Section 24.3.3 [Defining Minor Modes], page 546.

- Define a variable whose name ends in ‘`-mode`’. We call this the *mode variable*. The minor mode command should set this variable. The value will be `nil` if the mode is disabled, and `non-nil` if the mode is enabled. The variable should be buffer-local if the minor mode is buffer-local.

This variable is used in conjunction with the `minor-mode-alist` to display the minor mode name in the mode line. It also determines whether the minor mode keymap is active, via `minor-mode-map-alist` (see Section 23.9 [Controlling Active Maps], page 491). Individual commands or hooks can also check its value.

- Define a command, called the *mode command*, whose name is the same as the mode variable. Its job is to set the value of the mode variable, plus anything else that needs to be done to actually enable or disable the mode’s features.

The mode command should accept one optional argument. If called interactively with no prefix argument, it should toggle the mode (i.e., enable if it is disabled, and disable if it is enabled). If called interactively with a prefix argument, it should enable the mode if the argument is positive and disable it otherwise.

If the mode command is called from Lisp (i.e., non-interactively), it should enable the mode if the argument is omitted or `nil`; it should toggle the mode if the argument is the symbol `toggle`; otherwise it should treat the argument in the same way as for an interactive call with a numeric prefix argument, as described above.

The following example shows how to implement this behavior (it is similar to the code generated by the `define-minor-mode` macro):

```
(interactive (list (or current-prefix-arg 'toggle)))
(let ((enable
```

```
(if (eq arg 'toggle)
    (not foo-mode) ; this is the mode's mode variable
    (> (prefix-numeric-value arg) 0)))
(if enable
    do-enable
    do-disable))
```

The reason for this somewhat complex behavior is that it lets users easily toggle the minor mode interactively, and also lets the minor mode be easily enabled in a mode hook, like this:

```
(add-hook 'text-mode-hook 'foo-mode)
```

This behaves correctly whether or not `foo-mode` was already enabled, since the `foo-mode` mode command unconditionally enables the minor mode when it is called from Lisp with no argument. Disabling a minor mode in a mode hook is a little uglier:

```
(add-hook 'text-mode-hook (lambda () (foo-mode -1)))
```

However, this is not very commonly done.

Enabling or disabling a minor mode twice in direct succession should not fail and should do the same thing as enabling or disabling it only once. In other words, the minor mode command should be idempotent.

- Add an element to `minor-mode-alist` for each minor mode (see [Definition of minor-mode-alist], page 556), if you want to indicate the minor mode in the mode line. This element should be a list of the following form:

```
(mode-variable string)
```

Here `mode-variable` is the variable that controls enabling of the minor mode, and `string` is a short string, starting with a space, to represent the mode in the mode line. These strings must be short so that there is room for several of them at once.

When you add an element to `minor-mode-alist`, use `assq` to check for an existing element, to avoid duplication. For example:

```
(unless (assq 'leif-mode minor-mode-alist)
  (push '(leif-mode " Leif") minor-mode-alist))
```

or like this, using `add-to-list` (see Section 5.5 [List Variables], page 85):

```
(add-to-list 'minor-mode-alist '(leif-mode " Leif"))
```

In addition, several major mode conventions (see Section 24.2.1 [Major Mode Conventions], page 528) apply to minor modes as well: those regarding the names of global symbols, the use of a hook at the end of the initialization function, and the use of keymaps and other tables.

The minor mode should, if possible, support enabling and disabling via Custom (see Chapter 15 [Customization], page 277). To do this, the mode variable should be defined with `defcustom`, usually with `:type 'boolean`. If just setting the variable is not sufficient to enable the mode, you should also specify a `:set` method which enables the mode by invoking the mode command. Note in the variable's documentation string that setting the variable other than via Custom may not take effect. Also, mark the definition with an autoload cookie (see [autoload cookie], page 305), and specify a `:require` so that customizing the variable will load the library that defines the mode. For example:

```
;;###autoload
(defcustom msb-mode nil
  "Toggle msb-mode.
Setting this variable directly does not take effect;
use either \\[customize] or the function `msb-mode'."
  :set 'custom-set-minor-mode
  :initialize 'custom-initialize-default
  :version "20.4"
  :type 'boolean
  :group 'msb
  :require 'msb)
```

24.3.2 Keymaps and Minor Modes

Each minor mode can have its own keymap, which is active when the mode is enabled. To set up a keymap for a minor mode, add an element to the alist `minor-mode-map-alist`. See [Definition of `minor-mode-map-alist`], page 492.

One use of minor mode keymaps is to modify the behavior of certain self-inserting characters so that they do something else as well as self-insert. (Another way to customize `self-insert-command` is through `post-self-insert-hook`, see Section 33.5 [Commands for Insertion], page 884. Apart from this, the facilities for customizing `self-insert-command` are limited to special cases, designed for abbrevs and Auto Fill mode. Do not try substituting your own definition of `self-insert-command` for the standard one. The editor command loop handles this function specially.)

Minor modes may bind commands to key sequences consisting of `C-c` followed by a punctuation character. However, sequences consisting of `C-c` followed by one of `{}``<``>``:``;`, or a control character or digit, are reserved for major modes. Also, `C-c letter` is reserved for users. See Section D.2 [Key Binding Conventions], page 1334.

24.3.3 Defining Minor Modes

The macro `define-minor-mode` offers a convenient way of implementing a mode in one self-contained definition.

`define-minor-mode mode doc keyword-args... body...` [Macro]

This macro defines a new minor mode whose name is `mode` (a symbol). It defines a command named `mode` to toggle the minor mode, with `doc` as its documentation string.

The toggle command takes one optional (prefix) argument. If called interactively with no argument it toggles the mode on or off. A positive prefix argument enables the mode, any other prefix argument disables it. From Lisp, an argument of `toggle` toggles the mode, whereas an omitted or `nil` argument enables the mode. This makes it easy to enable the minor mode in a major mode hook, for example. If `doc` is `nil`, the macro supplies a default documentation string explaining the above.

By default, it also defines a variable named `mode`, which is set to `t` or `nil` by enabling or disabling the mode.

The `keyword-args` consist of keywords followed by corresponding values. A few keywords have special meanings:

:global *global*

If non-`nil`, this specifies that the minor mode should be global rather than buffer-local. It defaults to `nil`.

One of the effects of making a minor mode global is that the *mode* variable becomes a customization variable. Toggling it through the Customize interface turns the mode on and off, and its value can be saved for future Emacs sessions (see Section “Saving Customizations” in *The GNU Emacs Manual*). For the saved variable to work, you should ensure that the minor mode function is available each time Emacs starts; usually this is done by marking the `define-minor-mode` form as autoloaded.

:init-value *init-value*

This is the value to which the *mode* variable is initialized. Except in unusual circumstances (see below), this value must be `nil`.

:lighter *lighter*

The string *lighter* says what to display in the mode line when the mode is enabled; if it is `nil`, the mode is not displayed in the mode line.

:keymap *keymap*

The optional argument *keymap* specifies the keymap for the minor mode. If non-`nil`, it should be a variable name (whose value is a keymap), a keymap, or an alist of the form

(*key-sequence* . *definition*)

where each *key-sequence* and *definition* are arguments suitable for passing to `define-key` (see Section 23.12 [Changing Key Bindings], page 497). If *keymap* is a keymap or an alist, this also defines the variable `mode-map`.

:variable *place*

This replaces the default variable *mode*, used to store the state of the mode. If you specify this, the *mode* variable is not defined, and any *init-value* argument is unused. *place* can be a different named variable (which you must define yourself), or anything that can be used with the `setf` function (see Section 12.17 [Generalized Variables], page 224). *place* can also be a cons (`get` . `set`), where `get` is an expression that returns the current state, and `set` is a function of one argument (a state) which should be assigned to *place*.

:after-hook *after-hook*

This defines a single Lisp form which is evaluated after the mode hooks have run. It should not be quoted.

:interactive *value*

Minor modes are interactive commands by default. If *value* is `nil`, this is inhibited. If *value* is a list of symbols, it’s used to say which major modes this minor mode is useful in.

Any other keyword arguments are passed directly to the `defcustom` generated for the variable *mode*. See Section 15.3 [Variable Definitions], page 280, for the description of those keywords and their values.

The command named *mode* first performs the standard actions such as setting the variable named *mode* and then executes the *body* forms, if any. It then runs the mode hook variable *mode-hook* and finishes by evaluating any form in *:after-hook*. (Note that all of this, including running the hook, is done both when the mode is enabled and disabled.)

The initial value must be `nil` except in cases where (1) the mode is preloaded in Emacs, or (2) it is painless for loading to enable the mode even though the user did not request it. For instance, if the mode has no effect unless something else is enabled, and will always be loaded by that time, enabling it by default is harmless. But these are unusual circumstances. Normally, the initial value must be `nil`.

The name `easy-mmode-define-minor-mode` is an alias for this macro.

Here is an example of using `define-minor-mode`:

```
(define-minor-mode hungry-mode
  "Toggle Hungry mode.
  Interactively with no argument, this command toggles the mode.
  A positive prefix argument enables the mode, any other prefix
  argument disables it. From Lisp, argument omitted or nil enables
  the mode, `toggle' toggles the state.

  When Hungry mode is enabled, the control delete key
  gobbles all preceding whitespace except the last.
  See the command \\[hungry-electric-delete]."
  ; The initial value.
  nil
  ; The indicator for the mode line.
  " Hungry"
  ; The minor mode bindings.
  '(([C-backspace] . hungry-electric-delete)))
```

This defines a minor mode named “Hungry mode”, a command named `hungry-mode` to toggle it, a variable named `hungry-mode` which indicates whether the mode is enabled, and a variable named `hungry-mode-map` which holds the keymap that is active when the mode is enabled. It initializes the keymap with a key binding for `C-DEL`. There are no *body* forms—many minor modes don’t need any.

Here’s an equivalent way to write it:

```
(define-minor-mode hungry-mode
  "Toggle Hungry mode.
  ...rest of documentation as before..."
  ; The initial value.
  :init-value nil
  ; The indicator for the mode line.
  :lighter " Hungry"
  ; The minor mode bindings.
  :keymap
  '(([C-backspace] . hungry-electric-delete)
    ([C-M-backspace]
     . (lambda ()
        (interactive)
        (hungry-electric-delete t)))))
```

```
define-globalized-minor-mode global-mode mode turn-on [Macro]
  keyword-args... body...
```

This defines a global toggle named *global-mode* whose meaning is to enable or disable the buffer-local minor mode *mode* in all (or some; see below) buffers. It also executes the *body* forms. To turn on the minor mode in a buffer, it uses the function *turn-on*; to turn off the minor mode, it calls *mode* with -1 as argument. (The function *turn-on* is a separate function so it could determine whether to enable the minor mode or not when it is not a priori clear that it should always be enabled.)

Globally enabling the mode also affects buffers subsequently created by visiting files, and buffers that use a major mode other than Fundamental mode; but it does not detect the creation of a new buffer in Fundamental mode.

This macro defines the customization option *global-mode* (see Chapter 15 [Customization], page 277), which can be toggled via the Customize interface to turn the minor mode on and off. As with **define-minor-mode**, you should ensure that the **define-globalized-minor-mode** form is evaluated each time Emacs starts, for example by providing a **:require** keyword.

Use **:group group** in *keyword-args* to specify the custom group for the mode variable of the global minor mode.

By default, the buffer-local minor mode variable that says whether the mode is switched on or off is the same as the name of the mode itself. Use **:variable variable** if that's not the case—some minor modes use a different variable to store this state information.

Generally speaking, when you define a globalized minor mode, you should also define a non-globalized version, so that people could use it (or disable it) in individual buffers. This also allows them to disable a globally enabled minor mode in a specific major mode, by using that mode's hook.

If the macro is given a **:predicate** keyword, it will create a user option called the same as the global mode variable, but with **-modes** instead of **-mode** at the end, i.e. **global-modes**. This variable will be used in a predicate function that determines whether the minor mode should be activated in a particular major mode, and users can customize the value of the variable to control the modes in which the minor mode will be switched on. Valid values of **:predicate** (and thus valid values of the user option it creates) include **t** (use in all major modes), **nil** (don't use in any major modes), or a list of mode names, optionally preceded with **not** (as in **(not mode-name ...)**). These elements can be mixed, as shown in the following examples.

```
(c-mode (not mail-mode message-mode) text-mode)
```

This means “use in modes derived from **c-mode**, and not in modes derived from **message-mode** or **mail-mode**, but do use in modes derived from **text-mode**, and otherwise no other modes”.

```
((not c-mode) t)
```

This means “don't use in modes derived from **c-mode**, but do use everywhere else”.

```
(text-mode)
```

This means “use in modes derived from **text-mode**, but nowhere else”. (There's an implicit **nil** element at the end.)

buffer-local-set-state *variable value...* [Macro]

Minor modes often set buffer-local variables that affect some features in Emacs. When a minor mode is switched off, the mode is expected to restore the previous state of these variables. This convenience macro helps with doing that: It works much like `setq-local`, but returns an object that can be used to restore these values back to their previous values/states (using the companion function `buffer-local-restore-state`).

24.4 Mode Line Format

Each Emacs window (aside from minibuffer windows) typically has a mode line at the bottom, which displays status information about the buffer displayed in the window. The mode line contains information about the buffer, such as its name, associated file, depth of recursive editing, and major and minor modes. A window can also have a *header line*, which is much like the mode line but appears at the top of the window.

This section describes how to control the contents of the mode line and header line. We include it in this chapter because much of the information displayed in the mode line relates to the enabled major and minor modes.

24.4.1 Mode Line Basics

The contents of each mode line are specified by the buffer-local variable `mode-line-format` (see Section 24.4.3 [Mode Line Top], page 552). This variable holds a *mode line construct*: a template that controls what is displayed on the buffer’s mode line. The value of `header-line-format` specifies the buffer’s header line in the same way. All windows for the same buffer use the same `mode-line-format` and `header-line-format` unless a `mode-line-format` or `header-line-format` parameter has been specified for that window (see Section 29.27 [Window Parameters], page 776).

For efficiency, Emacs does not continuously recompute each window’s mode line and header line. It does so when circumstances appear to call for it—for instance, if you change the window configuration, switch buffers, narrow or widen the buffer, scroll, or modify the buffer. If you alter any of the variables referenced by `mode-line-format` or `header-line-format` (see Section 24.4.4 [Mode Line Variables], page 554), or any other data structures that affect how text is displayed (see Chapter 41 [Display], page 1129), you should use the function `force-mode-line-update` to update the display.

force-mode-line-update &optional *all* [Function]

This function forces Emacs to update the current buffer’s mode line and header line, based on the latest values of all relevant variables, during its next redisplay cycle. If the optional argument *all* is non-`nil`, it forces an update for all mode lines and header lines.

This function also forces an update of the menu bar and frame title.

The selected window’s mode line is usually displayed in a different color using the face `mode-line-active`. Other windows’ mode lines appear in the face `mode-line-inactive` instead. See Section 41.12 [Faces], page 1164.

mode-line-window-selected-p [Function]

If you want to have more extensive differences between the mode lines in selected and non-selected windows, you can use this predicate in an `:eval` construct. For instance, if you want to display the buffer name in bold in selected windows, but in italics in the other windows, you can say something like:

```
(setq-default
  mode-line-buffer-identification
  '(:eval (propertize "%12b"
    'face (if (mode-line-window-selected-p)
      'bold
      'italic))))
```

Some modes put a lot of data in the mode line, pushing elements at the end of the mode line off to the right. Emacs can “compress” the mode line if the `mode-line-compact` variable is non-`nil` by turning stretches of spaces into a single space. If this variable is `long`, this is only done when the mode line is wider than the currently selected window. (This computation is approximate, based on the number of characters, and not their displayed width.) This variable can be buffer-local to only compress mode-lines in certain buffers.

24.4.2 The Data Structure of the Mode Line

The mode line contents are controlled by a data structure called a *mode line construct*, made up of lists, strings, symbols, and numbers kept in buffer-local variables. Each data type has a specific meaning for the mode line appearance, as described below. The same data structure is used for constructing frame titles (see Section 30.6 [Frame Titles], page 821) and header lines (see Section 24.4.7 [Header Lines], page 559).

A mode line construct may be as simple as a fixed string of text, but it usually specifies how to combine fixed strings with variables’ values to construct the text. Many of these variables are themselves defined to have mode line constructs as their values.

Here are the meanings of various data types as mode line constructs:

string A string as a mode line construct appears verbatim except for %-constructs in it. These stand for substitution of other data; see Section 24.4.5 [%-Constructs], page 556.

If parts of the string have `face` properties, they control display of the text just as they would text in the buffer. Any characters which have no `face` properties are displayed, by default, in the face `mode-line` or `mode-line-inactive` (see Section “Standard Faces” in *The GNU Emacs Manual*). The `help-echo` and `keymap` properties in `string` have special meanings. See Section 24.4.6 [Properties in Mode], page 558.

symbol A symbol as a mode line construct stands for its value. The value of `symbol` is used as a mode line construct, in place of `symbol`. However, the symbols `t` and `nil` are ignored, as is any symbol whose value is `void`.

There is one exception: if the value of `symbol` is a string, it is displayed verbatim: the %-constructs are not recognized.

Unless `symbol` is marked as risky (i.e., it has a non-`nil` `risky-local-variable` property), all text properties specified in `symbol`’s value are ignored. This

includes the text properties of strings in *symbol*'s value, as well as all `:eval` and `:propertize` forms in it. (The reason for this is security: non-risky variables could be set automatically from file variables without prompting the user.)

`(string rest...)`
`(list rest...)`

A list whose first element is a string or list means to process all the elements recursively and concatenate the results. This is the most common form of mode line construct. (Note that text properties are handled specially (for reasons of efficiency) when displaying strings in the mode line: Only the text property on the first character of the string are considered, and they are then used over the entire string. If you need a string with different text properties, you have to use the special `:propertize` mode line construct.)

`(:eval form)`

A list whose first element is the symbol `:eval` says to evaluate *form*, and use the result as a string to display. Make sure this evaluation cannot load any files, as doing so could cause infinite recursion.

`(:propertize elt props...)`

A list whose first element is the symbol `:propertize` says to process the mode line construct *elt* recursively, then add the text properties specified by *props* to the result. The argument *props* should consist of zero or more pairs *text-property value*. If *elt* is or produces a string with text properties, all the characters of that string should have the same properties, or else some of them might be removed by `:propertize`.

`(symbol then else)`

A list whose first element is a symbol that is not a keyword specifies a conditional. Its meaning depends on the value of *symbol*. If *symbol* has a non-`nil` value, the second element, *then*, is processed recursively as a mode line construct. Otherwise, the third element, *else*, is processed recursively. You may omit *else*; then the mode line construct displays nothing if the value of *symbol* is `nil` or `void`.

`(width rest...)`

A list whose first element is an integer specifies truncation or padding of the results of *rest*. The remaining elements *rest* are processed recursively as mode line constructs and concatenated together. When *width* is positive, the result is space filled on the right if its width is less than *width*. When *width* is negative, the result is truncated on the right to $-width$ columns if its width exceeds $-width$.

For example, the usual way to show what percentage of a buffer is above the top of the window is to use a list like this: `(-3 "%p")`.

24.4.3 The Top Level of Mode Line Control

The variable in overall control of the mode line is `mode-line-format`.

mode-line-format

[User Option]

The value of this variable is a mode line construct that controls the contents of the mode-line. It is always buffer-local in all buffers.

If you set this variable to `nil` in a buffer, that buffer does not have a mode line. (A window that is just one line tall also does not display a mode line.)

The default value of `mode-line-format` is designed to use the values of other variables such as `mode-line-position` and `mode-line-modes` (which in turn incorporates the values of the variables `mode-name` and `minor-mode-alist`). Very few modes need to alter `mode-line-format` itself. For most purposes, it is sufficient to alter some of the variables that `mode-line-format` either directly or indirectly refers to.

If you do alter `mode-line-format` itself, the new value should use the same variables that appear in the default value (see Section 24.4.4 [Mode Line Variables], page 554), rather than duplicating their contents or displaying the information in another fashion. This way, customizations made by the user or by Lisp programs (such as `display-time` and major modes) via changes to those variables remain effective.

Here is a hypothetical example of a `mode-line-format` that might be useful for Shell mode (in reality, Shell mode does not set `mode-line-format`):

```
(setq mode-line-format
      (list "-"
            'mode-line-mule-info
            'mode-line-modified
            'mode-line-frame-identification
            "%b--"
            ;; Note that this is evaluated while making the list.
            ;; It makes a mode line construct which is just a string.
            (getenv "HOST")
            ":" 
            'default-directory
            " "
            'global-mode-string
            "%[("
            '(:eval (format-time-string "%F"))
            'mode-line-process
            'minor-mode-alist
            "%n"
            ")%]--"
            '(which-function-mode (" which-func-format "--"))
            '(line-number-mode "L%l--")
            '(column-number-mode "C%c--")
            '(-3 "%p")))
```

(The variables `line-number-mode`, `column-number-mode` and `which-function-mode` enable particular minor modes; as usual, these variable names are also the minor mode command names.)

24.4.4 Variables Used in the Mode Line

This section describes variables incorporated by the standard value of `mode-line-format` into the text of the mode line. There is nothing inherently special about these variables; any other variables could have the same effects on the mode line if the value of `mode-line-format` is changed to use them. However, various parts of Emacs set these variables on the understanding that they will control parts of the mode line; therefore, practically speaking, it is essential for the mode line to use them. Also see Section “Optional Mode Line” in *The GNU Emacs Manual*.

`mode-line-mule-info`

[Variable]

This variable holds the value of the mode line construct that displays information about the language environment, buffer coding system, and current input method. See Chapter 34 [Non-ASCII Characters], page 963.

`mode-line-modified`

[Variable]

This variable holds the value of the mode line construct that displays whether the current buffer is modified. Its default value displays ‘**’ if the buffer is modified, ‘--’ if the buffer is not modified, ‘%%’ if the buffer is read only, and ‘%*’ if the buffer is read only and modified.

Changing this variable does not force an update of the mode line.

`mode-line-frame-identification`

[Variable]

This variable identifies the current frame. Its default value displays " " if you are using a window system which can show multiple frames, or "-%F" on an ordinary terminal which shows only one frame at a time.

`mode-line-buffer-identification`

[Variable]

This variable identifies the buffer being displayed in the window. Its default value displays the buffer name, padded with spaces to at least 12 columns.

`mode-line-position`

[Variable]

This variable indicates the position in the buffer. Its default value displays the buffer percentage and, optionally, the buffer size, the line number and the column number.

`mode-line-percent-position`

[User Option]

This option is used in `mode-line-position`. Its value specifies both the buffer percentage to display (one of `nil`, “%o”, “%p”, “%P” or “%q”, see Section 24.4.5 [%-Constructs], page 556) and a width to space-fill or truncate to. You are recommended to set this option with the `customize-variable` facility.

`vc-mode`

[Variable]

The variable `vc-mode`, buffer-local in each buffer, records whether the buffer’s visited file is maintained with version control, and, if so, which kind. Its value is a string that appears in the mode line, or `nil` for no version control.

`mode-line-modes`

[Variable]

This variable displays the buffer’s major and minor modes. Its default value also displays the recursive editing level, information on the process status, and whether narrowing is in effect.

mode-line-remote [Variable]

This variable is used to show whether `default-directory` for the current buffer is remote.

mode-line-client [Variable]

This variable is used to identify `emacsclient` frames.

The following three variables are used in `mode-line-modes`:

mode-name [Variable]

This buffer-local variable holds the “pretty” name of the current buffer’s major mode. Each major mode should set this variable so that the mode name will appear in the mode line. The value does not have to be a string, but can use any of the data types valid in a mode-line construct (see Section 24.4.2 [Mode Line Data], page 551). To compute the string that will identify the mode name in the mode line, use `format-mode-line` (see Section 24.4.8 [Emulating Mode Line], page 560).

mode-line-process [Variable]

This buffer-local variable contains the mode line information on process status in modes used for communicating with subprocesses. It is displayed immediately following the major mode name, with no intervening space. For example, its value in the `*shell*` buffer is `(":%s")`, which allows the shell to display its status along with the major mode as: ‘`(Shell:run)`’. Normally this variable is `nil`.

mode-line-front-space [Variable]

This variable is displayed at the front of the mode line. By default, this construct is displayed right at the beginning of the mode line, except that if there is a memory-full message, it is displayed first.

mode-line-end-spaces [Variable]

This variable is displayed at the end of the mode line.

mode-line-misc-info [Variable]

Mode line construct for miscellaneous information. By default, this shows the information specified by `global-mode-string`.

mode-line-position-line-format [Variable]

The format used to display line numbers when `line-number-mode` (see Section “Optional Mode Line” in *The GNU Emacs Manual*) is switched on. ‘`%l`’ in the format will be replaced with the line number.

mode-line-position-column-format [Variable]

The format used to display column numbers when `column-number-mode` (see Section “Optional Mode Line” in *The GNU Emacs Manual*) is switched on. ‘`%c`’ in the format will be replaced with a zero-based column number, and ‘`%C`’ will be replaced with a one-based column number.

mode-line-position-column-line-format [Variable]

The format used to display column numbers when both `line-number-mode` and `column-number-mode` are switched on. See the previous two variables for the meaning of the ‘`%l`’, ‘`%c`’ and ‘`%C`’ format specs.

minor-mode-alist [Variable]

This variable holds an association list whose elements specify how the mode line should indicate that a minor mode is active. Each element of the `minor-mode-alist` should be a two-element list:

(*minor-mode-variable* *mode-line-string*)

More generally, *mode-line-string* can be any mode line construct. It appears in the mode line when the value of *minor-mode-variable* is non-`nil`, and not otherwise. These strings should begin with spaces so that they don't run together. Conventionally, the *minor-mode-variable* for a specific mode is set to a non-`nil` value when that minor mode is activated.

`minor-mode-alist` itself is not buffer-local. Each variable mentioned in the alist should be buffer-local if its minor mode can be enabled separately in each buffer.

global-mode-string [Variable]

This variable holds a mode line construct that, by default, appears in the mode line as part of `mode-line-misc-info`, just after the `which-function-mode` information if that minor mode is enabled, else after `mode-line-modes`. Elements that are added to this construct should normally end in a space (to ensure that consecutive `global-mode-string` elements display properly). For instance, the command `display-time` sets `global-mode-string` to refer to the variable `display-time-string`, which holds a string containing the time and load information.

The '%M' construct substitutes the value of `global-mode-string`. This construct is not used by the default mode line, as the variable itself is used in `mode-line-misc-info`.

Here is a simplified version of the default value of `mode-line-format`. The real default value also specifies addition of text properties.

```
("-"
 mode-line-mule-info
 mode-line-modified
 mode-line-frame-identification
 mode-line-buffer-identification
 " "
 mode-line-position
 (vc-mode vc-mode)
 " "
 mode-line-modes
 (which-function-mode ("" which-func-format "--"))
 (global-mode-string ("--" global-mode-string))
 "-%-")
```

24.4.5 %-Constructs in the Mode Line

Strings used as mode line constructs can use certain %-constructs to substitute various kinds of data. The following is a list of the defined %-constructs, and what they mean.

In any construct except '%%', you can add a decimal integer after the '%' to specify a minimum field width. If the width is less, the field is padded to that width. Purely numeric

constructs ('c', 'i', 'I', and 'l') are padded by inserting spaces to the left, and others are padded by inserting spaces to the right.

%b	The current buffer name, obtained with the <code>buffer-name</code> function. See Section 28.3 [Buffer Names], page 674.
%c	The current column number of point, counting from zero starting at the left margin of the window.
%C	The current column number of point, counting from one starting at the left margin of the window.
%e	When Emacs is nearly out of memory for Lisp objects, a brief message saying so. Otherwise, this is empty.
%f	The visited file name, obtained with the <code>buffer-file-name</code> function. See Section 28.4 [Buffer File Name], page 675.
%F	The title (only on a window system) or the name of the selected frame. See Section 30.4.3.1 [Basic Parameters], page 805.
%i	The size of the accessible part of the current buffer; basically <code>(- (point-max) (point-min))</code> .
%I	Like '%i', but the size is printed in a more readable way by using 'k' for 10^3 , 'M' for 10^6 , 'G' for 10^9 , etc., to abbreviate.
%l	The current line number of point, counting within the accessible portion of the buffer.
%M	The value of <code>global-mode-string</code> (which is part of <code>mode-line-misc-info</code> by default).
%n	'Narrow' when narrowing is in effect; nothing otherwise (see <code>narrow-to-region</code> in Section 31.4 [Narrowing], page 865).
%o	The degree of <i>travel</i> of the window through (the visible portion of) the buffer, i.e. the size of the text above the top of the window expressed as a percentage of all the text outside the window, or 'Top', 'Bottom' or 'All'.
%p	The percentage of the buffer text above the top of window, or 'Top', 'Bottom' or 'All'. Note that the default mode line construct truncates this to three characters.
%P	The percentage of the buffer text that is above the bottom of the window (which includes the text visible in the window, as well as the text above the top), plus 'Top' if the top of the buffer is visible on screen; or 'Bottom' or 'All'.
%q	The percentages of text above both the top and the bottom of the window, separated by '−', or 'All'.
%s	The status of the subprocess belonging to the current buffer, obtained with <code>process-status</code> . See Section 40.6 [Process Information], page 1092.
%z	The mnemonics of keyboard, terminal, and buffer coding systems.
%Z	Like '%z', but including the end-of-line format.

%*	‘%’ if the buffer is read only (see <code>buffer-read-only</code>); ‘*’ if the buffer is modified (see <code>buffer-modified-p</code>); ‘-’ otherwise. See Section 28.5 [Buffer Modification], page 677.
%+	‘*’ if the buffer is modified (see <code>buffer-modified-p</code>); ‘%’ if the buffer is read only (see <code>buffer-read-only</code>); ‘-’ otherwise. This differs from ‘%*’ only for a modified read-only buffer. See Section 28.5 [Buffer Modification], page 677.
%&	‘*’ if the buffer is modified, and ‘-’ otherwise.
%@	‘@’ if the buffer’s <code>default-directory</code> (see Section 26.9.4 [File Name Expansion], page 639) is on a remote machine, and ‘-’ otherwise.
%[An indication of the depth of recursive editing levels (not counting minibuffer levels): one ‘[’ for each editing level. See Section 22.13 [Recursive Editing], page 475.
%]	One ‘]’ for each recursive editing level (not counting minibuffer levels).
%-	Dashes sufficient to fill the remainder of the mode line.
%%	The character ‘%’—this is how to include a literal ‘%’ in a string in which %-constructs are allowed.

Obsolete %-Constructs

The following constructs should no longer be used.

%m	Obsolete; use the <code>mode-name</code> variable instead. The %m construct is inadequate, as it produces an empty string if the value of <code>mode-name</code> is a non-string mode-line construct (as in <code>emacs-lisp-mode</code> , for example).
----	--

24.4.6 Properties in the Mode Line

Certain text properties are meaningful in the mode line. The `face` property affects the appearance of text; the `help-echo` property associates help strings with the text, and `keymap` can make the text mouse-sensitive.

There are four ways to specify text properties for text in the mode line:

1. Put a string with a text property directly into the mode line data structure, but see Section 24.4.2 [Mode Line Data], page 551, for caveats for that.
2. Put a text property on a mode line %-construct such as ‘%12b’; then the expansion of the %-construct will have that same text property.
3. Use a `(:propertize elt props...)` construct to give `elt` a text property specified by `props`.
4. Use a list containing `:eval form` in the mode line data structure, and make `form` evaluate to a string that has a text property.

You can use the `keymap` property to specify a keymap. This keymap only takes real effect for mouse clicks; binding character keys and function keys to it has no effect, since it is impossible to move point into the mode line.

When the mode line refers to a variable which does not have a non-nil `risky-local-variable` property, any text properties given or specified within that variable’s values are

ignored. This is because such properties could otherwise specify functions to be called, and those functions could come from file local variables.

24.4.7 Window Header Lines

A window can have a *header line* at the top, just as it can have a mode line at the bottom. The header line feature works just like the mode line feature, except that it's controlled by `header-line-format`:

header-line-format [Variable]

This variable, local in every buffer, specifies how to display the header line, for windows displaying the buffer. The format of the value is the same as for `mode-line-format` (see Section 24.4.2 [Mode Line Data], page 551). It is normally `nil`, so that ordinary buffers have no header line.

If `display-line-numbers-mode` is turned on in a buffer (see Section “Display Custom” in *The GNU Emacs Manual*), the buffer text is indented on display by the amount of screen space needed to show the line numbers. By contrast, text of the header line is not automatically indented, because a header line never displays a line number, and because the text of the header line is not necessarily directly related to buffer text below it. If a Lisp program needs the header-line text to be aligned with buffer text (for example, if the buffer displays columnar data, like `tabulated-list-mode` does, see Section 24.2.7 [Tabulated List Mode], page 538), it should turn on the minor mode `header-line-indent-mode`.

header-line-indent-mode [Command]

This buffer-local minor mode tracks the changes of the width of the line-number display on screen (which may vary depending on the range of line numbers shown in the window), and allows Lisp programs to arrange that header-line text is always aligned with buffer text when the line-number width changes. Such Lisp programs should turn on this mode in the buffer, and use the variables `header-line-indent` and `header-line-indent-width` in the `header-line-format` to ensure it is adjusted to the text indentation at all times.

header-line-indent [Variable]

This variable's value is a whitespace string whose width is kept equal to the current width of line-numbers on display, provided that `header-line-indent-mode` is turned on in the buffer shown in the window. The number of spaces is calculated under the assumption that the face of the header-line text uses the same font, including size, as the frame's default font; if that assumption is false, use `header-line-indent-width`, described below, instead. This variable is intended to be used in simple situations where the header-line text needs to be indented as a whole to be realigned with buffer text, by prepending this variable's value to the actual header-line text. For example, the following definition of `header-line-format`:

```
(setq header-line-format
      `(" " header-line-indent ,my-header-line))
```

where `my-header-line` is the format string that produces the actual text of the header line, will make sure the header-line text is always indented like the buffer text below it.

header-line-indent-width

[Variable]

This variable's value is kept updated to provide the current width, in units of the frame's canonical character width, used for displaying the line numbers, provided that `header-line-indent-mode` is turned on in the buffer shown in the window. It can be used for aligning the header-line text with the buffer text when `header-line-indent` is not flexible enough. For example, if the header line uses a font whose metrics is different from the default face's font, your Lisp program can calculate the width of line-number display in pixels, by multiplying the value of this variable by the value returned by `frame-char-width` (see Section 30.3.2 [Frame Font], page 797), and then use the result to align header-line text using the `:align-to` display property spec (see Section 41.16.2 [Specified Space], page 1200) in pixels on the relevant parts of `header-line-format`.

window-header-line-height &optional window

[Function]

This function returns the height in pixels of `window`'s header line. `window` must be a live window, and defaults to the selected window.

A window that is just one line tall never displays a header line. A window that is two lines tall cannot display both a mode line and a header line at once; if it has a mode line, then it does not display a header line.

24.4.8 Emulating Mode Line Formatting

You can use the function `format-mode-line` to compute the text that would appear in a mode line or header line based on a certain mode line construct.

format-mode-line format &optional face window buffer

[Function]

This function formats a line of text according to `format` as if it were generating the mode line for `window`, but it also returns the text as a string. The argument `window` defaults to the selected window. If `buffer` is non-`nil`, all the information used is taken from `buffer`; by default, it comes from `window`'s buffer.

The value string normally has text properties that correspond to the faces, keymaps, etc., that the mode line would have. Any character for which no `face` property is specified by `format` gets a default value determined by `face`. If `face` is `t`, that stands for either `mode-line` if `window` is selected, otherwise `mode-line-inactive`. If `face` is `nil` or omitted, that stands for the default face. If `face` is an integer, the value returned by this function will have no text properties.

You can also specify other valid faces as the value of `face`. If specified, that face provides the `face` property for characters whose face is not specified by `format`.

Note that using `mode-line`, `mode-line-inactive`, or `header-line` as `face` will actually redisplay the mode line or the header line, respectively, using the current definitions of the corresponding face, in addition to returning the formatted string. (Other faces do not cause redisplay.)

For example, (`format-mode-line header-line-format`) returns the text that would appear in the selected window's header line (" " if it has no header line). (`format-mode-line header-line-format 'header-line`) returns the same text, with each character carrying the face that it will have in the header line itself, and also redraws the header line.

24.5 Imenu

Imenu is a feature that lets users select a definition or section in the buffer, from a menu which lists all of them, to go directly to that location in the buffer. Imenu works by constructing a buffer index which lists the names and buffer positions of the definitions, or other named portions of the buffer; then the user can choose one of them and move point to it. Major modes can add a menu bar item to use Imenu using `imenu-add-to-menubar`.

imenu-add-to-menubar name [Command]

This function defines a local menu bar item named *name* to run Imenu.

The user-level commands for using Imenu are described in the Emacs Manual (see Section “Imenu” in the *Emacs Manual*). This section explains how to customize Imenu’s method of finding definitions or buffer portions for a particular major mode.

The usual and simplest way is to set the variable `imenu-generic-expression`:

imenu-generic-expression [Variable]

This variable, if non-`nil`, is a list that specifies regular expressions for finding definitions for Imenu. Simple elements of `imenu-generic-expression` look like this:

`(menu-title regexp index)`

Here, if *menu-title* is non-`nil`, it says that the matches for this element should go in a submenu of the buffer index; *menu-title* itself specifies the name for the submenu. If *menu-title* is `nil`, the matches for this element go directly in the top level of the buffer index.

The second item in the list, *regexp*, is a regular expression (see Section 35.3 [Regular Expressions], page 995); anything in the buffer that it matches is considered a definition, something to mention in the buffer index. The third item, *index*, is a non-negative integer that indicates which subexpression in *regexp* matches the definition’s name.

An element can also look like this:

`(menu-title regexp index function arguments...)`

Each match for this element creates an index item, and when the index item is selected by the user, it calls *function* with arguments consisting of the item name, the buffer position, and *arguments*.

For Emacs Lisp mode, `imenu-generic-expression` could look like this:

```
((nil "^\s-*(def\\(un\\|subst\\|macro\\|advice\\)\\
\\s-+\\([-A-Za-z0-9+]+\\)" 2)
 ("*Vars*" "^\s-*(def\\(var\\|const\\)\\
\\s-+\\([-A-Za-z0-9+]+\\)" 2)
 ("*Types*"
  "^\s-*
  (def\\(type\\|struct\\|class\\|ine-condition\\)\\
  \\s-+\\([-A-Za-z0-9+]+\\)" 2))
```

Setting this variable makes it buffer-local in the current buffer.

imenu-case-fold-search [Variable]

This variable controls whether matching against the regular expressions in the value of `imenu-generic-expression` is case-sensitive: `t`, the default, means matching should ignore case.

Setting this variable makes it buffer-local in the current buffer.

imenu-syntax-alist

[Variable]

This variable is an alist of syntax table modifiers to use while processing **imenu-generic-expression**, to override the syntax table of the current buffer. Each element should have this form:

$$(\text{characters} . \text{syntax-description})$$

The CAR, *characters*, can be either a character or a string. The element says to give that character or characters the syntax specified by *syntax-description*, which is passed to **modify-syntax-entry** (see Section 36.3 [Syntax Table Functions], page 1027).

This feature is typically used to give word syntax to characters which normally have symbol syntax, and thus to simplify **imenu-generic-expression** and speed up matching. For example, Fortran mode uses it this way:

$$(\text{setq imenu-syntax-alist '((("_$" . "w"))))}$$

The **imenu-generic-expression** regular expressions can then use ‘\\sw+’ instead of ‘\\(\\sw\\\\|\\s_\\)+’. Note that this technique may be inconvenient when the mode needs to limit the initial character of a name to a smaller set of characters than are allowed in the rest of a name.

Setting this variable makes it buffer-local in the current buffer.

Another way to customize Imenu for a major mode is to set the variables **imenu-prev-index-position-function** and **imenu-extract-index-name-function**:

imenu-prev-index-position-function

[Variable]

If this variable is non-nil, its value should be a function that finds the next definition to put in the buffer index, scanning backward in the buffer from point. It should return nil if it doesn’t find another definition before point. Otherwise it should leave point at the place it finds a definition and return any non-nil value.

Setting this variable makes it buffer-local in the current buffer.

imenu-extract-index-name-function

[Variable]

If this variable is non-nil, its value should be a function to return the name for a definition, assuming point is in that definition as the **imenu-prev-index-position-function** function would leave it.

Setting this variable makes it buffer-local in the current buffer.

The last way to customize Imenu for a major mode is to set the variable **imenu-create-index-function**:

imenu-create-index-function

[Variable]

This variable specifies the function to use for creating a buffer index. The function should take no arguments, and return an index alist for the current buffer. It is called within **save-excursion**, so where it leaves point makes no difference.

The index alist can have three types of elements. Simple elements look like this:

$$(\text{index-name} . \text{index-position})$$

Selecting a simple element has the effect of moving to position *index-position* in the buffer. Special elements look like this:

```
(index-name index-position function arguments...)
```

Selecting a special element performs:

```
(funcall function  
    index-name index-position arguments...)
```

A nested sub-alist element looks like this:

```
(menu-title . sub-alist)
```

It creates the submenu *menu-title* specified by *sub-alist*.

The default value of `imenu-create-index-function` is `imenu-default-create-index-function`. This function calls the value of `imenu-prev-index-position-function` and the value of `imenu-extract-index-name-function` to produce the index alist. However, if either of these two variables is `nil`, the default function uses `imenu-generic-expression` instead.

Setting this variable makes it buffer-local in the current buffer.

If built with tree-sitter, Emacs can automatically generate an Imenu index if the major mode sets relevant variables.

treesit-simple-imenu-settings

[Variable]

This variable instructs Emacs how to generate Imenu indexes. It should be a list of (*category* *regexp* *pred* *name-fn*).

category should be the name of a category, like "Function", "Class", etc. *regexp* should be a regexp matching the type of nodes that belong to *category*. *pred* should be either `nil` or a function that takes a node as the argument. It should return non-`nil` if the node is a valid node for *category*, or `nil` if not.

category could also be `nil`, in which case the entries matched by *regexp* and *pred* are not grouped under *category*.

name-fn should be either `nil` or a function that takes a defun node and returns the name of that defun, e.g., the function name for a function definition. If *name-fn* is `nil`, `treesit-defun-name` (see Section 37.7 [Tree-sitter Major Modes], page 1061) is used instead.

`treesit-major-mode-setup` (see Section 37.7 [Tree-sitter Major Modes], page 1061) automatically sets up Imenu if this variable is non-`nil`.

24.6 Font Lock Mode

Font Lock mode is a buffer-local minor mode that automatically attaches `face` properties to certain parts of the buffer based on their syntactic role. How it parses the buffer depends on the major mode; most major modes define syntactic criteria for which faces to use in which contexts. This section explains how to customize Font Lock for a particular major mode.

Font Lock mode finds text to highlight in three ways: through parsing based on a full-blown parser (usually, via an external library or program), through syntactic parsing based on the Emacs's built-in syntax table, or through searching (usually for regular expressions). If enabled, parser-based fontification happens first (see Section 24.6.10 [Parser-based Font

Lock], page 578). Syntactic fontification happens next; it finds comments and string constants and highlights them. Search-based fontification happens last.

24.6.1 Font Lock Basics

The Font Lock functionality is based on several basic functions. Each of these calls the function specified by the corresponding variable. This indirection allows major and minor modes to modify the way fontification works in the buffers of that mode, and even use the Font Lock mechanisms for features that have nothing to do with fontification. (This is why the description below says “should” when it describes what the functions do: the mode can customize the values of the corresponding variables to do something entirely different.) The variables mentioned below are described in Section 24.6.4 [Other Font Lock Variables], page 571.

`font-lock-fontify-buffer`

This function should fontify the current buffer’s accessible portion, by calling the function specified by `font-lock-fontify-buffer-function`.

`font-lock-unfontify-buffer`

Used when turning Font Lock off to remove the fontification. Calls the function specified by `font-lock-unfontify-buffer-function`.

`font-lock-fontify-region` `beg` `end` &optional `loudly`

Should fontify the region between `beg` and `end`. If `loudly` is non-`nil`, should display status messages while fontifying. Calls the function specified by `font-lock-fontify-region-function`.

`font-lock-unfontify-region` `beg` `end`

Should remove fontification from the region between `beg` and `end`. Calls the function specified by `font-lock-unfontify-region-function`.

`font-lock-flush` &optional `beg` `end`

This function should mark the fontification of the region between `beg` and `end` as outdated. If not specified or `nil`, `beg` and `end` default to the beginning and end of the buffer’s accessible portion. Calls the function specified by `font-lock-flush-function`.

`font-lock-ensure` &optional `beg` `end`

This function should make sure the region between `beg` and `end` has been fontified. The optional arguments `beg` and `end` default to the beginning and the end of the buffer’s accessible portion. Calls the function specified by `font-lock-ensure-function`.

`font-lock-debug-fontify`

This is a convenience command meant to be used when developing font locking for a mode, and should not be called from Lisp code. It recomputes all the relevant variables and then calls `font-lock-fontify-region` on the entire buffer.

There are several variables that control how Font Lock mode highlights text. But major modes should not set any of these variables directly. Instead, they should set `font-lock-defaults` as a buffer-local variable. The value assigned to this variable is used, if and when Font Lock mode is enabled, to set all the other variables.

font-lock-defaults

[Variable]

This variable is set by modes to specify how to fontify text in that mode. It automatically becomes buffer-local when set. If its value is `nil`, Font Lock mode does no highlighting, and you can use the ‘Faces’ menu (under ‘Edit’ and then ‘Text Properties’ in the menu bar) to assign faces explicitly to text in the buffer.

If non-`nil`, the value should look like this:

```
(keywords [keywords-only [case-fold  
[syntax-alist other-vars...]]])
```

The first element, *keywords*, indirectly specifies the value of `font-lock-keywords` which directs search-based fontification. It can be a symbol, a variable or a function whose value is the list to use for `font-lock-keywords`. It can also be a list of several such symbols, one for each possible level of fontification. The first symbol specifies the ‘mode default’ level of fontification, the next symbol level 1 fontification, the next level 2, and so on. The ‘mode default’ level is normally the same as level 1. It is used when `font-lock-maximum-decoration` has a `nil` value. See Section 24.6.5 [Levels of Font Lock], page 572.

The second element, *keywords-only*, specifies the value of the variable `font-lock-keywords-only`. If this is omitted or `nil`, syntactic fontification (of strings and comments) is also performed. If this is non-`nil`, syntactic fontification is not performed. See Section 24.6.8 [Syntactic Font Lock], page 575.

The third element, *case-fold*, specifies the value of `font-lock-keywords-case-fold-search`. If it is non-`nil`, Font Lock mode ignores case during search-based fontification.

If the fourth element, *syntax-alist*, is non-`nil`, it should be a list of cons cells of the form (*char-or-string* . *string*). These are used to set up a syntax table for syntactic fontification; the resulting syntax table is stored in `font-lock-syntax-table`. If *syntax-alist* is omitted or `nil`, syntactic fontification uses the syntax table returned by the `syntax-table` function. See Section 36.3 [Syntax Table Functions], page 1027.

All the remaining elements (if any) are collectively called *other-vars*. Each of these elements should have the form (*variable* . *value*)—which means, make *variable* buffer-local and then set it to *value*. You can use these *other-vars* to set other variables that affect fontification, aside from those you can control with the first five elements. See Section 24.6.4 [Other Font Lock Variables], page 571.

If your mode fontifies text explicitly by adding `font-lock-face` properties, it can specify (`nil t`) for `font-lock-defaults` to turn off all automatic fontification. However, this is not required; it is possible to fontify some things using `font-lock-face` properties and set up automatic fontification for other parts of the text.

24.6.2 Search-based Fontification

The variable which directly controls search-based fontification is `font-lock-keywords`, which is typically specified via the *keywords* element in `font-lock-defaults`.

font-lock-keywords

[Variable]

The value of this variable is a list of the keywords to highlight. Lisp programs should not set this variable directly. Normally, the value is automatically set by Font Lock mode, using the *keywords* element in `font-lock-defaults`. The value can also be altered

using the functions `font-lock-add-keywords` and `font-lock-remove-keywords` (see Section 24.6.3 [Customizing Keywords], page 569).

Each element of `font-lock-keywords` specifies how to find certain cases of text, and how to highlight those cases. Font Lock mode processes the elements of `font-lock-keywords` one by one, and for each element, it finds and handles all matches. Ordinarily, once part of the text has been fontified already, this cannot be overridden by a subsequent match in the same text; but you can specify different behavior using the `override` element of a `subexp-highlighter`.

Each element of `font-lock-keywords` should have one of these forms:

`regexp` Highlight all matches for `regexp` using `font-lock-keyword-face`. For example,

```
;; Highlight occurrences of the word 'foo'  
;; using font-lock-keyword-face.  
"\\"<foo\\>"
```

Be careful when composing these regular expressions; a poorly written pattern can dramatically slow things down! The function `regexp-opt` (see Section 35.3.3 [Regexp Functions], page 1005) is useful for calculating optimal regular expressions to match several keywords.

`function` Find text by calling `function`, and highlight the matches it finds using `font-lock-keyword-face`.

When `function` is called, it receives one argument, the limit of the search; it should begin searching at point, and not search beyond the limit. It should return `non-nil` if it succeeds, and set the match data to describe the match that was found. Returning `nil` indicates failure of the search.

Fontification will call `function` repeatedly with the same limit, and with point where the previous invocation left it, until `function` fails. On failure, `function` need not reset point in any particular way.

`(matcher . subexp)`

In this kind of element, `matcher` is either a regular expression or a function, as described above. The CDR, `subexp`, specifies which subexpression of `matcher` should be highlighted (instead of the entire text that `matcher` matched).

```
;; Highlight the 'bar' in each occurrence of 'fubar';  
;; using font-lock-keyword-face.  
("fu\\(bar\\)" . 1)
```

`(matcher . facespec)`

In this kind of element, `facespec` is an expression whose value specifies the face to use for highlighting. In the simplest case, `facespec` is a Lisp variable (a symbol) whose value is a face name.

```
;; Highlight occurrences of 'fubar',  
;; using the face which is the value of fubar-face.  
("fubar" . fubar-face)
```

However, `facespec` can also evaluate to a list of this form:

`(subexp`

```
(face face prop1 val1 prop2 val2...))
```

to specify the face *face* and various additional text properties to put on the text that matches. If you do this, be sure to add the other text property names that you set in this way to the value of `font-lock-extra-managed-props` so that the properties will also be cleared out when they are no longer appropriate. Alternatively, you can set the variable `font-lock-unfontify-region-function` to a function that clears these properties. See Section 24.6.4 [Other Font Lock Variables], page 571.

(*matcher* . *subexp-highlighter*)

In this kind of element, *subexp-highlighter* is a list which specifies how to highlight matches found by *matcher*. It has the form:

```
(subexp facespec [override [laxmatch]])
```

The CAR, *subexp*, is an integer specifying which subexpression of the match to fontify (0 means the entire matching text). The second subelement, *facespec*, is an expression whose value specifies the face, as described above.

The last two values in *subexp-highlighter*, *override* and *laxmatch*, are optional flags. If *override* is `t`, this element can override existing fontification made by previous elements of `font-lock-keywords`. If it is `keep`, then each character is fontified if it has not been fontified already by some other element. If it is `prepend`, the face specified by *facespec* is added to the beginning of the `font-lock-face` property. If it is `append`, the face is added to the end of the `font-lock-face` property.

If *laxmatch* is non-`nil`, it means there should be no error if there is no subexpression numbered *subexp* in *matcher*. Obviously, fontification of the subexpression numbered *subexp* will not occur. However, fontification of other subexpressions (and other regexps) will continue. If *laxmatch* is `nil`, and the specified subexpression is missing, then an error is signaled which terminates search-based fontification.

Here are some examples of elements of this kind, and what they do:

```
;; Highlight occurrences of either 'foo' or 'bar', using
;; foo-bar-face, even if they have already been highlighted.
;; foo-bar-face should be a variable whose value is a face.
("foo\\|bar" 0 foo-bar-face t)
```

```
;; Highlight the first subexpression within each occurrence
;; that the function fubar-match finds,
;; using the face which is the value of fubar-face.
(fubar-match 1 fubar-face)
```

(*matcher* . *anchored-highlighter*)

In this kind of element, *anchored-highlighter* specifies how to highlight text that follows a match found by *matcher*. So a match found by *matcher* acts as the anchor for further searches specified by *anchored-highlighter*. *anchored-highlighter* is a list of the following form:

```
(anchored-matcher pre-form post-form subexp-highlighters...)
```

Here, *anchored-matcher*, like *matcher*, is either a regular expression or a function. After a match of *matcher* is found, point is at the end of the match. Now, Font

Lock evaluates the form *pre-form*. Then it searches for matches of *anchored-matcher* and uses *subexp-highlighters* to highlight these. A *subexp-highlighter* is as described above. Finally, Font Lock evaluates *post-form*.

The forms *pre-form* and *post-form* can be used to initialize before, and cleanup after, *anchored-matcher* is used. Typically, *pre-form* is used to move point to some position relative to the match of *matcher*, before starting with *anchored-matcher*. *post-form* might be used to move back, before resuming with *matcher*.

After Font Lock evaluates *pre-form*, it does not search for *anchored-matcher* beyond the end of the line. However, if *pre-form* returns a buffer position that is greater than the position of point after *pre-form* is evaluated, then the position returned by *pre-form* is used as the limit of the search instead. It is generally a bad idea to return a position greater than the end of the line; in other words, the *anchored-matcher* search should not span lines.

For example,

```
;; Highlight occurrences of the word ‘item’ following
;; an occurrence of the word ‘anchor’ (on the same line)
;; in the value of item-face.
("\\\\<anchor\\\\>" "\\\<item\\\\>" nil nil (0 item-face))
```

Here, *pre-form* and *post-form* are *nil*. Therefore searching for ‘item’ starts at the end of the match of ‘anchor’, and searching for subsequent instances of ‘anchor’ resumes from where searching for ‘item’ concluded.

(*matcher highlighters...*)

This sort of element specifies several *highlighter* lists for a single *matcher*. A *highlighter* list can be of the type *subexp-highlighter* or *anchored-highlighter* as described above.

For example,

```
;; Highlight occurrences of the word ‘anchor’ in the value
;; of anchor-face, and subsequent occurrences of the word
;; ‘item’ (on the same line) in the value of item-face.
("\\\\<anchor\\\\>" (0 anchor-face)
 ("\\\\<item\\\\>" nil nil (0 item-face)))
```

(*eval . form*)

Here *form* is an expression to be evaluated the first time this value of *font-lock-keywords* is used in a buffer. Its value should have one of the forms described in this table.

Warning: Do not design an element of *font-lock-keywords* to match text which spans lines; this does not work reliably. For details, see Section 24.6.9 [Multiline Font Lock], page 576.

You can use *case-fold* in *font-lock-defaults* to specify the value of *font-lock-keywords-case-fold-search* which says whether search-based fontification should be case-insensitive.

font-lock-keywords-case-fold-search

[Variable]

Non-*nil* means that regular expression matching for the sake of *font-lock-keywords* should be case-insensitive.

24.6.3 Customizing Search-Based Fontification

You can use `font-lock-add-keywords` to add additional search-based fontification rules to a major mode, and `font-lock-remove-keywords` to remove rules. You can also customize the `font-lock-ignore` option to selectively disable fontification rules for keywords that match certain criteria.

`font-lock-add-keywords mode keywords &optional how` [Function]

This function adds highlighting `keywords`, for the current buffer or for major mode `mode`. The argument `keywords` should be a list with the same format as the variable `font-lock-keywords`.

If `mode` is a symbol which is a major mode command name, such as `c-mode`, the effect is that enabling Font Lock mode in `mode` will add `keywords` to `font-lock-keywords`. Calling with a non-`nil` value of `mode` is correct only in your `~/.emacs` file.

If `mode` is `nil`, this function adds `keywords` to `font-lock-keywords` in the current buffer. This way of calling `font-lock-add-keywords` is usually used in mode hook functions.

By default, `keywords` are added at the beginning of `font-lock-keywords`. If the optional argument `how` is `set`, they are used to replace the value of `font-lock-keywords`. If `how` is any other non-`nil` value, they are added at the end of `font-lock-keywords`.

Some modes provide specialized support you can use in additional highlighting patterns. See the variables `c-font-lock-extra-types`, `c++-font-lock-extra-types`, and `java-font-lock-extra-types`, for example.

Warning: Major mode commands must not call `font-lock-add-keywords` under any circumstances, either directly or indirectly, except through their mode hooks. (Doing so would lead to incorrect behavior for some minor modes.) They should set up their rules for search-based fontification by setting `font-lock-keywords`.

`font-lock-remove-keywords mode keywords` [Function]

This function removes `keywords` from `font-lock-keywords` for the current buffer or for major mode `mode`. As in `font-lock-add-keywords`, `mode` should be a major mode command name or `nil`. All the caveats and requirements for `font-lock-add-keywords` apply here too. The argument `keywords` must exactly match the one used by the corresponding `font-lock-add-keywords`.

For example, the following code adds two fontification patterns for C mode: one to fontify the word ‘`FIXME`’, even in comments, and another to fontify the words ‘`and`’, ‘`or`’ and ‘`not`’ as keywords.

```
(font-lock-add-keywords 'c-mode
  '(("\\\<\\((FIXME\\):" 1 font-lock-warning-face prepend)
    ("\\\<\\(and\\|or\\|not\\)\\\\>" . font-lock-keyword-face)))
```

This example affects only C mode proper. To add the same patterns to C mode *and* all modes derived from it, do this instead:

```
(add-hook 'c-mode-hook
  (lambda ()
    (font-lock-add-keywords nil
      '(("\\\<\\((FIXME\\):" 1 font-lock-warning-face prepend)
```

```
("\\"<\\(and\\|or\\|not\\)\\>" .
  font-lock-keyword-face))))
```

font-lock-ignore

[User Option]

This option defines conditions for selectively disabling fontifications due to certain Font Lock keywords. If non-**nil**, its value is a list of elements of the following form:

```
(symbol condition ...)
```

Here, *symbol* is a symbol, usually a major or minor mode. The subsequent *conditions* of a *symbol*'s list element will be in effect if *symbol* is bound and its value is non-**nil**. For a mode's symbol, it means that the current major mode is derived from that mode, or that minor mode is enabled in the buffer. When a *condition* is in effect, any fontifications caused by **font-lock-keywords** elements that match the *condition* will be disabled.

Each *condition* can be one of the following:

a symbol This condition matches any element of Font Lock keywords that references the symbol. This is usually a face, but can be any symbol referenced by an element of the **font-lock-keywords** list. The symbol can contain wildcards: ***** matches any string in the symbol's name, **?** matches a single character, and **[char-set]**, where *char-set* is a string of one or more characters, matches a single character from the set.

a string This condition matches any element of Font Lock keywords whose *matcher* is a regexp which matches the string. In other words, this condition matches a Font Lock rule which highlights the string. Thus, the string could be a specific program keyword whose highlighting you want to disable.

(pred function)

This condition matches any element of Font Lock keywords for which *function*, when called with the element as the argument, returns non-**nil**.

(not condition)

This matches if *condition* doesn't.

(and condition ...)

This matches if each of the *conditions* matches.

(or condition ...)

This matches if at least one of the *conditions* matches.

(except condition)

This condition can only be used at top level or inside an **or** clause. It undoes the effect of a previously matching condition on the same level.

As an example, consider the following setting:

```
(setq font-lock-ignore
  '((prog-mode font-lock-*-face
            (except help-echo))
    (emacs-lisp-mode (except ";;###autoload"))
    (whitespace-mode whitespace-empty-at-bob-regexp)
    (makefile-mode (except *))))
```

Line by line, this does the following:

1. In all programming modes, disable fontifications due to all font-lock keywords that apply one of the standard font-lock faces (excluding strings and comments, which are covered by syntactic Font Lock).
2. However, keep any keywords that add a `help-echo` text property.
3. In Emacs Lisp mode, also keep the highlighting of autoload cookies, which would have been excluded by the first condition.
4. When `whitespace-mode` (a minor mode) is enabled, also don't highlight an empty line at beginning of buffer.
5. Finally, in Makefile mode, don't apply any conditions.

24.6.4 Other Font Lock Variables

This section describes additional variables that a major mode can set by means of `other-vars` in `font-lock-defaults` (see Section 24.6.1 [Font Lock Basics], page 564).

font-lock-mark-block-function

[Variable]

If this variable is non-`nil`, it should be a function that is called with no arguments, to choose an enclosing range of text for refontification for the command `M-x font-lock-fontify-block`.

The function should report its choice by placing the region around it. A good choice is a range of text large enough to give proper results, but not too large so that refontification becomes slow. Typical values are `mark-defun` for programming modes or `mark-paragraph` for textual modes.

font-lock-extra-managed-props

[Variable]

This variable specifies additional properties (other than `font-lock-face`) that are being managed by Font Lock mode. It is used by `font-lock-default-unfontify-region`, which normally only manages the `font-lock-face` property. If you want Font Lock to manage other properties as well, you must specify them in a `facespec` in `font-lock-keywords` as well as add them to this list. See Section 24.6.2 [Search-based Fontification], page 565.

font-lock-fontify-buffer-function

[Variable]

Function to use for fontifying the buffer. The default value is `font-lock-default-fontify-buffer`.

font-lock-unfontify-buffer-function

[Variable]

Function to use for unfontifying the buffer. This is used when turning off Font Lock mode. The default value is `font-lock-default-unfontify-buffer`.

font-lock-fontify-region-function

[Variable]

Function to use for fontifying a region. It should take two arguments, the beginning and end of the region, and an optional third argument `verbose`. If `verbose` is non-`nil`, the function should print status messages. The default value is `font-lock-default-fontify-region`.

font-lock-unfontify-region-function

[Variable]

Function to use for unfontifying a region. It should take two arguments, the beginning and end of the region. The default value is `font-lock-default-unfontify-region`.

font-lock-flush-function [Variable]

Function to use for declaring that a region's fontification is out of date. It takes two arguments, the beginning and end of the region. The default value of this variable is `font-lock-after-change-function`.

font-lock-ensure-function [Variable]

Function to use for making sure a region of the current buffer has been fontified. It is called with two arguments, the beginning and end of the region. The default value of this variable is a function that calls `font-lock-default-fontify-buffer` if the buffer is not fontified; the effect is to make sure the entire accessible portion of the buffer is fontified.

jit-lock-register function &optional contextual [Function]

This function tells Font Lock mode to run the Lisp function *function* any time it has to fontify or refontify part of the current buffer. It calls *function* before calling the default fontification functions, and gives it two arguments, *start* and *end*, which specify the region to be fontified or refontified. If *function* performs fontifications, it can return a list of the form `(jit-lock-bounds beg . end)`, to indicate the bounds of the region it actually fontified; Just-In-Time (a.k.a. “JIT”) font-lock will use this information to optimize subsequent redisplay cycles and regions of buffer text it will pass to future calls to *function*.

The optional argument *contextual*, if non-`nil`, forces Font Lock mode to always refontify a syntactically relevant part of the buffer, and not just the modified lines. This argument can usually be omitted.

When Font Lock is activated in a buffer, it calls this function with a non-`nil` value of *contextual* if the value of `font-lock-keywords-only` (see Section 24.6.8 [Syntactic Font Lock], page 575) is `nil`.

jit-lock-unregister function [Function]

If *function* was previously registered as a fontification function using `jit-lock-register`, this function unregisters it.

jit-lock-debug-mode &optional arg [Command]

This is a minor mode whose purpose is to help in debugging code that is run by JIT font-lock. When this mode is enabled, most of the code that JIT font-lock normally runs during redisplay cycles, where Lisp errors are suppressed, is instead run by a timer. Thus, this mode allows using debugging aids such as `debug-on-error` (see Section 19.1.1 [Error Debugging], page 333) and Edebug (see Section 19.2 [Edebug], page 344) for finding and fixing problems in font-lock code and any other code run by JIT font-lock. Another command that could be useful when developing and debugging font-lock is `font-lock-debug-fontify`, see Section 24.6.1 [Font Lock Basics], page 564.

24.6.5 Levels of Font Lock

Some major modes offer three different levels of fontification. You can define multiple levels by using a list of symbols for *keywords* in `font-lock-defaults`. Each symbol specifies one level of fontification; it is up to the user to choose one of these levels, normally by setting

`font-lock-maximum-decoration` (see Section “Font Lock” in the *GNU Emacs Manual*). The chosen level’s symbol value is used to initialize `font-lock-keywords`.

Here are the conventions for how to define the levels of fontification:

- Level 1: highlight function declarations, file directives (such as include or import directives), strings and comments. The idea is speed, so only the most important and top-level components are fontified.
- Level 2: in addition to level 1, highlight all language keywords, including type names that act like keywords, as well as named constant values. The idea is that all keywords (either syntactic or semantic) should be fontified appropriately.
- Level 3: in addition to level 2, highlight the symbols being defined in function and variable declarations, and all builtin function names, wherever they appear.

24.6.6 Precalculated Fontification

Some major modes such as `list-buffers` and `occur` construct the buffer text programmatically. The easiest way for them to support Font Lock mode is to specify the faces of text when they insert the text in the buffer.

The way to do this is to specify the faces in the text with the special text property `font-lock-face` (see Section 33.19.4 [Special Properties], page 924). When Font Lock mode is enabled, this property controls the display, just like the `face` property. When Font Lock mode is disabled, `font-lock-face` has no effect on the display.

It is ok for a mode to use `font-lock-face` for some text and also use the normal Font Lock machinery. But if the mode does not use the normal Font Lock machinery, it should not set the variable `font-lock-defaults`. In this case the `face` property will not be overridden, so using the `face` property could work too. However, using `font-lock-face` is generally preferable as it allows the user to control the fontification by toggling `font-lock-mode`, and lets the code work regardless of whether the mode uses Font Lock machinery or not.

24.6.7 Faces for Font Lock

Font Lock mode can highlight using any face, but Emacs defines several faces specifically for Font Lock to use to highlight text. These *Font Lock faces* are listed below. They can also be used by major modes for syntactic highlighting outside of Font Lock mode (see Section 24.2.1 [Major Mode Conventions], page 528).

Each of these symbols is both a face name, and a variable whose default value is the symbol itself. Thus, the default value of `font-lock-comment-face` is `font-lock-comment-face`.

The faces are listed with descriptions of their typical usage, and in order of greater to lesser prominence. If a mode’s syntactic categories do not fit well with the usage descriptions, the faces can be assigned using the ordering as a guide.

`font-lock-warning-face`

for a construct that is peculiar (e.g., an unescaped confusable quote in an Emacs Lisp symbol like ‘‘foo’), or that greatly changes the meaning of other text, like ‘;; ;###autoload’ in Emacs Lisp and ‘#error’ in C.

`font-lock-function-name-face`

for the name of a function being defined or declared.

font-lock-function-call-face
for the name of a function being called. This face inherits, by default, from **font-lock-function-name-face**.

font-lock-variable-name-face
for the name of a variable being defined or declared.

font-lock-variable-use-face
for the name of a variable being referenced. This face inherits, by default, from **font-lock-variable-name-face**.

font-lock-keyword-face
for a keyword with special syntactic significance, like ‘`for`’ and ‘`if`’ in C.

font-lock-comment-face
for comments.

font-lock-comment-delimiter-face
for comments delimiters, like ‘`/*`’ and ‘`*/`’ in C. On most terminals, this inherits from **font-lock-comment-face**.

font-lock-type-face
for the names of user-defined data types.

font-lock-constant-face
for the names of constants, like ‘`NULL`’ in C.

font-lock-builtin-face
for the names of built-in functions.

font-lock-preprocessor-face
for preprocessor commands. This inherits, by default, from **font-lock-builtin-face**.

font-lock-string-face
for string constants.

font-lock-doc-face
for documentation embedded in program code inside specially-formed comments or strings. This face inherits, by default, from **font-lock-string-face**.

font-lock-doc-markup-face
for mark-up elements in text using **font-lock-doc-face**. It is typically used for the mark-up constructs in documentation embedded in program code, following conventions such as Haddock, Javadoc or Doxygen. This face inherits, by default, from **font-lock-constant-face**.

font-lock-negation-char-face
for easily-overlooked negation characters.

font-lock-escape-face
for escape sequences in strings. This face inherits, by default, from **font-lock-regexp-grouping-backslash**.

Here is an example in Python, where the escape sequence `\n` is used:

```
print('Hello world!\n')
```

font-lock-number-face
for numbers.

font-lock-operator-face
for operators.

font-lock-property-name-face
for properties of an object, such as the declaration of fields in a struct. This face inherits, by default, from **font-lock-variable-name-face**.

font-lock-property-use-face
for properties of an object, such as use of fields in a struct. This face inherits, by default, from **font-lock-property-name-face**.

For example,

```
typedef struct
{
    int prop;
    // ^ property
} obj;

int main()
{
    obj o;
    o.prop = 3;
    // ^ property
}
```

font-lock-punctuation-face
for punctuation such as brackets and delimiters.

font-lock-bracket-face
for brackets (e.g., (), [], {}). This face inherits, by default, from **font-lock-punctuation-face**.

font-lock-delimiter-face
for delimiters (e.g., ;, :, ,). This face inherits, by default, from **font-lock-punctuation-face**.

font-lock-misc-punctuation-face
for punctuation that is not a bracket or delimiter. This face inherits, by default, from **font-lock-punctuation-face**.

24.6.8 Syntactic Font Lock

Syntactic fontification uses a syntax table (see Chapter 36 [Syntax Tables], page 1022) to find and highlight syntactically relevant text. If enabled, it runs prior to search-based fontification. The variable **font-lock-syntactic-face-function**, documented below, determines which syntactic constructs to highlight. There are several variables that affect syntactic fontification; you should set them by means of **font-lock-defaults** (see Section 24.6.1 [Font Lock Basics], page 564).

Whenever Font Lock mode performs syntactic fontification on a stretch of text, it first calls the function specified by **syntax-propertize-function**. Major modes can use this to apply **syntax-table** text properties to override the buffer's syntax table in special cases. See Section 36.4 [Syntax Properties], page 1029.

font-lock-keywords-only [Variable]

If the value of this variable is `non-nil`, Font Lock does not do syntactic fontification, only search-based fontification based on `font-lock-keywords`. It is normally set by Font Lock mode based on the `keywords-only` element in `font-lock-defaults`. If the value is `nil`, Font Lock will call `jit-lock-register` (see Section 24.6.4 [Other Font Lock Variables], page 571) to set up for automatic refontification of buffer text following a modified line to reflect the new syntactic context due to the change.

To use only syntactic fontification, this variable should be `non-nil`, while `font-lock-keywords` should be set to `nil` (see Section 24.6.1 [Font Lock Basics], page 564).

font-lock-syntax-table [Variable]

This variable holds the syntax table to use for fontification of comments and strings. It is normally set by Font Lock mode based on the `syntax-alist` element in `font-lock-defaults`. If this value is `nil`, syntactic fontification uses the buffer’s syntax table (the value returned by the function `syntax-table`; see Section 36.3 [Syntax Table Functions], page 1027).

font-lock-syntactic-face-function [Variable]

If this variable is `non-nil`, it should be a function to determine which face to use for a given syntactic element (a string or a comment).

The function is called with one argument, the parse state at point returned by `parse-partial-sexp`, and should return a face. The default value returns `font-lock-comment-face` for comments and `font-lock-string-face` for strings (see Section 24.6.7 [Faces for Font Lock], page 573).

This variable is normally set through the “other” elements in `font-lock-defaults`:

```
(setq-local font-lock-defaults
  `(
    ,(python-font-lock-keywords
      nil nil nil nil
      (font-lock-syntactic-face-function
        . python-font-lock-syntactic-face-function))))
```

24.6.9 Multiline Font Lock Constructs

Normally, elements of `font-lock-keywords` should not match across multiple lines; that doesn’t work reliably, because Font Lock usually scans just part of the buffer, and it can miss a multi-line construct that crosses the line boundary where the scan starts. (The scan normally starts at the beginning of a line.)

Making elements that match multiline constructs work properly has two aspects: correct *identification* and correct *rehighlighting*. The first means that Font Lock finds all multiline constructs. The second means that Font Lock will correctly rehighlight all the relevant text when a multiline construct is changed—for example, if some of the text that was previously part of a multiline construct ceases to be part of it. The two aspects are closely related, and often getting one of them to work will appear to make the other also work. However, for reliable results you must attend explicitly to both aspects.

There are three ways to ensure correct identification of multiline constructs:

- Add a function to `font-lock-extend-region-functions` that does the *identification* and extends the scan so that the scanned text never starts or ends in the middle of a multiline construct.

- Use the `font-lock-fontify-region-function` hook similarly to extend the scan so that the scanned text never starts or ends in the middle of a multiline construct.
- Somehow identify the multiline construct right when it gets inserted into the buffer (or at any point after that but before font-lock tries to highlight it), and mark it with a `font-lock-multiline` which will instruct font-lock not to start or end the scan in the middle of the construct.

There are several ways to do rehighlighting of multiline constructs:

- Place a `font-lock-multiline` property on the construct. This will rehighlight the whole construct if any part of it is changed. In some cases you can do this automatically by setting the `font-lock-multiline` variable, which see.
- Make sure `jit-lock-contextually` is set and rely on it doing its job. This will only rehighlight the part of the construct that follows the actual change, and will do it after a short delay. This only works if the highlighting of the various parts of your multiline construct never depends on text in subsequent lines. Since `jit-lock-contextually` is activated by default, this can be an attractive solution.
- Place a `jit-lock-defer-multiline` property on the construct. This works only if `jit-lock-contextually` is used, and with the same delay before rehighlighting, but like `font-lock-multiline`, it also handles the case where highlighting depends on subsequent lines.
- If parsing the *syntax* of a construct depends on it being parsed in one single chunk, you can add the `syntax-multiline` text property over the construct in question. The most common use for this is when the syntax property to apply to ‘FOO’ depend on some later text ‘BAR’: By placing this text property over the whole of ‘FOO...BAR’, you make sure that any change of ‘BAR’ will also cause the syntax property of ‘FOO’ to be recomputed. Note: For this to work, the mode needs to add `syntax-propertize-multiline` to `syntax-propertize-extend-region-functions`.

24.6.9.1 Font Lock Multiline

One way to ensure reliable rehighlighting of multiline Font Lock constructs is to put on them the text property `font-lock-multiline`. It should be present and non-nil for text that is part of a multiline construct.

When Font Lock is about to highlight a range of text, it first extends the boundaries of the range as necessary so that they do not fall within text marked with the `font-lock-multiline` property. Then it removes any `font-lock-multiline` properties from the range, and highlights it. The highlighting specification (mostly `font-lock-keywords`) must reinstall this property each time, whenever it is appropriate.

Warning: don’t use the `font-lock-multiline` property on large ranges of text, because that will make rehighlighting slow.

`font-lock-multiline` [Variable]

If the `font-lock-multiline` variable is set to `t`, Font Lock will try to add the `font-lock-multiline` property automatically on multiline constructs. This is not a universal solution, however, since it slows down Font Lock somewhat. It can miss some multiline constructs, or make the property larger or smaller than necessary.

For elements whose *matcher* is a function, the function should ensure that submatch 0 covers the whole relevant multiline construct, even if only a small subpart will be highlighted. It is often just as easy to add the `font-lock-multiline` property by hand.

The `font-lock-multiline` property is meant to ensure proper refontification; it does not automatically identify new multiline constructs. Identifying them requires that Font Lock mode operate on large enough chunks at a time. This will happen by accident on many cases, which may give the impression that multiline constructs magically work. If you set the `font-lock-multiline` variable `non-nil`, this impression will be even stronger, since the highlighting of those constructs which are found will be properly updated from then on. But that does not work reliably.

To find multiline constructs reliably, you must either manually place the `font-lock-multiline` property on the text before Font Lock mode looks at it, or use `font-lock-fontify-region-function`.

24.6.9.2 Region to Fontify after a Buffer Change

When a buffer is changed, the region that Font Lock refontifies is by default the smallest sequence of whole lines that spans the change. While this works well most of the time, sometimes it doesn't—for example, when a change alters the syntactic meaning of text on an earlier line.

You can enlarge (or even reduce) the region to refontify by setting the following variable:

`font-lock-extend-after-change-region-function` [Variable]

This buffer-local variable is either `nil` or a function for Font Lock mode to call to determine the region to scan and fontify.

The function is given three parameters, the standard `beg`, `end`, and `old-len` from `after-change-functions` (see Section 33.34 [Change Hooks], page 961). It should return either a cons of the beginning and end buffer positions (in that order) of the region to fontify, or `nil` (which means choose the region in the standard way). This function needs to preserve point, the match-data, and the current restriction. The region it returns may start or end in the middle of a line.

Since this function is called after every buffer change, it should be reasonably fast.

24.6.10 Parser-based Font Lock

Besides simple syntactic font lock and regexp-based font lock, Emacs also provides complete syntactic font lock with the help of a parser. Currently, Emacs uses the tree-sitter library (see Chapter 37 [Parsing Program Source], page 1039) for this purpose.

Parser-based font lock and other font lock mechanisms are not mutually exclusive. By default, if enabled, parser-based font lock runs first, replacing syntactic font lock, followed by regexp-based font lock.

Although parser-based font lock doesn't share the same customization variables with regexp-based font lock, it uses similar customization schemes. The tree-sitter counterpart of `font-lock-keywords` is `treesit-font-lock-settings`.

In general, tree-sitter fontification works as follows:

- A Lisp program (usually, part of a major mode) provides a *query* consisting of *patterns*, each pattern associated with a *capture name*.
- The tree-sitter library finds the nodes in the parse tree that match these patterns, tags the nodes with the corresponding capture names, and returns them to the Lisp program.
- The Lisp program uses the returned nodes to highlight the portions of buffer text corresponding to each node as appropriate, using the tagged capture names of the nodes to determine the correct fontification. For example, a node tagged `font-lock-keyword` would be highlighted in `font-lock-keyword` face.

For more information about queries, patterns, and capture names, see Section 37.5 [Pattern Matching], page 1052.

To set up tree-sitter fontification, a major mode should first set `treesit-font-lock-settings` with the output of `treesit-font-lock-rules`, then call `treesit-major-mode-setup`.

`treesit-font-lock-rules &rest query-specs` [Function]

This function is used to set `treesit-font-lock-settings`. It takes care of compiling queries and other post-processing, and outputs a value that `treesit-font-lock-settings` accepts. Here's an example:

```
(treesit-font-lock-rules
  :language 'javascript
  :feature 'constant
  :override t
  '((true) @font-lock-constant-face
    (false) @font-lock-constant-face)
  :language 'html
  :feature 'script
  "(script_element) @font-lock-builtin-face")
```

This function takes a series of *query-specs*, where each *query-spec* is a *query* preceded by one or more *keyword/value* pairs. Each *query* is a tree-sitter query in either the string, s-expression, or compiled form.

For each *query*, the *keyword/value* pairs that precede it add meta information to it. The `:language` keyword declares *query*'s language. The `:feature` keyword sets the feature name of *query*. Users can control which features are enabled with `treesit-font-lock-level` and `treesit-font-lock-feature-list` (described below). These two keywords are mandatory.

Other keywords are optional:

Keyword	Value	Description
<code>:override</code>	<code>nil</code>	If the region already has a face, discard the new face
	<code>t</code>	Always apply the new face
	<code>append</code>	Append the new face to existing ones
	<code>prepend</code>	Prepend the new face to existing ones
	<code>keep</code>	Fill-in regions without an existing face

Lisp programs mark patterns in *query* with capture names (names that start with `@`), and tree-sitter will return matched nodes tagged with those same capture names.

For the purpose of fontification, capture names in *query* should be face names like `font-lock-keyword-face`. The captured node will be fontified with that face.

A capture name can also be a function name, in which case the function is called with 4 arguments: *node* and *override*, *start* and *end*, where *node* is the node itself, *override* is the `:override` property of the rule which captured this node, and *start* and *end* limit the region which this function should fontify. (If this function wants to respect the *override* argument, it can use `treesit-fontify-with-override`.)

Beyond the 4 arguments presented, this function should accept more arguments as optional arguments for future extensibility.

If a capture name is both a face and a function, the face takes priority. If a capture name is neither a face nor a function, it is ignored.

`treesit-font-lock-feature-list` [Variable]

This is a list of lists of feature symbols. Each element of the list is a list that represents a decoration level. `treesit-font-lock-level` controls which levels are activated.

Each element of the list is a list of the form `(feature ...)`, where each *feature* corresponds to the `:feature` value of a query defined in `treesit-font-lock-rules`. Removing a feature symbol from this list disables the corresponding query during font-lock.

Common feature names, for many programming languages, include `definition`, `type`, `assignment`, `builtin`, `constant`, `keyword`, `string-interpolation`, `comment`, `doc`, `string`, `operator`, `preprocessor`, `escape-sequence`, and `key`. Major modes are free to subdivide or extend these common features.

Some of these features warrant some explanation: `definition` highlights whatever is being defined, e.g., the function name in a function definition, the struct name in a struct definition, the variable name in a variable definition; `assignment` highlights whatever is being assigned to, e.g., the variable or field in an assignment statement; `key` highlights keys in key-value pairs, e.g., keys in a JSON object or Python dictionary; `doc` highlights docstrings or doc-comments.

For example, the value of this variable could be:

```
((comment string doc) ; level 1
  (function-name keyword type builtin constant) ; level 2
  (variable-name string-interpolation key)) ; level 3
```

Major modes should set this variable before calling `treesit-major-mode-setup`.

For this variable to take effect, a Lisp program should call `treesit-font-lock-recompute-features` (which resets `treesit-font-lock-settings` accordingly), or `treesit-major-mode-setup` (which calls `treesit-font-lock-recompute-features`).

`treesit-font-lock-settings` [Variable]

A list of settings for tree-sitter based font lock. The exact format of each setting is considered internal. One should always use `treesit-font-lock-rules` to set this variable.

Multi-language major modes should provide range functions in `treesit-range-functions`, and Emacs will set the ranges accordingly before fontifying a region (see Section 37.6 [Multiple Languages], page 1057).

24.7 Automatic Indentation of code

For programming languages, an important feature of a major mode is to provide automatic indentation. There are two parts: one is to decide what is the right indentation of a line, and the other is to decide when to reindent a line. By default, Emacs reindents a line whenever you type a character in `electric-indent-chars`, which by default only includes Newline. Major modes can add chars to `electric-indent-chars` according to the syntax of the language.

Deciding what is the right indentation is controlled in Emacs by `indent-line-function` (see Section 33.17.2 [Mode-Specific Indent], page 911). For some modes, the *right* indentation cannot be known reliably, typically because indentation is significant so several indentations are valid but with different meanings. In that case, the mode should set `electric-indent-inhibit` to make sure the line is not constantly re-indented against the user's wishes.

Writing a good indentation function can be difficult and to a large extent it is still a black art. Many major mode authors will start by writing a simple indentation function that works for simple cases, for example by comparing with the indentation of the previous text line. For most programming languages that are not really line-based, this tends to scale very poorly: improving such a function to let it handle more diverse situations tends to become more and more difficult, resulting in the end with a large, complex, unmaintainable indentation function which nobody dares to touch.

A good indentation function will usually need to actually parse the text, according to the syntax of the language. Luckily, it is not necessary to parse the text in as much detail as would be needed for a compiler, but on the other hand, the parser embedded in the indentation code will want to be somewhat friendly to syntactically incorrect code.

Good maintainable indentation functions usually fall into two categories: either parsing forward from some safe starting point until the position of interest, or parsing backward from the position of interest. Neither of the two is a clearly better choice than the other: parsing backward is often more difficult than parsing forward because programming languages are designed to be parsed forward, but for the purpose of indentation it has the advantage of not needing to guess a safe starting point, and it generally enjoys the property that only a minimum of text will be analyzed to decide the indentation of a line, so indentation will tend to be less affected by syntax errors in some earlier unrelated piece of code. Parsing forward on the other hand is usually easier and has the advantage of making it possible to reindent efficiently a whole region at a time, with a single parse.

Rather than write your own indentation function from scratch, it is often preferable to try and reuse some existing ones or to rely on a generic indentation engine. There are sadly few such engines. The CC-mode indentation code (used with C, C++, Java, Awk and a few other such modes) has been made more generic over the years, so if your language seems somewhat similar to one of those languages, you might try to use that engine. Another one is SMIE which takes an approach in the spirit of Lisp sexps and adapts it to non-Lisp languages. Yet another one is to rely on a full-blown parser, for example, the tree-sitter library.

24.7.1 Simple Minded Indentation Engine

SMIE is a package that provides a generic navigation and indentation engine. Based on a very simple parser using an operator precedence grammar, it lets major modes extend the

sexp-based navigation of Lisp to non-Lisp languages as well as provide a simple to use but reliable auto-indentation.

Operator precedence grammar is a very primitive technology for parsing compared to some of the more common techniques used in compilers. It has the following characteristics: its parsing power is very limited, and it is largely unable to detect syntax errors, but it has the advantage of being algorithmically efficient and able to parse forward just as well as backward. In practice that means that SMIE can use it for indentation based on backward parsing, that it can provide both `forward-sexp` and `backward-sexp` functionality, and that it will naturally work on syntactically incorrect code without any extra effort. The downside is that it also means that most programming languages cannot be parsed correctly using SMIE, at least not without resorting to some special tricks (see Section 24.7.1.5 [SMIE Tricks], page 585).

24.7.1.1 SMIE Setup and Features

SMIE is meant to be a one-stop shop for structural navigation and various other features which rely on the syntactic structure of code, in particular automatic indentation. The main entry point is `smie-setup` which is a function typically called while setting up a major mode.

`smie-setup` *grammar* *rules-function* &*rest* *keywords* [Function]

Setup SMIE navigation and indentation. *grammar* is a grammar table generated by `smie-prec2->grammar`. *rules-function* is a set of indentation rules for use on `smie-rules-function`. *keywords* are additional arguments, which can include the following keywords:

- `:forward-token` *fun*: Specify the forward lexer to use.
- `:backward-token` *fun*: Specify the backward lexer to use.

Calling this function is sufficient to make commands such as `forward-sexp`, `backward-sexp`, and `transpose-sexps` be able to properly handle structural elements other than just the paired parentheses already handled by syntax tables. For example, if the provided grammar is precise enough, `transpose-sexps` can correctly transpose the two arguments of a `+` operator, taking into account the precedence rules of the language.

Calling `smie-setup` is also sufficient to make TAB indentation work in the expected way, extends `blink-matching-paren` to apply to elements like `begin...end`, and provides some commands that you can bind in the major mode keymap.

`smie-close-block` [Command]

This command closes the most recently opened (and not yet closed) block.

`smie-down-list` &*optional arg* [Command]

This command is like `down-list` but it also pays attention to nesting of tokens other than parentheses, such as `begin...end`.

24.7.1.2 Operator Precedence Grammars

SMIE's precedence grammars simply give to each token a pair of precedences: the left-precedence and the right-precedence. We say $T_1 < T_2$ if the right-precedence of token T_1 is less than the left-precedence of token T_2 . A good way to read this $<$ is as a kind of parenthesis:

if we find $\dots T1 \text{ something } T2 \dots$ then that should be parsed as $\dots (T1 \text{ something } T2) \dots$ rather than as $\dots T1 (\text{ something }) T2 \dots$. The latter interpretation would be the case if we had $T1 > T2$. If we have $T1 = T2$, it means that token $T2$ follows token $T1$ in the same syntactic construction, so typically we have "begin" = "end". Such pairs of precedences are sufficient to express left-associativity or right-associativity of infix operators, nesting of tokens like parentheses and many other cases.

smie-prec2->grammar table

[Function]

This function takes a *prec2* grammar *table* and returns an alist suitable for use in **smie-setup**. The *prec2* table is itself meant to be built by one of the functions below.

smie-merge-prec2s &rest tables

[Function]

This function takes several *prec2* *tables* and merges them into a new *prec2* *table*.

smie-precs->prec2 precs

[Function]

This function builds a *prec2* *table* from a table of precedences *precs*. *precs* should be a list, sorted by precedence (for example "+" will come before "*"), of elements of the form (**assoc** *op* ...), where each *op* is a token that acts as an operator; **assoc** is their associativity, which can be either **left**, **right**, **assoc**, or **nonassoc**. All operators in a given element share the same precedence level and associativity.

smie-bnf->prec2 bnf &rest resolvers

[Function]

This function lets you specify the grammar using a BNF notation. It accepts a *bnf* description of the grammar along with a set of conflict resolution rules *resolvers*, and returns a *prec2* *table*.

bnf is a list of nonterminal definitions of the form (*nonterm* *rhs1* *rhs2* ...) where each *rhs* is a (non-empty) list of terminals (aka tokens) or non-terminals.

Not all grammars are accepted:

- An *rhs* cannot be an empty list (an empty list is never needed, since SMIE allows all non-terminals to match the empty string anyway).
- An *rhs* cannot have 2 consecutive non-terminals: each pair of non-terminals needs to be separated by a terminal (aka token). This is a fundamental limitation of operator precedence grammars.

Additionally, conflicts can occur:

- The returned *prec2* *table* holds constraints between pairs of tokens, and for any given pair only one constraint can be present: $T1 < T2$, $T1 = T2$, or $T1 > T2$.
- A token can be an **opener** (something similar to an open-paren), a **closer** (like a close-paren), or **neither** of the two (e.g., an infix operator, or an inner token like "else").

Precedence conflicts can be resolved via *resolvers*, which is a list of *precs* *tables* (see **smie-precs->prec2**): for each precedence conflict, if those *precs* *tables* specify a particular constraint, then the conflict is resolved by using this constraint instead, else a conflict is reported and one of the conflicting constraints is picked arbitrarily and the others are simply ignored.

24.7.1.3 Defining the Grammar of a Language

The usual way to define the SMIE grammar of a language is by defining a new global variable that holds the precedence table by giving a set of BNF rules. For example, the grammar definition for a small Pascal-like language could look like:

```
(require 'smie)
(defvar sample-smie-grammar
  (smie-prec2->grammar
    (smie-bnf->prec2
      '((id)
        (inst ("begin" insts "end")
              ("if" exp "then" inst "else" inst)
              (id ":=" exp)
              (exp))
        (insts (insts ";" insts) (inst)))
        (exp (exp "+" exp)
              (exp "*" exp)
              ("(" exps ")"))
        (expss (expss "," exps) (exp)))
      '((assoc ";"))
      '((assoc ","))
      '((assoc "+") (assoc "*")))))
```

A few things to note:

- The above grammar does not explicitly mention the syntax of function calls: SMIE will automatically allow any sequence of sexps, such as identifiers, balanced parentheses, or `begin ... end` blocks to appear anywhere anyway.
- The grammar category `id` has no right hand side: this does not mean that it can match only the empty string, since as mentioned any sequence of sexps can appear anywhere anyway.
- Because non terminals cannot appear consecutively in the BNF grammar, it is difficult to correctly handle tokens that act as terminators, so the above grammar treats `";"` as a statement *separator* instead, which SMIE can handle very well.
- Separators used in sequences (such as `,` and `";"` above) are best defined with BNF rules such as `(foo (foo "separator" foo) ...)` which generate precedence conflicts which are then resolved by giving them an explicit `(assoc "separator")`.
- The `("(" exps "))` rule was not needed to pair up parens, since SMIE will pair up any characters that are marked as having paren syntax in the syntax table. What this rule does instead (together with the definition of `expss`) is to make it clear that `,` should not appear outside of parentheses.
- Rather than have a single *prec* table to resolve conflicts, it is preferable to have several tables, so as to let the BNF part of the grammar specify relative precedences where possible.
- Unless there is a very good reason to prefer `left` or `right`, it is usually preferable to mark operators as associative, using `assoc`. For that reason `"+"` and `"*"` are defined above as `assoc`, although the language defines them formally as left associative.

24.7.1.4 Defining Tokens

SMIE comes with a predefined lexical analyzer which uses syntax tables in the following way: any sequence of characters that have word or symbol syntax is considered a token, and so is any sequence of characters that have punctuation syntax. This default lexer is often a good starting point but is rarely actually correct for any given language. For example, it will consider "2,+3" to be composed of 3 tokens: "2", "+", and "3".

To describe the lexing rules of your language to SMIE, you need 2 functions, one to fetch the next token, and another to fetch the previous token. Those functions will usually first skip whitespace and comments and then look at the next chunk of text to see if it is a special token. If so it should skip the token and return a description of this token. Usually this is simply the string extracted from the buffer, but it can be anything you want. For example:

```
(defvar sample-keywords-regexp
  (regexp-opt '("+" "*" "," ";" ">" ">=" "<" "<=" ":" "=")))
(defun sample-smie-forward-token ()
  (forward-comment (point-max))
  (cond
    ((looking-at sample-keywords-regexp)
     (goto-char (match-end 0))
     (match-string-no-properties 0))
    (t (buffer-substring-no-properties
         (point)
         (progn (skip-syntax-forward "w_")
                (point))))))
(defun sample-smie-backward-token ()
  (forward-comment (- (point)))
  (cond
    ((looking-back sample-keywords-regexp (- (point) 2) t)
     (goto-char (match-beginning 0))
     (match-string-no-properties 0))
    (t (buffer-substring-no-properties
         (point)
         (progn (skip-syntax-backward "w_")
                (point)))))))
```

Notice how those lexers return the empty string when in front of parentheses. This is because SMIE automatically takes care of the parentheses defined in the syntax table. More specifically if the lexer returns `nil` or an empty string, SMIE tries to handle the corresponding text as a sexp according to syntax tables.

24.7.1.5 Living With a Weak Parser

The parsing technique used by SMIE does not allow tokens to behave differently in different contexts. For most programming languages, this manifests itself by precedence conflicts when converting the BNF grammar.

Sometimes, those conflicts can be worked around by expressing the grammar slightly differently. For example, for Modula-2 it might seem natural to have a BNF grammar that looks like this:

```

...
(inst ("IF" exp "THEN" insts "ELSE" insts "END")
      ("CASE" exp "OF" cases "END")
      ...)
(cases (cases "|" cases)
      (caselabel ":" insts)
      ("ELSE" insts))
...

```

But this will create conflicts for "ELSE": on the one hand, the IF rule implies (among many other things) that "ELSE" = "END"; but on the other hand, since "ELSE" appears within `cases`, which appears left of "END", we also have "ELSE" > "END". We can solve the conflict either by using:

```

...
(inst ("IF" exp "THEN" insts "ELSE" insts "END")
      ("CASE" exp "OF" cases "END")
      ("CASE" exp "OF" cases "ELSE" insts "END")
      ...)
(cases (cases "|" cases) (caselabel ":" insts))
...

```

or

```

...
(inst ("IF" exp "THEN" else "END")
      ("CASE" exp "OF" cases "END")
      ...)
(else (insts "ELSE" insts))
(cases (cases "|" cases) (caselabel ":" insts) (else))
...

```

Reworking the grammar to try and solve conflicts has its downsides, tho, because SMIE assumes that the grammar reflects the logical structure of the code, so it is preferable to keep the BNF closer to the intended abstract syntax tree.

Other times, after careful consideration you may conclude that those conflicts are not serious and simply resolve them via the `resolvers` argument of `smie-bnf->prec2`. Usually this is because the grammar is simply ambiguous: the conflict does not affect the set of programs described by the grammar, but only the way those programs are parsed. This is typically the case for separators and associative infix operators, where you want to add a resolver like '`((assoc "|"))`'. Another case where this can happen is for the classic *dangling else* problem, where you will use '`((assoc "else" "then"))`'. It can also happen for cases where the conflict is real and cannot really be resolved, but it is unlikely to pose a problem in practice.

Finally, in many cases some conflicts will remain despite all efforts to restructure the grammar. Do not despair: while the parser cannot be made more clever, you can make the lexer as smart as you want. So, the solution is then to look at the tokens involved in the conflict and to split one of those tokens into 2 (or more) different tokens. E.g., if the grammar needs to distinguish between two incompatible uses of the token "`begin`", make the lexer return different tokens (say "`begin-fun`" and "`begin-plain`") depending

on which kind of "begin" it finds. This pushes the work of distinguishing the different cases to the lexer, which will thus have to look at the surrounding text to find ad-hoc clues.

24.7.1.6 Specifying Indentation Rules

Based on the provided grammar, SMIE will be able to provide automatic indentation without any extra effort. But in practice, this default indentation style will probably not be good enough. You will want to tweak it in many different cases.

SMIE indentation is based on the idea that indentation rules should be as local as possible. To this end, it relies on the idea of *virtual* indentation, which is the indentation that a particular program point would have if it were at the beginning of a line. Of course, if that program point is indeed at the beginning of a line, its virtual indentation is its current indentation. But if not, then SMIE uses the indentation algorithm to compute the virtual indentation of that point. Now in practice, the virtual indentation of a program point does not have to be identical to the indentation it would have if we inserted a newline before it. To see how this works, the SMIE rule for indentation after a `{` in C does not care whether the `{` is standing on a line of its own or is at the end of the preceding line. Instead, these different cases are handled in the indentation rule that decides how to indent before a `{`.

Another important concept is the notion of *parent*: The *parent* of a token, is the head token of the nearest enclosing syntactic construct. For example, the parent of an `else` is the `if` to which it belongs, and the parent of an `if`, in turn, is the lead token of the surrounding construct. The command `backward-sexp` jumps from a token to its parent, but there are some caveats: for *openers* (tokens which start a construct, like `if`), you need to start with point before the token, while for others you need to start with point after the token. `backward-sexp` stops with point before the parent token if that is the *opener* of the token of interest, and otherwise it stops with point after the parent token.

SMIE indentation rules are specified using a function that takes two arguments *method* and *arg* where the meaning of *arg* and the expected return value depend on *method*.

method can be:

- `:after`, in which case *arg* is a token and the function should return the *offset* to use for indentation after *arg*.
- `:before`, in which case *arg* is a token and the function should return the *offset* to use to indent *arg* itself.
- `:elem`, in which case the function should return either the *offset* to use to indent function arguments (if *arg* is the symbol `arg`) or the basic indentation step (if *arg* is the symbol `basic`).
- `:list-intro`, in which case *arg* is a token and the function should return `non-nil` if the token is followed by a list of expressions (not separated by any token) rather than an expression.

When *arg* is a token, the function is called with point just before that token. A return value of `nil` always means to fallback on the default behavior, so the function should return `nil` for arguments it does not expect.

offset can be:

- `nil`: use the default indentation rule.
- `(column . column)`: indent to column *column*.

- *number*: offset by *number*, relative to a base token which is the current token for `:after` and its parent for `:before`.

24.7.1.7 Helper Functions for Indentation Rules

SMIE provides various functions designed specifically for use in the indentation rules function (several of those functions break if used in another context). These functions all start with the prefix `smie-rule-`.

smie-rule-bolp [Function]

Return non-`nil` if the current token is the first on the line.

smie-rule-hanging-p [Function]

Return non-`nil` if the current token is *hanging*. A token is *hanging* if it is the last token on the line and if it is preceded by other tokens: a lone token on a line is not hanging.

smie-rule-next-p &rest tokens [Function]

Return non-`nil` if the next token is among *tokens*.

smie-rule-prev-p &rest tokens [Function]

Return non-`nil` if the previous token is among *tokens*.

smie-rule-parent-p &rest parents [Function]

Return non-`nil` if the current token's parent is among *parents*.

smie-rule-sibling-p [Function]

Return non-`nil` if the current token's parent is actually a sibling. This is the case for example when the parent of a `,` is just the previous `,`.

smie-rule-parent &optional offset [Function]

Return the proper offset to align the current token with the parent. If non-`nil`, *offset* should be an integer giving an additional offset to apply.

smie-rule-separator method [Function]

Indent current token as a *separator*.

By *separator*, we mean here a token whose sole purpose is to separate various elements within some enclosing syntactic construct, and which does not have any semantic significance in itself (i.e., it would typically not exist as a node in an abstract syntax tree).

Such a token is expected to have an associative syntax and be closely tied to its syntactic parent. Typical examples are `,` in lists of arguments (enclosed inside parentheses), or `;` in sequences of instructions (enclosed in a `{...}` or `begin...end` block).

method should be the method name that was passed to `smie-rules-function`.

24.7.1.8 Sample Indentation Rules

Here is an example of an indentation function:

```
(defun sample-smie-rules (kind token)
  (pcase (cons kind token)
    `(:elem . basic) sample-indent-basic)
    `(_ . ",") (smie-rule-separator kind))
    `(:after . ":=") sample-indent-basic)
    `(:before . ,(or `"begin" `"( " `"{""))
      (if (smie-rule-hanging-p) (smie-rule-parent)))
    `(:before . "if")
      (and (not (smie-rule-bolp)) (smie-rule-prev-p "else")
        (smie-rule-parent))))
```

A few things to note:

- The first case indicates the basic indentation increment to use. If `sample-indent-basic` is `nil`, then SMIE uses the global setting `smie-indent-basic`. The major mode could have set `smie-indent-basic` buffer-locally instead, but that is discouraged.
- The rule for the token `,` make SMIE try to be more clever when the comma separator is placed at the beginning of lines. It tries to outdent the separator so as to align the code after the comma; for example:

```
x = longfunctionname (
  arg1
  , arg2
);
```

- The rule for indentation after `:=` exists because otherwise SMIE would treat `:=` as an infix operator and would align the right argument with the left one.
- The rule for indentation before `"begin"` is an example of the use of virtual indentation: This rule is used only when `"begin"` is hanging, which can happen only when `"begin"` is not at the beginning of a line. So this is not used when indenting `"begin"` itself but only when indenting something relative to this `"begin"`. Concretely, this rule changes the indentation from:

```
if x > 0 then begin
  dosomething(x);
end
```

to

```
if x > 0 then begin
  dosomething(x);
end
```

- The rule for indentation before `"if"` is similar to the one for `"begin"`, but where the purpose is to treat `"else if"` as a single unit, so as to align a sequence of tests rather than indent each test further to the right. This function does this only in the case where the `"if"` is not placed on a separate line, hence the `smie-rule-bolp` test.

If we know that the `"else"` is always aligned with its `"if"` and is always at the beginning of a line, we can use a more efficient rule:

```
((equal token "if")
```

```
(and (not (smie-rule-bolp))
     (smie-rule-prev-p "else")
     (save-excursion
       (sample-smie-backward-token)
       (cons 'column (current-column)))))
```

The advantage of this formulation is that it reuses the indentation of the previous "else", rather than going all the way back to the first "if" of the sequence.

24.7.1.9 Customizing Indentation

If you are using a mode whose indentation is provided by SMIE, you can customize the indentation to suit your preferences. You can do this on a per-mode basis (using the option `smie-config`), or a per-file basis (using the function `smie-config-local` in a file-local variable specification).

`smie-config`

[User Option]

This option lets you customize indentation on a per-mode basis. It is an alist with elements of the form `(mode . rules)`. For the precise form of rules, see the variable's documentation; but you may find it easier to use the command `smie-config-guess`.

`smie-config-guess`

[Command]

This command tries to work out appropriate settings to produce your preferred style of indentation. Simply call the command while visiting a file that is indented with your style.

`smie-config-save`

[Command]

Call this command after using `smie-config-guess`, to save your settings for future sessions.

`smie-config-show-indent &optional move`

[Command]

This command displays the rules that are used to indent the current line.

`smie-config-set-indent`

[Command]

This command adds a local rule to adjust the indentation of the current line.

`smie-config-local rules`

[Function]

This function adds `rules` as indentation rules for the current buffer. These add to any mode-specific rules defined by the `smie-config` option. To specify custom indentation rules for a specific file, add an entry to the file's local variables of the form: `eval: (smie-config-local '(rules))`.

24.7.2 Parser-based Indentation

When built with the tree-sitter library (see Chapter 37 [Parsing Program Source], page 1039), Emacs is capable of parsing the program source and producing a syntax tree. This syntax tree can be used for guiding the program source indentation commands. For maximum flexibility, it is possible to write a custom indentation function that queries the syntax tree and indents accordingly for each language, but that is a lot of work. It is more convenient to use the simple indentation engine described below: then the major mode needs only write some indentation rules, and the engine takes care of the rest.

To enable the parser-based indentation engine, either set `treesit-simple-indent-rules` and call `treesit-major-mode-setup`, or equivalently, set the value of `indent-line-function` to `treesit-indent`.

`treesit-indent-function`

[Variable]

This variable stores the actual function called by `treesit-indent`. By default, its value is `treesit-simple-indent`. In the future we might add other, more complex indentation engines.

Writing indentation rules

`treesit-simple-indent-rules`

[Variable]

This local variable stores indentation rules for every language. It is an alist with elements of the form `(language . rules)`, where `language` is a language symbol, and `rules` is a list with elements of the form `(matcher anchor offset)`.

First, Emacs passes the smallest tree-sitter node at the beginning of the current line to `matcher`; if it returns non-`nil`, this rule is applicable. Then Emacs passes the node to `anchor`, which returns a buffer position. Emacs takes the column number of that position, adds `offset` to it, and the result is the indentation column for the current line. The `matcher` and `anchor` are functions, and Emacs provides convenient defaults for them.

Each `matcher` or `anchor` is a function that takes three arguments: `node`, `parent`, and `bol`. The argument `bol` is the buffer position whose indentation is required: the position of the first non-whitespace character after the beginning of the line. The argument `node` is the largest node that starts at that position (and is not a root node); and `parent` is the parent of `node`. However, when that position is in a whitespace or inside a multi-line string, no node can start at that position, so `node` is `nil`. In that case, `parent` would be the smallest node that spans that position.

`matcher` should return non-`nil` if the rule is applicable, and `anchor` should return a buffer position.

`offset` can be an integer, a variable whose value is an integer, or a function that returns an integer. If it is a function, it is passed `node`, `parent`, and `bol`, like matchers and anchors.

`treesit-simple-indent-presets`

[Variable]

This is a list of defaults for `matchers` and `anchors` in `treesit-simple-indent-rules`. Each of them represents a function that takes 3 arguments: `node`, `parent`, and `bol`. The available default functions are:

`no-node` This matcher is a function that is called with 3 arguments: `node`, `parent`, and `bol`. It returns non-`nil`, indicating a match, if `node` is `nil`, i.e., there is no node that starts at `bol`. This is the case when `bol` is on an empty line or inside a multi-line string, etc.

`parent-is`

This matcher is a function of one argument, `type`; it returns a function that is called with 3 arguments: `node`, `parent`, and `bol`, and returns non-`nil` (i.e., a match) if `parent`'s type matches regexp `type`.

node-is	This matcher is a function of one argument, <i>type</i> ; it returns a function that is called with 3 arguments: <i>node</i> , <i>parent</i> , and <i>bol</i> , and returns non-nil if <i>node</i> 's type matches regexp <i>type</i> .
field-is	This matcher is a function of one argument, <i>name</i> ; it returns a function that is called with 3 arguments: <i>node</i> , <i>parent</i> , and <i>bol</i> , and returns non-nil if <i>node</i> 's field name in <i>parent</i> matches regexp <i>name</i> .
query	This matcher is a function of one argument, <i>query</i> ; it returns a function that is called with 3 arguments: <i>node</i> , <i>parent</i> , and <i>bol</i> , and returns non-nil if querying <i>parent</i> with <i>query</i> captures <i>node</i> (see Section 37.5 [Pattern Matching], page 1052).
match	This matcher is a function of 5 arguments: <i>node-type</i> , <i>parent-type</i> , <i>node-field</i> , <i>node-index-min</i> , and <i>node-index-max</i>). It returns a function that is called with 3 arguments: <i>node</i> , <i>parent</i> , and <i>bol</i> , and returns non-nil if <i>node</i> 's type matches regexp <i>node-type</i> , <i>parent</i> 's type matches regexp <i>parent-type</i> , <i>node</i> 's field name in <i>parent</i> matches regexp <i>node-field</i> , and <i>node</i> 's index among its siblings is between <i>node-index-min</i> and <i>node-index-max</i> . If the value of an argument is nil, this matcher doesn't check that argument. For example, to match the first child where parent is <i>argument_list</i> , use <code>(match nil "argument_list" nil 0 0)</code>
	In addition, <i>node-type</i> can be a special value null , which matches when the value of <i>node</i> is nil .
n-p-gp	Short for “node-parent-grandparent”, this matcher is a function of 3 arguments: <i>node-type</i> , <i>parent-type</i> , and <i>grandparent-type</i> . It returns a function that is called with 3 arguments: <i>node</i> , <i>parent</i> , and <i>bol</i> , and returns non-nil if: (1) <i>node-type</i> matches <i>node</i> 's type, and (2) <i>parent-type</i> matches <i>parent</i> 's type, and (3) <i>grandparent-type</i> matches <i>parent</i> 's parent's type. If any of <i>node-type</i> , <i>parent-type</i> , and <i>grandparent-type</i> is nil , this function doesn't check for it.
comment-end	This matcher is a function that is called with 3 arguments: <i>node</i> , <i>parent</i> , and <i>bol</i> , and returns non-nil if point is before a comment-ending token. Comment-ending tokens are defined by regexp comment-end-skip .
catch-all	This matcher is a function that is called with 3 arguments: <i>node</i> , <i>parent</i> , and <i>bol</i> . It always returns non-nil, indicating a match.
first-sibling	This anchor is a function that is called with 3 arguments: <i>node</i> , <i>parent</i> , and <i>bol</i> , and returns the start of the first child of <i>parent</i> .
nth-sibling	This anchor is a function of two arguments: <i>n</i> , and an optional argument <i>named</i> . It returns a function that is called with 3 arguments: <i>node</i> , <i>parent</i> , and <i>bol</i> , and returns the start of the <i>n</i> th child of <i>parent</i> . If <i>named</i> is

non-`nil`, only named children are counted (see [tree-sitter named node], page 1041).

`parent` This anchor is a function that is called with 3 arguments: `node`, `parent`, and `bol`, and returns the start of `parent`.

`grand-parent`

This anchor is a function that is called with 3 arguments: `node`, `parent`, and `bol`, and returns the start of `parent`'s parent.

`great-grand-parent`

This anchor is a function that is called with 3 arguments: `node`, `parent`, and `bol`, and returns the start of `parent`'s parent's parent.

`parent-bol`

This anchor is a function that is called with 3 arguments: `node`, `parent`, and `bol`, and returns the first non-space character on the line which `parent`'s start is on.

`standalone-parent`

This anchor is a function that is called with 3 arguments: `node`, `parent`, and `bol`. It finds the first ancestor node (parent, grandparent, etc.) of `node` that starts on its own line, and return the start of that node. “Starting on its own line” means there is only whitespace character before the node on the line which the node's start is on.

`prev-sibling`

This anchor is a function that is called with 3 arguments: `node`, `parent`, and `bol`, and returns the start of the previous sibling of `node`.

`no-indent`

This anchor is a function that is called with 3 arguments: `node`, `parent`, and `bol`, and returns the start of `node`.

`prev-line`

This anchor is a function that is called with 3 arguments: `node`, `parent`, and `bol`, and returns the first non-whitespace character on the previous line.

`column-0`

This anchor is a function that is called with 3 arguments: `node`, `parent`, and `bol`, and returns the beginning of the current line, which is at column 0.

`comment-start`

This anchor is a function that is called with 3 arguments: `node`, `parent`, and `bol`, and returns the position after the comment-start token. Comment-start tokens are defined by regular expression `comment-start-skip`. This function assumes `parent` is the comment node.

`prev-adaptive-prefix`

This anchor is a function that is called with 3 arguments: `node`, `parent`, and `bol`. It tries to match `adaptive-fill-regexp` to the text at the beginning of the previous non-empty line. If there is a match, this function returns

the end of the match, otherwise it returns `nil`. However, if the current line begins with a prefix (e.g., ‘-’), return the beginning of the prefix of the previous line instead, so that the two prefixes align. This anchor is useful for an `indent-relative-like` indent behavior for block comments.

Indentation utilities

Here are some utility functions that can help writing parser-based indentation rules.

`treesit-check-indent mode`

[Command]

This command checks the current buffer’s indentation against major mode `mode`. It indents the current buffer according to `mode` and compares the results with the current indentation. Then it pops up a buffer showing the differences. Correct indentation (target) is shown in green color, current indentation is shown in red color.

It is also helpful to use `treesit-inspect-mode` (see Section 37.1 [Language Grammar], page 1039) when writing indentation rules.

24.8 Desktop Save Mode

Desktop Save Mode is a feature to save the state of Emacs from one session to another. The user-level commands for using Desktop Save Mode are described in the GNU Emacs Manual (see Section “Saving Emacs Sessions” in *the GNU Emacs Manual*). Modes whose buffers visit a file, don’t have to do anything to use this feature.

For buffers not visiting a file to have their state saved, the major mode must bind the buffer local variable `desktop-save-buffer` to a non-`nil` value.

`desktop-save-buffer`

[Variable]

If this buffer-local variable is non-`nil`, the buffer will have its state saved in the desktop file at desktop save. If the value is a function, it is called at desktop save with argument `desktop-dirname`, and its value is saved in the desktop file along with the state of the buffer for which it was called. When file names are returned as part of the auxiliary information, they should be formatted using the call

`(desktop-file-name file-name desktop-dirname)`

For buffers not visiting a file to be restored, the major mode must define a function to do the job, and that function must be listed in the alist `desktop-buffer-mode-handlers`.

`desktop-buffer-mode-handlers`

[Variable]

Alist with elements

`(major-mode . restore-buffer-function)`

The function `restore-buffer-function` will be called with argument list

`(buffer-file-name buffer-name desktop-buffer-misc)`

and it should return the restored buffer. Here `desktop-buffer-misc` is the value returned by the function optionally bound to `desktop-save-buffer`.

25 Documentation

GNU Emacs has convenient built-in help facilities, most of which derive their information from documentation strings associated with functions and variables. This chapter describes how to access documentation strings in Lisp programs.

The contents of a documentation string should follow certain conventions. In particular, its first line should be a complete sentence (or two complete sentences) that briefly describes what the function or variable does. See Section D.6 [Documentation Tips], page 1337, for how to write good documentation strings.

Note that the documentation strings for Emacs are not the same thing as the Emacs manual. Manuals have their own source files, written in the Texinfo language; documentation strings are specified in the definitions of the functions and variables they apply to. A collection of documentation strings is not sufficient as a manual because a good manual is not organized in that fashion; it is organized in terms of topics of discussion.

For commands to display documentation strings, see Section “Help” in *The GNU Emacs Manual*.

25.1 Documentation Basics

A documentation string is written using the Lisp syntax for strings, with double-quote characters surrounding the text. It is, in fact, an actual Lisp string. When the string appears in the proper place in a function or variable definition, it serves as the function’s or variable’s documentation.

In a function definition (a `lambda` or `defun` form), the documentation string is specified after the argument list, and is normally stored directly in the function object. See Section 13.2.4 [Function Documentation], page 235. You can also put function documentation in the `function-documentation` property of a function name (see Section 25.2 [Accessing Documentation], page 596).

In a variable definition (a `defvar` form), the documentation string is specified after the initial value. See Section 12.5 [Defining Variables], page 194. The string is stored in the variable’s `variable-documentation` property.

Sometimes, Emacs does not keep documentation strings in memory. There are two such circumstances. Firstly, to save memory, the documentation for primitive functions (see Section 13.1 [What Is a Function], page 230) and built-in variables is kept in a file named `DOC`, in the directory specified by `doc-directory` (see Section 25.2 [Accessing Documentation], page 596). Secondly, when a function or variable is loaded from a byte-compiled file, Emacs avoids loading its documentation string (see Section 17.3 [Docs and Compilation], page 319). In both cases, Emacs looks up the documentation string from the file only when needed, such as when the user calls `C-h f (describe-function)` for a function.

Documentation strings can contain special key substitution sequences, referring to key bindings which are looked up only when the user views the documentation. This allows the help commands to display the correct keys even if a user rearranges the default key bindings. See Section 25.3 [Keys in Documentation], page 598.

In the documentation string of an autoloaded command (see Section 16.5 [Autoload], page 304), these key-substitution sequences have an additional special effect: they cause

C-h f on the command to trigger autoloading. (This is needed for correctly setting up the hyperlinks in the *Help* buffer.)

25.2 Access to Documentation Strings

documentation-property *symbol property &optional verbatim* [Function]

This function returns the documentation string recorded in *symbol*'s property list under property *property*. It is most often used to look up the documentation strings of variables, for which *property* is **variable-documentation**. However, it can also be used to look up other kinds of documentation, such as for customization groups (but for function documentation, use the **documentation** function, below).

If the property value refers to a documentation string stored in the **DOC** file or a byte-compiled file, this function looks up that string and returns it.

If the property value isn't **nil**, isn't a string, and doesn't refer to text in a file, then it is evaluated as a Lisp expression to obtain a string.

Finally, this function passes the string through **substitute-command-keys** to substitute key bindings (see Section 25.3 [Keys in Documentation], page 598). It skips this step if *verbatim* is non-**nil**.

```
(documentation-property 'command-line-processed
  'variable-documentation)
  ⇒ "Non-nil once command line has been processed"
(symbol-plist 'command-line-processed)
  ⇒ (variable-documentation 188902)
(documentation-property 'emacs 'group-documentation)
  ⇒ "Customization of the One True Editor."
```

documentation *function &optional verbatim* [Function]

This function returns the documentation string of *function*. It handles macros, named keyboard macros, and special forms, as well as ordinary functions.

If *function* is a symbol, this function first looks for the **function-documentation** property of that symbol; if that has a non-**nil** value, the documentation comes from that value (if the value is not a string, it is evaluated).

If *function* is not a symbol, or if it has no **function-documentation** property, then **documentation** extracts the documentation string from the actual function definition, reading it from a file if called for.

Finally, unless *verbatim* is non-**nil**, this function calls **substitute-command-keys**. The result is the documentation string to return.

The **documentation** function signals a **void-function** error if *function* has no function definition. However, it is OK if the function definition has no documentation string. In that case, **documentation** returns **nil**.

function-documentation *function* [Function]

Generic function used by **documentation** to extract the raw docstring from a function object. You can specify how to get the docstring of a specific function type by adding a corresponding method to it.

face-documentation *face* [Function]

This function returns the documentation string of *face* as a face.

Here is an example of using the two functions, `documentation` and `documentation-property`, to display the documentation strings for several symbols in a `*Help*` buffer.

```
(defun describe-symbols (pattern)
  "Describe the Emacs Lisp symbols matching PATTERN.
  All symbols that have PATTERN in their name are described
  in the *Help* buffer."
  (interactive "sDescribe symbols matching: ")
  (let ((describe-func
         (lambda (s)
           ;; Print description of symbol.
           (if (fboundp s) ; It is a function.
               (princ
                 (format "%s\t%s\n%s\n\n" s
                         (if (commandp s)
                             (let ((keys (where-is-internal s)))
                               (if keys
                                   (concat
                                     "Keys: "
                                     (mapconcat 'key-description
                                               keys " ")))
                               "Keys: none"))
                             "Function"))
               (or (documentation s)
                   "not documented"))))

           (if (boundp s) ; It is a variable.
               (princ
                 (format "%s\t%s\n%s\n\n" s
                         (if (custom-variable-p s)
                             "Option " "Variable")
                         (or (documentation-property
                               s 'variable-documentation)
                             "not documented")))))
           sym-list)

  ;; Build a list of symbols that match pattern.
  (mapatoms (lambda (sym)
              (if (string-match pattern (symbol-name sym))
                  (setq sym-list (cons sym sym-list)))))

  ;; Display the data.
  (help-setup-xref (list 'describe-symbols pattern)
                  (called-interactively-p 'interactive))
  (with-help-window (help-buffer)
    (mapcar describe-func (sort sym-list 'string<)))))
```

The `describe-symbols` function works like `apropos`, but provides more information.

```
(describe-symbols "goal")

----- Buffer: *Help* -----
goal-column      Option
Semipermanent goal column for vertical motion, as set by ...

minibuffer-temporary-goal-position      Variable
not documented
```

```

set-goal-column Keys: C-x C-n
Set the current horizontal position as a goal for C-n and C-p.
Those commands will move to this position in the line moved to
rather than trying to keep the same horizontal position.
With a non-nil argument ARG, clears out the goal column
so that C-n and C-p resume vertical motion.
The goal column is stored in the variable 'goal-column'.

(fn ARG)

temporary-goal-column  Variable
Current goal column for vertical motion.
It is the column where point was at the start of the current run
of vertical motion commands.

When moving by visual lines via the function 'line-move-visual', it is a cons
cell (COL . HSCROLL), where COL is the x-position, in pixels,
divided by the default column width, and HSCROLL is the number of
columns by which window is scrolled from left margin.

When the 'track-eol' feature is doing its job, the value is
'most-positive-fixnum'.
----- Buffer: *Help* -----

```

Snarf-documentation *filename*

[Function]

This function is used when building Emacs, just before the runnable Emacs is dumped. It finds the positions of the documentation strings stored in the file *filename*, and records those positions into memory in the function definitions and variable property lists. See Section E.1 [Building Emacs], page 1346.

Emacs reads the file *filename* from the `emacs/etc` directory. When the dumped Emacs is later executed, the same file will be looked for in the directory `doc-directory`. Usually *filename* is "DOC".

doc-directory

[Variable]

This variable holds the name of the directory which should contain the file "DOC" that contains documentation strings for built-in functions and variables.

In most cases, this is the same as `data-directory`. They may be different when you run Emacs from the directory where you built it, without actually installing it. See [Definition of `data-directory`], page 604.

25.3 Substituting Key Bindings in Documentation

When documentation strings refer to key sequences, they should use the current, actual key bindings. They can do so using certain special text sequences described below. Accessing documentation strings in the usual way substitutes current key binding information for these special sequences. This works by calling `substitute-command-keys`. You can also call that function yourself.

Here is a list of the special sequences and what they mean:

\[command]

stands for a key sequence that will invoke *command*, or '`M-x command`' if *command* has no key bindings.

`\{mapvar}`

stands for a summary of the keymap which is the value of the variable *mapvar*. The summary is made using `describe-bindings`. The summary will normally exclude menu bindings, but if the *include-menus* argument to `substitute-command-keys` is non-*nil*, the menu bindings will be included.

`\<mapvar>`

stands for no text itself. It is used only for a side effect: it specifies *mapvar*'s value as the keymap for any following '`\[command]`' sequences in this documentation string.

`\`KEYSEQ'`

stands for a key sequence *KEYSEQ*, which will use the same face as a command substitution. This should be used only when a key sequence has no corresponding command, for example when it is read directly with `read-key-sequence`. It must be a valid key sequence according to `key-valid-p`. It can also be used with command names, like '`\ M-x foo`', where you want this to be fontified like a keyboard sequence, but you want to inhibit translating it into a key sequence like '`\[foo]`' does.

- (grave accent) stands for a left quote. This generates a left single quotation mark, an apostrophe, or a grave accent depending on the value of `text-quoting-style`. See Section 25.4 [Text Quoting Style], page 600.
- ' (apostrophe) stands for a right quote. This generates a right single quotation mark or an apostrophe depending on the value of `text-quoting-style`.
- `\=` quotes the following character and is discarded; thus, '`\=```' puts '````' into the output, '`\=\\[`' puts '`\\[`' into the output, and '`\=\\=`' puts '`\\=`' into the output.
- `\+` This indicates that the symbol directly following should not be marked as link in the `*Help*` buffer.

Please note: Each '`\`' must be doubled when written in a string in Emacs Lisp.

`substitute-command-keys string &optional no-face include-menus` [Function]

This function scans *string* for the above special sequences and replaces them by what they stand for, returning the result as a string. This permits display of documentation that refers accurately to the user's own customized key bindings. By default, the key bindings are given a special face `help-key-binding`, but if the optional argument *no-face* is non-*nil*, the function doesn't add this face to the produced string.

If a command has multiple bindings, this function normally uses the first one it finds. You can specify one particular key binding by assigning an `:advertised-binding` symbol property to the command, like this:

```
(put 'undo :advertised-binding [?\C-/])
```

The `:advertised-binding` property also affects the binding shown in menu items (see Section 23.18.5 [Menu Bar], page 516). The property is ignored if it specifies a key binding that the command does not actually have.

Here are examples of the special sequences:

```
(substitute-command-keys
  "To abort recursive edit, type `\\[abort-recursive-edit]'."
  ⇒ "To abort recursive edit, type 'C-]'.")
```

```
(substitute-command-keys
  "The keys that are defined for the minibuffer here are:
  \\{minibuffer-local-must-match-map}")
⇒ "The keys that are defined for the minibuffer here are:

?
  minibuffer-completion-help
SPC
  minibuffer-complete-word
TAB
  minibuffer-complete
C-j
  minibuffer-complete-and-exit
RET
  minibuffer-complete-and-exit
C-g
  abort-recursive-edit
"
```

The keymap description will normally exclude menu items, but if `include-menus` is non-nil, include them.

```
(substitute-command-keys
  "To abort a recursive edit from the minibuffer, type \
`\\<minibuffer-local-must-match-map>\\[abort-recursive-edit]'")
⇒ "To abort a recursive edit from the minibuffer, type 'C-g'."
```

substitute-quotes *string* [Function]
 This function works like `substitute-command-keys`, but only replaces quote characters.

There are other special conventions for the text in documentation strings—for instance, you can refer to functions, variables, and sections of this manual. See Section D.6 [Documentation Tips], page 1337, for details.

25.4 Text Quoting Style

Typically, grave accents and apostrophes are treated specially in documentation strings and diagnostic messages, and translate to matching single quotation marks (also called “curved quotes”). For example, the documentation string “Alias for ‘foo’.” and the function call (`message “Alias for `foo’.”`) both translate to “Alias for ‘foo’.”. Less commonly, Emacs displays grave accents and apostrophes as themselves, or as apostrophes only (e.g., “Alias for ’foo’.”). Documentation strings and message formats should be written so that they display well with any of these styles. For example, the documentation string “Alias for ‘foo’.” is probably not what you want, as it can display as “Alias for ’foo’.”, an unusual style in English.

Sometimes you may need to display a grave accent or apostrophe without translation, regardless of text quoting style. In a documentation string, you can do this with escapes. For example, in the documentation string “\\=(a ,(sin 0)) ==> (a 0.0)” the grave accent is intended to denote Lisp code, so it is escaped and displays as itself regardless of quoting style. In a call to `message` or `error`, you can avoid translation by using a format “%s” with an argument that is a call to `format`. For example, (`(message "%s" (format "^(a ,(sin %S)) ==> (a %S)" x (sin x)))`) displays a message that starts with grave accent regardless of text quoting style.

text-quoting-style [User Option]

The value of this user option is a symbol that specifies the style Emacs should use for single quotes in the wording of help and messages. If the option’s value is `curve`,

the style is ‘like this’ with curved single quotes. If the value is `straight`, the style is ‘like this’ with straight apostrophes. If the value is `grave`, quotes are not translated and the style is ‘like this’ with grave accent and apostrophe, the standard style before Emacs version 25. The default value `nil` acts like `curve` if curved single quotes seem to be displayable, and like `grave` otherwise.

This option is useful on platforms that have problems with curved quotes. You can customize it freely according to your personal preference.

text-quoting-style

[Function]

You should not read the value of the variable `text-quoting-style` directly. Instead, use this function with the same name to dynamically compute the correct quoting style on the current terminal in the `nil` case described above.

25.5 Describing Characters for Help Messages

These functions convert events, key sequences, or characters to textual descriptions. These descriptions are useful for including arbitrary text characters or key sequences in messages, because they convert non-printing and whitespace characters to sequences of printing characters. The description of a non-whitespace printing character is the character itself.

key-description sequence &optional prefix

[Function]

This function returns a string containing the Emacs standard notation for the input events in `sequence`. If `prefix` is non-`nil`, it is a sequence of input events leading up to `sequence` and is included in the return value. Both arguments may be strings, vectors or lists. See Section 22.7 [Input Events], page 440, for more information about valid events.

```
(key-description [?\M-3 delete])
  ⇒ "M-3 <delete>"
(key-description [delete] "\M-3")
  ⇒ "M-3 <delete>"
```

See also the examples for `single-key-description`, below.

single-key-description event &optional no-angles

[Function]

This function returns a string describing `event` in the standard Emacs notation for keyboard input. A normal printing character appears as itself, but a control character turns into a string starting with ‘C-’, a meta character turns into a string starting with ‘M-’, and space, tab, etc., appear as ‘SPC’, ‘TAB’, etc. A function key symbol appears inside angle brackets ‘<...>’. An event that is a list appears as the name of the symbol in the CAR of the list, inside angle brackets.

If the optional argument `no-angles` is non-`nil`, the angle brackets around function keys and event symbols are omitted; this is for compatibility with old versions of Emacs which didn’t use the brackets.

```
(single-key-description ?\C-x)
  ⇒ "C-x"
(key-description "\C-x \M-y \n \t \r \f123")
  ⇒ "C-x SPC M-y SPC C-j SPC TAB SPC RET SPC C-1 1 2 3"
(single-key-description 'delete)
  ⇒ "<delete>"
(single-key-description 'C-mouse-1)
  ⇒ "C-<mouse-1>"
```

```
(single-key-description 'C-mouse-1 t)
⇒ "C-mouse-1"
```

text-char-description *character* [Function]

This function returns a string describing *character* in the standard Emacs notation for characters that can appear in text—similar to `single-key-description`, except that the argument must be a valid character code that passes a `characterp` test (see Section 34.5 [Character Codes], page 967). The function produces descriptions of control characters with a leading caret (which is how Emacs usually displays control characters in buffers). Characters with modifier bits will cause this function to signal an error (ASCII characters with the Control modifier are an exception, they are represented as control characters).

```
(text-char-description ?\C-c)
⇒ "^\C"
(text-char-description ?\M-m)
error Wrong type argument: characterp, 134217837
```

read-kbd-macro *string* &optional *need-vector* [Command]

This function is used mainly for operating on keyboard macros, but it can also be used as a rough inverse for `key-description`. You call it with a string containing key descriptions, separated by spaces; it returns a string or vector containing the corresponding events. (This may or may not be a single valid key sequence, depending on what events you use; see Section 23.1 [Key Sequences], page 480.) If *need-vector* is non-nil, the return value is always a vector.

25.6 Help Functions

Emacs provides a variety of built-in help functions, all accessible to the user as subcommands of the prefix `C-h`. For more information about them, see Section “Help” in *The GNU Emacs Manual*. Here we describe some program-level interfaces to the same information.

apropos *pattern* &optional *do-all* [Command]

This function finds all meaningful symbols whose names contain a match for the apropos pattern *pattern*. An apropos pattern is either a word to match, a space-separated list of words of which at least two must match, or a regular expression (if any special regular expression characters occur). A symbol is meaningful if it has a definition as a function, variable, or face, or has properties.

The function returns a list of elements that look like this:

```
(symbol score function-doc variable-doc
plist-doc widget-doc face-doc group-doc)
```

Here, *score* is an integer measure of how important the symbol seems to be as a match. Each of the remaining elements is a documentation string, or `nil`, for *symbol* as a function, variable, etc.

It also displays the symbols in a buffer named `*Apropos*`, each with a one-line description taken from the beginning of its documentation string.

If *do-all* is non-nil, or if the user option `apropos-do-all` is non-nil, then `apropos` also shows key bindings for the functions that are found; it also shows *all* interned symbols, not just meaningful ones (and it lists them in the return value as well).

help-map

[Variable]

The value of this variable is a local keymap for characters following the Help key, *C-h*.

help-command

[Prefix Command]

This symbol is not a function; its function definition cell holds the keymap known as `help-map`. It is defined in `help.el` as follows:

```
(keymap-set global-map (key-description (string help-char)) 'help-command)
(fset 'help-command help-map)
```

help-char

[User Option]

The value of this variable is the help character—the character that Emacs recognizes as meaning Help. By default, its value is 8, which stands for *C-h*. When Emacs reads this character, if `help-form` is a non-nil Lisp expression, it evaluates that expression, and displays the result in a window if it is a string.

Usually the value of `help-form` is `nil`. Then the help character has no special meaning at the level of command input, and it becomes part of a key sequence in the normal way. The standard key binding of *C-h* is a prefix key for several general-purpose help features.

The help character is special after prefix keys, too. If it has no binding as a subcommand of the prefix key, it runs `describe-prefix-bindings`, which displays a list of all the subcommands of the prefix key.

help-event-list

[User Option]

The value of this variable is a list of event types that serve as alternative help characters. These events are handled just like the event specified by `help-char`.

help-form

[Variable]

If this variable is non-nil, its value is a form to evaluate whenever the character `help-char` is read. If evaluating the form produces a string, that string is displayed.

A command that calls `read-event`, `read-char-choice`, `read-char`, `read-char-from-minibuffer`, or `y-or-n-p` probably should bind `help-form` to a non-nil expression while it does input. (The time when you should not do this is when *C-h* has some other meaning.) Evaluating this expression should result in a string that explains what the input is for and how to enter it properly.

Entry to the minibuffer binds this variable to the value of `minibuffer-help-form` (see [Definition of minibuffer-help-form], page 421).

prefix-help-command

[Variable]

This variable holds a function to print help for a prefix key. The function is called when the user types a prefix key followed by the help character, and the help character has no binding after that prefix. The variable's default value is `describe-prefix-bindings`.

describe-prefix-bindings

[Command]

This function calls `describe-bindings` to display a list of all the subcommands of the prefix key of the most recent key sequence. The prefix described consists of all but the last event of that key sequence. (The last event is, presumably, the help character.)

The following two functions are meant for modes that want to provide help without relinquishing control, such as the electric modes. Their names begin with ‘Helper’ to distinguish them from the ordinary help functions.

Helper-describe-bindings [Command]

This command pops up a window displaying a help buffer containing a listing of all of the key bindings from both the local and global keymaps. It works by calling `describe-bindings`.

Helper-help [Command]

This command provides help for the current mode. It prompts the user in the minibuffer with the message ‘Help (Type ? for further options)’, and then provides assistance in finding out what the key bindings are, and what the mode is intended for. It returns `nil`.

This can be customized by changing the map `Helper-help-map`.

data-directory [Variable]

This variable holds the name of the directory in which Emacs finds certain documentation and text files that come with Emacs.

help-buffer [Function]

This function returns the name of the help buffer, which is normally `*Help*`; if such a buffer does not exist, it is first created.

with-help-window *buffer-or-name* *body*... [Macro]

This macro evaluates *body* like `with-output-to-temp-buffer` (see Section 41.8 [Temporary Displays], page 1146), inserting any output produced by its forms into a buffer specified by *buffer-or-name*, which can be a buffer or the name of a buffer. (Frequently, *buffer-or-name* is the value returned by the function `help-buffer`.) This macro puts the specified buffer into Help mode and displays a message telling the user how to quit and scroll the help window. It selects the help window if the current value of the user option `help-window-select` has been set accordingly. It returns the last value in *body*.

help-setup-xref *item* *interactive-p* [Function]

This function updates the cross reference data in the `*Help*` buffer, which is used to regenerate the help information when the user clicks on the ‘Back’ or ‘Forward’ buttons. Most commands that use the `*Help*` buffer should invoke this function before clearing the buffer. The *item* argument should have the form `(function . args)`, where *function* is a function to call, with argument list *args*, to regenerate the help buffer. The *interactive-p* argument is non-`nil` if the calling command was invoked interactively; in that case, the stack of items for the `*Help*` buffer’s ‘Back’ buttons is cleared.

See [describe-symbols example], page 597, for an example of using `help-buffer`, `with-help-window`, and `help-setup-xref`.

make-help-screen *fname* *help-line* *help-text* *help-map* [Macro]

This macro defines a help command named *fname* that acts like a prefix key that shows a list of the subcommands it offers.

When invoked, *fname* displays *help-text* in a window, then reads and executes a key sequence according to *help-map*. The string *help-text* should describe the bindings available in *help-map*.

The command *fname* is defined to handle a few events itself, by scrolling the display of *help-text*. When *fname* reads one of those special events, it does the scrolling and then reads another event. When it reads an event that is not one of those few, and which has a binding in *help-map*, it executes that key's binding and then returns.

The argument *help-line* should be a single-line summary of the alternatives in *help-map*. In the current version of Emacs, this argument is used only if you set the option **three-step-help** to t.

This macro is used in the command **help-for-help** which is the binding of *C-h C-h*.

three-step-help [User Option]
 If this variable is non-nil, commands defined with **make-help-screen** display their *help-line* strings in the echo area at first, and display the longer *help-text* strings only if the user types the help character again.

25.7 Documentation Groups

Emacs can list functions based on various groupings. For instance, **string-trim** and **mapconcat** are “string” functions, so *M-x shortdoc RET string RET* will give an overview of functions that operate on strings.

The documentation groups are created with the **define-short-documentation-group** macro.

define-short-documentation-group *group &rest functions* [Macro]
 Define *group* as a group of functions, and provide short summaries of using those functions. The optional argument *functions* is a list whose elements are of the form:

```
(func [keyword val] ...)
```

The following keywords are recognized:

:eval The value should be a form that has no side effect when evaluated. The form will be used in the documentation by printing it with **prin1** (see Section 20.5 [Output Functions], page 377). However, if the form is a string, it will be inserted as-is, and the string will then be **read** to yield the form. In any case, the form will then be evaluated, and the result used. For instance:

```
:eval (concat "foo" "bar" "zot")
:eval "(make-string 5 ?x)"
```

will result in:

```
(concat "foo" "bar" "zot")
⇒ "foobazot"
(make-string 5 ?x)
⇒ "xxxxx"
```

(The reason for allowing both Lisp forms and strings here is so that printing could be controlled in the few cases where a certain presentation of the form is wished for. In the example, ‘?x’ would otherwise have been printed as ‘120’ if it hadn’t been included in a string.)

:no-eval

This is like **:eval**, except that the form will not be evaluated. In these cases, a **:result** element of some kind (see below) should be included.

```
:no-eval (file-symlink-p "/tmp/foo")
:eg-result t
```

:no-eval*

Like **:no-eval**, but always inserts ‘[it depends]’ as the result. For instance:

```
:no-eval* (buffer-string)
```

will result in:

```
(buffer-string)
→ [it depends]
```

:no-value

Like **:no-eval**, but is used when the function in question has no well-defined return value, and is used for side effect only.

:result Used to output the result from non-evaluating example forms.

```
:no-eval (setcar list 'c)
:result c
```

:eg-result

Used to output an example result from non-evaluating example forms. For instance:

```
:no-eval (looking-at "f[0-9]")
:eg-result t
```

will result in:

```
(looking-at "f[0-9]")
eg. → t
```

:result-string**:eg-result-string**

These two are the same as **:result** and **:eg-result**, respectively, but are inserted as is. This is useful when the result is unreadable or should be of a particular form:

```
:no-eval (find-file "/tmp/foo")
:eg-result-string "#<buffer foo>"
:no-eval (default-file-modes)
:eg-result-string "#o755"
```

:no-manual

Indicates that this function is not documented in the manual.

:args By default, the function’s actual argument list is shown. If **:args** is present, they are used instead.

```
:args (regexp string)
```

Here's a very short example:

```
(define-short-documentation-group string
  "Creating Strings"
  (substring
   :eval (substring "foobar" 0 3)
   :eval (substring "foobar" 3))
  (concat
   :eval (concat "foo" "bar" "zot")))
```

The first argument is the name of the group to be defined, and then follows any number of function descriptions.

A function can belong to any number of documentation groups.

In addition to function descriptions, the list can also have string elements, which are used to divide a documentation group into sections.

shortdoc-add-function *group section elem* [Function]

Lisp packages can add functions to groups with this function. Each *elem* should be a function description, as described above. *group* is the function group, and *section* is what section in the function group to insert the function into.

If *group* doesn't exist, it will be created. If *section* doesn't exist, it will be added to the end of the function group.

26 Files

This chapter describes the Emacs Lisp functions and variables to find, create, view, save, and otherwise work with files and directories. A few other file-related functions are described in Chapter 28 [Buffers], page 671, and those related to backups and auto-saving are described in Chapter 27 [Backups and Auto-Saving], page 659.

Many of the file functions take one or more arguments that are file names. A file name is a string. Most of these functions expand file name arguments using the function `expand-file-name`, so that `~` is handled correctly, as are relative file names (including `..`/ and the empty string). See Section 26.9.4 [File Name Expansion], page 639.

In addition, certain *magic* file names are handled specially. For example, when a remote file name is specified, Emacs accesses the file over the network via an appropriate protocol. See Section “Remote Files” in *The GNU Emacs Manual*. This handling is done at a very low level, so you may assume that all the functions described in this chapter accept magic file names as file name arguments, except where noted. See Section 26.12 [Magic File Names], page 649, for details.

When file I/O functions signal Lisp errors, they usually use the condition `file-error` (see Section 11.7.3.3 [Handling Errors], page 182). The error message is in most cases obtained from the operating system, according to locale `system-messages-locale`, and decoded using coding system `locale-coding-system` (see Section 34.12 [Locales], page 991).

26.1 Visiting Files

Visiting a file means reading a file into a buffer. Once this is done, we say that the buffer is *visiting* that file, and call the file *the visited file* of the buffer.

A file and a buffer are two different things. A file is information recorded permanently in the computer (unless you delete it). A buffer, on the other hand, is information inside of Emacs that will vanish at the end of the editing session (or when you kill the buffer). When a buffer is visiting a file, it contains information copied from the file. The copy in the buffer is what you modify with editing commands. Changes to the buffer do not change the file; to make the changes permanent, you must save the buffer, which means copying the altered buffer contents back into the file.

Despite the distinction between files and buffers, people often refer to a file when they mean a buffer and vice-versa. Indeed, we say, “I am editing a file”, rather than, “I am editing a buffer that I will soon save as a file of the same name”. Humans do not usually need to make the distinction explicit. When dealing with a computer program, however, it is good to keep the distinction in mind.

26.1.1 Functions for Visiting Files

This section describes the functions normally used to visit files. For historical reasons, these functions have names starting with ‘`find-`’ rather than ‘`visit-`’. See Section 28.4 [Buffer File Name], page 675, for functions and variables that access the visited file name of a buffer or that find an existing buffer by its visited file name.

In a Lisp program, if you want to look at the contents of a file but not alter it, the fastest way is to use `insert-file-contents` in a temporary buffer. Visiting the file is not necessary and takes longer. See Section 26.3 [Reading from Files], page 614.

find-file *filename* &optional *wildcards* [Command]

This command selects a buffer visiting the file *filename*, using an existing buffer if there is one, and otherwise creating a new buffer and reading the file into it. It also returns that buffer.

Aside from some technical details, the body of the **find-file** function is basically equivalent to:

```
(switch-to-buffer (find-file-noselect filename nil nil wildcards))
```

(See **switch-to-buffer** in Section 29.12 [Switching Buffers], page 721.)

If *wildcards* is non-*nil*, which is always true in an interactive call, then **find-file** expands wildcard characters in *filename* and visits all the matching files.

When **find-file** is called interactively, it prompts for *filename* in the minibuffer.

find-file-literally *filename* [Command]

This command visits *filename*, like **find-file** does, but it does not perform any format conversions (see Section 26.13 [Format Conversion], page 654), character code conversions (see Section 34.10 [Coding Systems], page 976), or end-of-line conversions (see Section 34.10.1 [Coding System Basics], page 977). The buffer visiting the file is made unibyte, and its major mode is Fundamental mode, regardless of the file name. File local variable specifications in the file (see Section 12.12 [File Local Variables], page 213) are ignored, and automatic decompression and adding a newline at the end of the file due to **require-final-newline** (see Section 26.2 [Saving Buffers], page 612) are also disabled.

Note that if Emacs already has a buffer visiting the same file non-literally, it will not visit the same file literally, but instead just switch to the existing buffer. If you want to be sure of accessing a file's contents literally, you should create a temporary buffer and then read the file contents into it using **insert-file-contents-literally** (see Section 26.3 [Reading from Files], page 614).

find-file-noselect *filename* &optional *nowarn rawfile wildcards* [Function]

This function is the guts of all the file-visiting functions. It returns a buffer visiting the file *filename*. You may make the buffer current or display it in a window if you wish, but this function does not do so.

The function returns an existing buffer if there is one; otherwise it creates a new buffer and reads the file into it. When **find-file-noselect** uses an existing buffer, it first verifies that the file has not changed since it was last visited or saved in that buffer. If the file has changed, this function asks the user whether to reread the changed file. If the user says ‘yes’, any edits previously made in the buffer are lost.

Reading the file involves decoding the file's contents (see Section 34.10 [Coding Systems], page 976), including end-of-line conversion, and format conversion (see Section 26.13 [Format Conversion], page 654). If *wildcards* is non-*nil*, then **find-file-noselect** expands wildcard characters in *filename* and visits all the matching files.

This function displays warning or advisory messages in various peculiar cases, unless the optional argument *nowarn* is non-*nil*. For example, if it needs to create a buffer, and there is no file named *filename*, it displays the message ‘(New file)’ in the echo area, and leaves the buffer empty.

The `find-file-noselect` function normally calls `after-find-file` after reading the file (see Section 26.1.2 [Subroutines of Visiting], page 611). That function sets the buffer major mode, parses local variables, warns the user if there exists an auto-save file more recent than the file just visited, and finishes by running the functions in `find-file-hook`.

If the optional argument `rawfile` is non-`nil`, then `after-find-file` is not called, and the `find-file-not-found-functions` are not run in case of failure. What's more, a non-`nil` `rawfile` value suppresses coding system conversion and format conversion.

The `find-file-noselect` function usually returns the buffer that is visiting the file `filename`. But, if wildcards are actually used and expanded, it returns a list of buffers that are visiting the various files.

```
(find-file-noselect "/etc/fstab")
⇒ #<buffer fstab>
```

`find-file-other-window` *filename* &`optional wildcards` [Command]

This command selects a buffer visiting the file `filename`, but does so in a window other than the selected window. It may use another existing window or split a window; see Section 29.12 [Switching Buffers], page 721.

When this command is called interactively, it prompts for `filename`.

`find-file-read-only` *filename* &`optional wildcards` [Command]

This command selects a buffer visiting the file `filename`, like `find-file`, but it marks the buffer as read-only. See Section 28.7 [Read Only Buffers], page 680, for related functions and variables.

When this command is called interactively, it prompts for `filename`.

`find-file-wildcards` [User Option]

If this variable is non-`nil`, then the various `find-file` commands check for wildcard characters and visit all the files that match them (when invoked interactively or when their `wildcards` argument is non-`nil`). If this option is `nil`, then the `find-file` commands ignore their `wildcards` argument and never treat wildcard characters specially.

`find-file-hook` [User Option]

The value of this variable is a list of functions to be called after a file is visited. The file's local-variables specification (if any) will have been processed before the hooks are run. The buffer visiting the file is current when the hook functions are run.

This variable is a normal hook. See Section 24.1 [Hooks], page 524.

`find-file-not-found-functions` [Variable]

The value of this variable is a list of functions to be called when `find-file` or `find-file-noselect` is passed a nonexistent file name. `find-file-noselect` calls these functions as soon as it detects a nonexistent file. It calls them in the order of the list, until one of them returns non-`nil`. `buffer-file-name` is already set up.

This is not a normal hook because the values of the functions are used, and in many cases only some of the functions are called.

find-file-literally [Variable]

This buffer-local variable, if set to a non-nil value, makes `save-buffer` behave as if the buffer were visiting its file literally, i.e., without conversions of any kind. The command `find-file-literally` sets this variable's local value, but other equivalent functions and commands can do that as well, e.g., to avoid automatic addition of a newline at the end of the file. This variable is permanent local, so it is unaffected by changes of major modes.

26.1.2 Subroutines of Visiting

The `find-file-noselect` function uses two important subroutines which are sometimes useful in user Lisp code: `create-file-buffer` and `after-find-file`. This section explains how to use them.

create-file-buffer filename [Function]

This function creates a suitably named buffer for visiting `filename`, and returns it. It uses `filename` (sans directory) as the name if that name is free; otherwise, it appends a string such as '`<2>`' to get an unused name. See also Section 28.9 [Creating Buffers], page 684. Note that the `uniquify` library affects the result of this function. See Section "Uniquify" in *The GNU Emacs Manual*.

Please note: `create-file-buffer` does *not* associate the new buffer with a file and does not select the buffer. It also does not use the default major mode.

```
(create-file-buffer "foo")
  ⇒ #<buffer foo>
(create-file-buffer "foo")
  ⇒ #<buffer foo<2>>
(create-file-buffer "foo")
  ⇒ #<buffer foo<3>>
```

This function is used by `find-file-noselect`. It uses `generate-new-buffer` (see Section 28.9 [Creating Buffers], page 684).

after-find-file &optional error warn noauto [Function]
after-find-file-from-revert-buffer nomodes

This function sets the buffer major mode, and parses local variables (see Section 24.2.2 [Auto Major Mode], page 531). It is called by `find-file-noselect` and by the default revert function (see Section 27.3 [Reverting], page 667).

If reading the file got an error because the file does not exist, but its directory does exist, the caller should pass a non-nil value for `error`. In that case, `after-find-file` issues a warning: '(`New file`)'. For more serious errors, the caller should usually not call `after-find-file`.

If `warn` is non-nil, then this function issues a warning if an auto-save file exists and is more recent than the visited file.

If `noauto` is non-nil, that says not to enable or disable Auto-Save mode. The mode remains enabled if it was enabled before.

If `after-find-file-from-revert-buffer` is non-nil, that means this call was from `revert-buffer`. This has no direct effect, but some mode functions and hook functions check the value of this variable.

If `nomodes` is non-`nil`, that means don't alter the buffer's major mode, don't process local variables specifications in the file, and don't run `find-file-hook`. This feature is used by `revert-buffer` in some cases.

The last thing `after-find-file` does is call all the functions in the list `find-file-hook`.

26.2 Saving Buffers

When you edit a file in Emacs, you are actually working on a buffer that is visiting that file—that is, the contents of the file are copied into the buffer and the copy is what you edit. Changes to the buffer do not change the file until you *save* the buffer, which means copying the contents of the buffer into the file. Buffers which are not visiting a file can still be “saved”, in a sense, using functions in the buffer-local `write-contents-functions` hook.

save-buffer &optional backup-option [Command]

This function saves the contents of the current buffer in its visited file if the buffer has been modified since it was last visited or saved. Otherwise it does nothing.

`save-buffer` is responsible for making backup files. Normally, `backup-option` is `nil`, and `save-buffer` makes a backup file only if this is the first save since visiting the file. Other values for `backup-option` request the making of backup files in other circumstances:

- With an argument of 4 or 64, reflecting 1 or 3 `C-u`'s, the `save-buffer` function marks this version of the file to be backed up when the buffer is next saved.
- With an argument of 16 or 64, reflecting 2 or 3 `C-u`'s, the `save-buffer` function unconditionally backs up the previous version of the file before saving it.
- With an argument of 0, unconditionally do *not* make any backup file.

save-some-buffers &optional save-silently-p pred [Command]

This command saves some modified file-visiting buffers. Normally it asks the user about each buffer. But if `save-silently-p` is non-`nil`, it saves all the file-visiting buffers without querying the user.

The optional `pred` argument provides a predicate that controls which buffers to ask about (or to save silently if `save-silently-p` is non-`nil`). If `pred` is `nil`, that means to use the value of `save-some-buffers-default-predicate` instead of `pred`. If the result is `nil`, it means ask only about file-visiting buffers. If it is `t`, that means also offer to save certain other non-file buffers—those that have a non-`nil` buffer-local value of `buffer-offer-save` (see Section 28.10 [Killing Buffers], page 685). A user who says ‘yes’ to saving a non-file buffer is asked to specify the file name to use. The `save-buffers-kill-emacs` function passes the value `t` for `pred`.

If the predicate is neither `t` nor `nil`, then it should be a function of no arguments. It will be called in each buffer to decide whether to offer to save that buffer. If it returns a non-`nil` value in a certain buffer, that means do offer to save that buffer.

write-file filename &optional confirm [Command]

This function writes the current buffer into file `filename`, makes the buffer visit that file, and marks it not modified. Then it renames the buffer based on `filename`, appending a string like ‘`<2>`’ if necessary to make a unique buffer name. It does most of this work

by calling `set-visited-file-name` (see Section 28.4 [Buffer File Name], page 675) and `save-buffer`.

If `confirm` is non-`nil`, that means to ask for confirmation before overwriting an existing file. Interactively, confirmation is required, unless the user supplies a prefix argument.

If `filename` is a directory name (see Section 26.9.3 [Directory Names], page 637), `write-file` uses the name of the visited file, in directory `filename`. If the buffer is not visiting a file, it uses the buffer name instead.

Saving a buffer runs several hooks. It also performs format conversion (see Section 26.13 [Format Conversion], page 654). Note that these hooks, described below, are only run by `save-buffer`, they are not run by other primitives and functions that write buffer text to files, and in particular auto-saving (see Section 27.2 [Auto-Saving], page 664) doesn't run these hooks.

`write-file-functions`

[Variable]

The value of this variable is a list of functions to be called before writing out a buffer to its visited file. If one of them returns non-`nil`, the file is considered already written and the rest of the functions are not called, nor is the usual code for writing the file executed.

If a function in `write-file-functions` returns non-`nil`, it is responsible for making a backup file (if that is appropriate). To do so, execute the following code:

```
(or buffer-backed-up (backup-buffer))
```

You might wish to save the file modes value returned by `backup-buffer` and use that (if non-`nil`) to set the mode bits of the file that you write. This is what `save-buffer` normally does. See Section 27.1.1 [Making Backup Files], page 659.

The hook functions in `write-file-functions` are also responsible for encoding the data (if desired): they must choose a suitable coding system and end-of-line conversion (see Section 34.10.3 [Lisp and Coding Systems], page 979), perform the encoding (see Section 34.10.7 [Explicit Encoding], page 988), and set `last-coding-system-used` to the coding system that was used (see Section 34.10.2 [Encoding and I/O], page 978).

If you set this hook locally in a buffer, it is assumed to be associated with the file or the way the contents of the buffer were obtained. Thus the variable is marked as a permanent local, so that changing the major mode does not alter a buffer-local value. On the other hand, calling `set-visited-file-name` will reset it. If this is not what you want, you might like to use `write-contents-functions` instead.

Even though this is not a normal hook, you can use `add-hook` and `remove-hook` to manipulate the list. See Section 24.1 [Hooks], page 524.

`write-contents-functions`

[Variable]

This works just like `write-file-functions`, but it is intended for hooks that pertain to the buffer's contents, not to the particular visited file or its location, and can be used to create arbitrary save processes for buffers that aren't visiting files at all. Such hooks are usually set up by major modes, as buffer-local bindings for this variable. This variable automatically becomes buffer-local whenever it is set; switching to a new major mode always resets this variable, but calling `set-visited-file-name` does not.

If any of the functions in this hook returns non-`nil`, the file is considered already written and the rest are not called and neither are the functions in `write-file-functions`. When using this hook to save buffers that are not visiting files (for instance, special-mode buffers), keep in mind that, if the function fails to save correctly and returns a `nil` value, `save-buffer` will go on to prompt the user for a file to save the buffer in. If this is undesirable, consider having the function fail by raising an error.

before-save-hook [User Option]

This normal hook runs before a buffer is saved in its visited file, regardless of whether that is done normally or by one of the hooks described above. For instance, the `copyright.el` program uses this hook to make sure the file you are saving has the current year in its copyright notice.

after-save-hook [User Option]

This normal hook runs after a buffer has been saved in its visited file.

file-precious-flag [User Option]

If this variable is non-`nil`, then `save-buffer` protects against I/O errors while saving by writing the new file to a temporary name instead of the name it is supposed to have, and then renaming it to the intended name after it is clear there are no errors. This procedure prevents problems such as a lack of disk space from resulting in an invalid file.

As a side effect, backups are necessarily made by copying. See Section 27.1.2 [Rename or Copy], page 661. Yet, at the same time, saving a precious file always breaks all hard links between the file you save and other file names.

Some modes give this variable a non-`nil` buffer-local value in particular buffers.

require-final-newline [User Option]

This variable determines whether files may be written out that do *not* end with a newline. If the value of the variable is `t`, then `save-buffer` silently adds a newline at the end of the buffer whenever it does not already end in one. If the value is `visit`, Emacs adds a missing newline just after it visits the file. If the value is `visit-save`, Emacs adds a missing newline both on visiting and on saving. For any other non-`nil` value, `save-buffer` asks the user whether to add a newline each time the case arises.

If the value of the variable is `nil`, then `save-buffer` doesn't add newlines at all. `nil` is the default value, but a few major modes set it to `t` in particular buffers.

See also the function `set-visited-file-name` (see Section 28.4 [Buffer File Name], page 675).

26.3 Reading from Files

To copy the contents of a file into a buffer, use the function `insert-file-contents`. (Don't use the command `insert-file` in a Lisp program, as that sets the mark.)

insert-file-contents filename &optional visit beg end replace [Function]

This function inserts the contents of file `filename` into the current buffer after point. It returns a list of the absolute file name and the length of the data inserted. An error is signaled if `filename` is not the name of a file that can be read.

This function checks the file contents against the defined file formats, and converts the file contents if appropriate and also calls the functions in the list `after-insert-file-functions`. See Section 26.13 [Format Conversion], page 654. Normally, one of the functions in the `after-insert-file-functions` list determines the coding system (see Section 34.10 [Coding Systems], page 976) used for decoding the file’s contents, including end-of-line conversion. However, if the file contains null bytes, it is by default visited without any code conversions. See Section 34.10.3 [Lisp and Coding Systems], page 979.

If `visit` is non-`nil`, this function additionally marks the buffer as unmodified and sets up various fields in the buffer so that it is visiting the file `filename`: these include the buffer’s visited file name and its last save file modtime. This feature is used by `find-file-noselect` and you probably should not use it yourself.

If `beg` and `end` are non-`nil`, they should be numbers that are byte offsets specifying the portion of the file to insert. In this case, `visit` must be `nil`. For example,

```
(insert-file-contents filename nil 0 500)
```

inserts the characters coded by the first 500 bytes of a file.

If `beg` or `end` happens to be in the middle of a character’s multibyte sequence, Emacs’s character code conversion will insert one or more eight-bit characters (a.k.a. “raw bytes”) (see Section 34.7 [Character Sets], page 973) into the buffer. If you want to read part of a file this way, we recommend to bind `coding-system-for-read` to a suitable value around the call to this function (see Section 34.10.6 [Specifying Coding Systems], page 986), and to write Lisp code which will check for raw bytes at the boundaries, read the entire sequence of these bytes, and convert them back to valid characters.

If the argument `replace` is non-`nil`, it means to replace the contents of the buffer (actually, just the accessible portion) with the contents of the file. This is better than simply deleting the buffer contents and inserting the whole file, because (1) it preserves some marker positions and (2) it puts less data in the undo list.

It is possible to read a special file (such as a FIFO or an I/O device) with `insert-file-contents`, as long as `replace`, and `visit` and `beg` are `nil`. However, you should normally use an `end` argument for these files to avoid inserting (potentially) unlimited data into the buffer (for instance, when inserting data from `/dev/urandom`).

insert-file-contents-literally *filename* &**optional** *visit* *beg* *end* [Function]
 replace

This function works like `insert-file-contents` except that each byte in the file is handled separately, being converted into an eight-bit character if needed. It does not run `after-insert-file-functions`, and does not do format decoding, character code conversion, automatic uncompression, and so on.

If you want to pass a file name to another process so that another program can read the file, use the function `file-local-copy`; see Section 26.12 [Magic File Names], page 649.

26.4 Writing to Files

You can write the contents of a buffer, or part of a buffer, directly to a file on disk using the `append-to-file` and `write-region` functions. Don't use these functions to write to files that are being visited; that could cause confusion in the mechanisms for visiting.

`append-to-file start end filename` [Command]

This function appends the contents of the region delimited by `start` and `end` in the current buffer to the end of file `filename`. If that file does not exist, it is created. This function returns `nil`.

An error is signaled if you cannot write or create `filename`.

When called from Lisp, this function is completely equivalent to:

```
(write-region start end filename t)
```

`write-region start end filename &optional append visit lockname mustbenew` [Command]

This function writes the region delimited by `start` and `end` in the current buffer into the file specified by `filename`.

If `start` is `nil`, then the command writes the entire buffer contents (*not* just the accessible portion) to the file and ignores `end`.

If `start` is a string, then `write-region` writes or appends that string, rather than text from the buffer. `end` is ignored in this case.

If `append` is non-`nil`, then the specified text is appended to the existing file contents (if any). If `append` is a number, `write-region` seeks to that byte offset from the start of the file and writes the data from there.

If `mustbenew` is non-`nil`, then `write-region` asks for confirmation if `filename` names an existing file. If `mustbenew` is the symbol `excl`, then `write-region` does not ask for confirmation, but instead it signals an error `file-already-exists` if the file already exists. Although `write-region` normally follows a symbolic link and creates the pointed-to file if the symbolic link is dangling, it does not follow symbolic links if `mustbenew` is `excl`.

The test for an existing file, when `mustbenew` is `excl`, uses a special system feature. At least for files on a local disk, there is no chance that some other program could create a file of the same name before Emacs does, without Emacs's noticing.

If `visit` is `t`, then Emacs establishes an association between the buffer and the file: the buffer is then visiting that file. It also sets the last file modification time for the current buffer to `filename`'s modtime, and marks the buffer as not modified. This feature is used by `save-buffer`, but you probably should not use it yourself.

If `visit` is a string, it specifies the file name to visit. This way, you can write the data to one file (`filename`) while recording the buffer as visiting another file (`visit`). The argument `visit` is used in the echo area message and also for file locking; `visit` is stored in `buffer-file-name`. This feature is used to implement `file-precious-flag`; don't use it yourself unless you really know what you're doing.

The optional argument `lockname`, if non-`nil`, specifies the file name to use for purposes of locking and unlocking, overriding `filename` and `visit` for that purpose.

The function `write-region` converts the data which it writes to the appropriate file formats specified by `buffer-file-format` and also calls the functions in the list `write-region-annotate-functions`. See Section 26.13 [Format Conversion], page 654.

Normally, `write-region` displays the message ‘Wrote *filename*’ in the echo area. This message is inhibited if `visit` is neither `t` nor `nil` nor a string, or if Emacs is operating in batch mode (see Section 42.17 [Batch Mode], page 1289). This feature is useful for programs that use files for internal purposes, files that the user does not need to know about.

write-region-inhibit-fsync [Variable]

If this variable’s value is `nil`, `write-region` uses the `fsync` system call after writing a file. Although this slows Emacs down, it lessens the risk of data loss after power failure. If the value is `t`, Emacs does not use `fsync`. The default value is `nil` when Emacs is interactive, and `t` when Emacs runs in batch mode. See Section 26.8 [Files and Storage], page 634.

with-temp-file *file body...* [Macro]

The `with-temp-file` macro evaluates the *body* forms with a temporary buffer as the current buffer; then, at the end, it writes the buffer contents into file *file*. It kills the temporary buffer when finished, restoring the buffer that was current before the `with-temp-file` form. Then it returns the value of the last form in *body*.

The current buffer is restored even in case of an abnormal exit via `throw` or error (see Section 11.7 [Nonlocal Exits], page 177).

Like `with-temp-buffer` (see [Current Buffer], page 673), the temporary buffer used by this macro does not run the hooks `kill-buffer-hook`, `kill-buffer-query-functions` (see Section 28.10 [Killing Buffers], page 685), and `buffer-list-update-hook` (see Section 28.8 [Buffer List], page 681).

26.5 File Locks

When two users edit the same file at the same time, they are likely to interfere with each other. Emacs tries to prevent this situation from arising by recording a *file lock* when a file is being modified. Emacs can then detect the first attempt to modify a buffer visiting a file that is locked by another Emacs job, and ask the user what to do. The file lock is really a file, a symbolic link with a special name, stored in the same directory as the file you are editing. The name is constructed by prepending `.#` to the file name of the buffer. The target of the symbolic link will be of the form `user@host.pid:boot`, where `user` is replaced with the current username (from `user-login-name`), `host` with the name of the host where Emacs is running (from `system-name`), `pid` with Emacs’s process id, and `boot` with the time since the last reboot. `:boot` is omitted if the boot time is unavailable. (On file systems that do not support symbolic links, a regular file is used instead, with contents of the form `user@host.pid:boot`.)

When you access files using NFS, there may be a small probability that you and another user will both lock the same file simultaneously. If this happens, it is possible for the two users to make changes simultaneously, but Emacs will still warn the user who saves second.

Also, the detection of modification of a buffer visiting a file changed on disk catches some cases of simultaneous editing; see Section 28.6 [Modification Time], page 678.

file-locked-p *filename*

[Function]

This function returns **nil** if the file *filename* is not locked. It returns **t** if it is locked by this Emacs process, and it returns the name of the user who has locked it if it is locked by some other job.

```
(file-locked-p "foo")
⇒ nil
```

lock-buffer &**optional** *filename*

[Function]

This function locks the file *filename*, if the current buffer is modified. The argument *filename* defaults to the current buffer's visited file. Nothing is done if the current buffer is not visiting a file, or is not modified, or if the option **create-lockfiles** is **nil**.

unlock-buffer

[Function]

This function unlocks the file being visited in the current buffer, if the buffer is modified. If the buffer is not modified, then the file should not be locked, so this function does nothing. It also does nothing if the current buffer is not visiting a file, or is not locked. This function handles file system errors by calling **display-warning** and otherwise ignores the error.

create-lockfiles

[User Option]

If this variable is **nil**, Emacs does not lock files.

lock-file-name-transforms

[User Option]

By default, Emacs creates the lock files in the same directory as the files that are being locked. This can be changed by customizing this variable. It has the same syntax as **auto-save-file-name-transforms** (see Section 27.2 [Auto-Saving], page 664). For instance, to make Emacs write all the lock files to **/var/tmp/**, you could say something like:

```
(setq lock-file-name-transforms
      '("^\./.*\(\[^/\]+\\)\\" "/var/tmp/\1" t))
```

ask-user-about-lock *file other-user*

[Function]

This function is called when the user tries to modify *file*, but it is locked by another user named *other-user*. The default definition of this function asks the user to say what to do. The value this function returns determines what Emacs does next:

- A value of **t** says to grab the lock on the file. Then this user may edit the file and *other-user* loses the lock.
- A value of **nil** says to ignore the lock and let this user edit the file anyway.
- This function may instead signal a **file-locked** error, in which case the change that the user was about to make does not take place.

The error message for this error looks like this:

[error] File is locked: file other-user

where **file** is the name of the file and *other-user* is the name of the user who has locked the file.

If you wish, you can replace the `ask-user-about-lock` function with your own version that makes the decision in another way.

remote-file-name-inhibit-locks

[User Option]

You can prevent the creation of remote lock files by setting the variable `remote-file-name-inhibit-locks` to `t`.

lock-file-mode

[Command]

This command, called interactively, toggles the local value of `create-lockfiles` in the current buffer.

26.6 Information about Files

This section describes the functions for retrieving various types of information about files (or directories or symbolic links), such as whether a file is readable or writable, and its size. These functions all take arguments which are file names. Except where noted, these arguments need to specify existing files, or an error is signaled.

Be careful with file names that end in spaces. On some filesystems (notably, MS-Windows), trailing whitespace characters in file names are silently and automatically ignored.

26.6.1 Testing Accessibility

These functions test for permission to access a file for reading, writing, or execution. Unless explicitly stated otherwise, they follow symbolic links. See Section 26.6.2 [Kinds of Files], page 621.

On some operating systems, more complex sets of access permissions can be specified, via mechanisms such as Access Control Lists (ACLs). See Section 26.6.5 [Extended Attributes], page 627, for how to query and set those permissions.

file-exists-p *filename*

[Function]

This function returns `t` if a file named *filename* appears to exist. This does not mean you can necessarily read the file, only that you can probably find out its attributes. (On GNU and other POSIX-like systems, this is true if the file exists and you have execute permission on the containing directories, regardless of the permissions of the file itself.)

If the file does not exist, or if there was trouble determining whether the file exists, this function returns `nil`.

Since a file name that is an empty string is interpreted relative to the current buffer's default directory (see Section 26.9.2 [Relative File Names], page 637), calling `file-exists-p` with an argument that is an empty string will report about the buffer's default directory.

Directories are files, so `file-exists-p` can return `t` when given a directory. However, because `file-exists-p` follows symbolic links, it returns `t` for a symbolic link name only if the target of the link exists; if your Lisp program needs to consider *dangling symlinks* whose target doesn't exist as existing files, use `file-attributes` (see Section 26.6.4 [File Attributes], page 624) instead of `file-exists-p`.

file-readable-p *filename* [Function]

This function returns `t` if a file named *filename* exists and you can read it. It returns `nil` otherwise.

file-executable-p *filename* [Function]

This function returns `t` if a file named *filename* exists and you can execute it. It returns `nil` otherwise. On GNU and other POSIX-like systems, if the file is a directory, execute permission means you can check the existence and attributes of files inside the directory, and open those files if their modes permit.

file-writable-p *filename* [Function]

This function returns `t` if the file *filename* can be written or created by you, and `nil` otherwise. A file is writable if the file exists and you can write it. It is creatable if it does not exist, but its parent directory does exist and you can write in that directory.

In the example below, `foo` is not writable because the parent directory does not exist, even though the user could create such a directory.

```
(file-writable-p "~/no-such-dir/foo")
⇒ nil
```

file-accessible-directory-p *dirname* [Function]

This function returns `t` if you have permission to open existing files in the directory whose name as a file is *dirname*; otherwise (e.g., if there is no such directory), it returns `nil`. The value of *dirname* may be either a directory name (such as `/foo/`) or the file name of a file which is a directory (such as `/foo`, without the final slash).

For example, from the following we deduce that any attempt to read a file in `/foo/` will give an error:

```
(file-accessible-directory-p "/foo")
⇒ nil
```

with-existing-directory *body...* [Macro]

This macro ensures that `default-directory` is bound to an existing directory before executing *body*. If `default-directory` already exists, that's preferred, and otherwise some other directory is used. This macro can be useful, for instance, when calling an external command that requires that it's running in a directory that exists. The chosen directory is not guaranteed to be writable.

access-file *filename string* [Function]

If you can read *filename* this function returns `nil`; otherwise it signals an error using *string* as the error message text.

file-ownership-preserved-p *filename &optional group* [Function]

This function returns `t` if deleting the file *filename* and then creating it anew would keep the file's owner unchanged. It also returns `t` for nonexistent files.

If the optional argument *group* is non-`nil`, this function also checks that the file's group would be unchanged.

This function does not follow symbolic links.

file-modes *filename* &**optional flag** [Function]

This function returns the *mode bits* of *filename*—an integer summarizing its read, write, and execution permissions. This function follows symbolic links. If the file does not exist, the return value is `nil`.

See Section “File permissions” in *The GNU Coreutils Manual*, for a description of mode bits. For example, if the low-order bit is 1, the file is executable by all users; if the second-lowest-order bit is 1, the file is writable by all users; etc. The highest possible value is 4095 (7777 octal), meaning that everyone has read, write, and execute permission, the SUID bit is set for both others and group, and the sticky bit is set.

By default this function follows symbolic links. However, if the optional argument *flag* is the symbol `nofollow`, this function does not follow *filename* if it is a symbolic link; this can help prevent inadvertently obtaining the mode bits of a file somewhere else, and is more consistent with **file-attributes** (see Section 26.6.4 [File Attributes], page 624).

See Section 26.7 [Changing Files], page 629, for the **set-file-modes** function, which can be used to set these permissions.

```
(file-modes "~/junk/diffs" 'nofollow)
⇒ 492                                ; Decimal integer.
(format "%o" 492)
⇒ "754"                               ; Convert to octal.

(set-file-modes "~/junk/diffs" #o666 'nofollow)
⇒ nil

$ ls -l diffs
-rw-rw-rw- 1 lewis lewis 3063 Oct 30 16:00 diffs
```

MS-DOS note: On MS-DOS, there is no such thing as an executable file mode bit. So **file-modes** considers a file executable if its name ends in one of the standard executable extensions, such as `.com`, `.bat`, `.exe`, and some others. Files that begin with the POSIX-standard ‘#!’ signature, such as shell and Perl scripts, are also considered executable. Directories are also reported as executable, for compatibility with POSIX. These conventions are also followed by **file-attributes** (see Section 26.6.4 [File Attributes], page 624).

26.6.2 Distinguishing Kinds of Files

This section describes how to distinguish various kinds of files, such as directories, symbolic links, and ordinary files.

Symbolic links are ordinarily followed wherever they appear. For example, to interpret the file name `a/b/c`, any of `a`, `a/b`, and `a/b/c` can be symbolic links that are followed, possibly recursively if the link targets are themselves symbolic links. However, a few functions do not follow symbolic links at the end of a file name (`a/b/c` in this example). Such a function is said to *not follow symbolic links*.

file-symlink-p *filename* [Function]

If the file *filename* is a symbolic link, this function does not follow it and instead returns its link target as a string. (The link target string is not necessarily the full

absolute file name of the target; determining the full file name that the link points to is nontrivial, see below.)

If the file *filename* is not a symbolic link, or does not exist, or if there is trouble determining whether it is a symbolic link, `file-symlink-p` returns `nil`.

Here are a few examples of using this function:

```
(file-symlink-p "not-a-symlink")
  ⇒ nil
(file-symlink-p "sym-link")
  ⇒ "not-a-symlink"
(file-symlink-p "sym-link2")
  ⇒ "sym-link"
(file-symlink-p "/bin")
  ⇒ "/pub/bin"
```

Note that in the third example, the function returned `sym-link`, but did not proceed to resolve it, although that file is itself a symbolic link. That is because this function does not follow symbolic links—the process of following the symbolic links does not apply to the last component of the file name.

The string that this function returns is what is recorded in the symbolic link; it may or may not include any leading directories. This function does *not* expand the link target to produce a fully-qualified file name, and in particular does not use the leading directories, if any, of the *filename* argument if the link target is not an absolute file name. Here's an example:

```
(file-symlink-p "/foo/bar/baz")
  ⇒ "some-file"
```

Here, although `/foo/bar/baz` was given as a fully-qualified file name, the result is not, and in fact does not have any leading directories at all. And since `some-file` might itself be a symbolic link, you cannot simply prepend leading directories to it, nor even naively use `expand-file-name` (see Section 26.9.4 [File Name Expansion], page 639) to produce its absolute file name.

For this reason, this function is seldom useful if you need to determine more than just the fact that a file is or isn't a symbolic link. If you actually need the file name of the link target, use `file-chase-links` or `file-truename`, described in Section 26.6.3 [Truenames], page 623.

`file-directory-p filename` [Function]

This function returns `t` if *filename* is the name of an existing directory. It returns `nil` if *filename* does not name a directory, or if there is trouble determining whether it is a directory. This function follows symbolic links.

```
(file-directory-p "~rms")
  ⇒ t
(file-directory-p "~rms/lewis/files.texi")
  ⇒ nil
(file-directory-p "~rms/lewis/no-such-file")
  ⇒ nil
(file-directory-p "$HOME")
  ⇒ nil
```

```
(file-directory-p
  (substitute-in-file-name "$HOME"))
⇒ t

file-regular-p filename [Function]
```

This function returns `t` if the file *filename* exists and is a regular file (not a directory, named pipe, terminal, or other I/O device). It returns `nil` if *filename* does not exist or is not a regular file, or if there is trouble determining whether it is a regular file. This function follows symbolic links.

26.6.3 Truenames

The *truename* of a file is the name that you get by following symbolic links at all levels until none remain, then simplifying away ‘`.`’ and ‘`..`’ appearing as name components. This results in a sort of canonical name for the file. A file does not always have a unique truename; the number of distinct truenames a file has is equal to the number of hard links to the file. However, truenames are useful because they eliminate symbolic links as a cause of name variation.

```
file-truename filename [Function]
```

This function returns the truename of the file *filename*. If the argument is not an absolute file name, this function first expands it against `default-directory`.

This function does not expand environment variables. Only `substitute-in-file-name` does that. See [Definition of `substitute-in-file-name`], page 640.

If you may need to follow symbolic links preceding ‘`..`’ appearing as a name component, call `file-truename` without prior direct or indirect calls to `expand-file-name`. Otherwise, the file name component immediately preceding ‘`..`’ will be simplified away before `file-truename` is called. To eliminate the need for a call to `expand-file-name`, `file-truename` handles ‘`~`’ in the same way that `expand-file-name` does.

If the target of a symbolic links has remote file name syntax, `file-truename` returns it quoted. See Section 26.9.4 [Functions that Expand Filenames], page 639.

```
file-chase-links filename &optional limit [Function]
```

This function follows symbolic links, starting with *filename*, until it finds a file name which is not the name of a symbolic link. Then it returns that file name. This function does *not* follow symbolic links at the level of parent directories.

If you specify a number for *limit*, then after chasing through that many links, the function just returns what it has even if that is still a symbolic link.

To illustrate the difference between `file-chase-links` and `file-truename`, suppose that `/usr/foo` is a symbolic link to the directory `/home/foo`, and `/home/foo/hello` is an ordinary file (or at least, not a symbolic link) or nonexistent. Then we would have:

```
(file-chase-links "/usr/foo/hello")
;; This does not follow the links in the parent directories.
⇒ "/usr/foo/hello"
(file-truename "/usr/foo/hello")
;; Assuming that /home is not a symbolic link.
⇒ "/home/foo/hello"
```

file-equal-p *file1 file2*

[Function]

This function returns **t** if the files *file1* and *file2* name the same file. This is similar to comparing their truenames, except that remote file names are also handled in an appropriate manner. If *file1* or *file2* does not exist, the return value is unspecified.

file-name-case-insensitive-p *filename*

[Function]

Sometimes file names or their parts need to be compared as strings, in which case it's important to know whether the underlying filesystem is case-insensitive. This function returns **t** if file *filename* is on a case-insensitive filesystem. It always returns **t** on MS-DOS and MS-Windows. On Cygwin and macOS, filesystems may or may not be case-insensitive, and the function tries to determine case-sensitivity by a runtime test. If the test is inconclusive, the function returns **t** on Cygwin and **nil** on macOS.

Currently this function always returns **nil** on platforms other than MS-DOS, MS-Windows, Cygwin, and macOS. It does not detect case-insensitivity of mounted filesystems, such as Samba shares or NFS-mounted Windows volumes. On remote hosts, it assumes **t** for the ‘**smb**’ method. For all other connection methods, runtime tests are performed.

vc-responsible-backend *file*

[Function]

This function determines the responsible VC backend of the given *file*. For example, if **emacs.c** is a file tracked by Git, (**vc-responsible-backend "emacs.c"**) returns ‘**Git**’. Note that if *file* is a symbolic link, **vc-responsible-backend** will not resolve it—the backend of the symbolic link file itself is reported. To get the backend VC of the file to which *file* refers, wrap *file* with a symbolic link resolving function such as **file-chase-links**:

```
(vc-responsible-backend (file-chase-links "emacs.c"))
```

26.6.4 File Attributes

This section describes the functions for getting detailed information about a file, including the owner and group numbers, the number of names, the inode number, the size, and the times of access and modification.

file-newer-than-file-p *filename1 filename2*

[Function]

This function returns **t** if the file *filename1* is newer than file *filename2*. If *filename1* does not exist, it returns **nil**. If *filename1* does exist, but *filename2* does not, it returns **t**.

In the following example, assume that the file **aug-19** was written on the 19th, **aug-20** was written on the 20th, and the file **no-file** doesn't exist at all.

```
(file-newer-than-file-p "aug-19" "aug-20")
  ⇒ nil
(file-newer-than-file-p "aug-20" "aug-19")
  ⇒ t
(file-newer-than-file-p "aug-19" "no-file")
  ⇒ t
(file-newer-than-file-p "no-file" "aug-19")
  ⇒ nil
```

file-has-changed-p *filename tag* [Function]

This function returns `non-nil` if the time stamp of *filename* has changed since the last call. When called for the first time for some *filename*, it records the last modification time and size of the file, and returns `non-nil` when *filename* exists. Thereafter, when called for the same *filename*, it compares the current time stamp and size with the recorded ones, and returns `non-nil` only if either the time stamp or the size (or both) are different. This is useful when a Lisp program wants to re-read a file whenever it changes. With an optional argument *tag*, which must be a symbol, the size and modification time comparisons are limited to calls with the same tag.

file-attributes *filename &optional id-format* [Function]

This function returns a list of attributes of file *filename*. If the specified file does not exist, it returns `nil`. This function does not follow symbolic links. The optional parameter *id-format* specifies the preferred format of attributes UID and GID (see below)—the valid values are `'string` and `'integer`. The latter is the default, but we plan to change that, so you should specify a `non-nil` value for *id-format* if you use the returned UID or GID.

On GNU platforms when operating on a local file, this function is atomic: if the filesystem is simultaneously being changed by some other process, this function returns the file's attributes either before or after the change. Otherwise this function is not atomic, and might return `nil` if it detects the race condition, or might return a hodgepodge of the previous and current file attributes.

Accessor functions are provided to access the elements in this list. The accessors are mentioned along with the descriptions of the elements below.

The elements of the list, in order, are:

0. `t` for a directory, a string for a symbolic link (the name linked to), or `nil` for a text file (`file-attribute-type`).
1. The number of names the file has (`file-attribute-link-number`). Alternate names, also known as hard links, can be created by using the `add-name-to-file` function (see Section 26.7 [Changing Files], page 629).
2. The file's UID, normally as a string (`file-attribute-user-id`). However, if it does not correspond to a named user, the value is an integer.
3. The file's GID, likewise (`file-attribute-group-id`).
4. The time of last access as a Lisp timestamp (`file-attribute-access-time`). The timestamp is in the style of `current-time` (see Section 42.5 [Time of Day], page 1270) and is truncated to that of the filesystem's timestamp resolution; for example, on some FAT-based filesystems, only the date of last access is recorded, so this time will always hold the midnight of the day of the last access.
5. The time of last modification as a Lisp timestamp (`file-attribute-modification-time`). This is the last time when the file's contents were modified.
6. The time of last status change as a Lisp timestamp (`file-attribute-status-change-time`). This is the time of the last change to the file's access mode bits, its owner and group, and other information recorded in the filesystem for the file, beyond the file's contents.

7. The size of the file in bytes (`file-attribute-size`).
8. The file's modes, as a string of ten letters or dashes, as in ‘ls -l’ (`file-attribute-modes`).
9. An unspecified value, present for backward compatibility.
10. The file's inode number (`file-attribute-inode-number`), a nonnegative integer.
11. The filesystem's identifier of the device that the file is on (`file-attribute-device-number`), an integer or a cons cell of two integers. The latter is sometimes used by remote files, in order to distinguish remote filesystems from local ones.

The file's inode and device together give enough information to distinguish any two files on the system—no two files can have the same values for both of these attributes. This tuple that uniquely identifies the file is returned by `file-attribute-file-identifier`.

For example, here are the file attributes for `files.texi`:

```
(file-attributes "files.texi" 'string)
⇒ (nil 1 "lh" "users"
     (20614 64019 50040 152000)
     (20000 23 0 0)
     (20614 64555 902289 872000)
     122295 "-rw-rw-rw-"
     t 6473924464520138
     1014478468)
```

and here is how the result is interpreted:

<code>nil</code>	is neither a directory nor a symbolic link.
<code>1</code>	has only one name (the name <code>files.texi</code> in the current default directory).
<code>"lh"</code>	is owned by the user with name ‘ <code>lh</code> ’.
<code>"users"</code>	is in the group with name ‘ <code>users</code> ’.
<code>(20614 64019 50040 152000)</code>	was last accessed on October 23, 2012, at 20:12:03.050040152 UTC. (This timestamp is <code>(1351023123050040152 . 1000000000)</code> if <code>current-time-list</code> is <code>nil</code> .)
<code>(20000 23 0 0)</code>	was last modified on July 15, 2001, at 08:53:43.000000000 UTC. (This timestamp is <code>(1310720023000000000 . 1000000000)</code> if <code>current-time-list</code> is <code>nil</code> .)
<code>(20614 64555 902289 872000)</code>	last had its status changed on October 23, 2012, at 20:20:59.902289872 UTC. (This timestamp is <code>(1351023659902289872 . 1000000000)</code> if <code>current-time-list</code> is <code>nil</code> .)
<code>122295</code>	is 122295 bytes long. (It may not contain 122295 characters, though, if some of the bytes belong to multibyte sequences, and also if the end-of-line format is CR-LF.)

```
--rw-rw-rw--
has a mode of read and write access for the owner, group, and world.

t
is merely a placeholder; it carries no information.

6473924464520138
has an inode number of 6473924464520138.

1014478468
is on the file-system device whose number is 1014478468.
```

file-nlinks *filename*

[Function]

This function returns the number of names (i.e., hard links) that file *filename* has. If the file does not exist, this function returns **nil**. Note that symbolic links have no effect on this function, because they are not considered to be names of the files they link to. This function does not follow symbolic links.

```
$ ls -l foo*
-rw-rw-rw- 2 rms rms 4 Aug 19 01:27 foo
-rw-rw-rw- 2 rms rms 4 Aug 19 01:27 foo1

(file-nlinks "foo")
⇒ 2
(file-nlinks "doesnt-exist")
⇒ nil
```

26.6.5 Extended File Attributes

On some operating systems, each file can be associated with arbitrary *extended file attributes*. At present, Emacs supports querying and setting two specific sets of extended file attributes: Access Control Lists (ACLs) and SELinux contexts. These extended file attributes are used, on some systems, to impose more sophisticated file access controls than the basic Unix-style permissions discussed in the previous sections.

A detailed explanation of ACLs and SELinux is beyond the scope of this manual. For our purposes, each file can be associated with an *ACL*, which specifies its properties under an ACL-based file control system, and/or an *SELinux context*, which specifies its properties under the SELinux system.

file-acl *filename*

[Function]

This function returns the ACL for the file *filename*. The exact Lisp representation of the ACL is unspecified (and may change in future Emacs versions), but it is the same as what **set-file-acl** takes for its *acl* argument (see Section 26.7 [Changing Files], page 629).

The underlying ACL implementation is platform-specific; on GNU/Linux and BSD, Emacs uses the POSIX ACL interface, while on MS-Windows Emacs emulates the POSIX ACL interface with native file security APIs.

If ACLs are not supported or the file does not exist, then the return value is **nil**.

file-selinux-context *filename*

[Function]

This function returns the SELinux context of the file *filename*, as a list of the form (*user role type range*). The list elements are the context's user, role, type, and

range respectively, as Lisp strings; see the SELinux documentation for details about what these actually mean. The return value has the same form as what `set-file-selinux-context` takes for its `context` argument (see Section 26.7 [Changing Files], page 629).

If SELinux is not supported or the file does not exist, then the return value is `(nil nil nil nil)`.

file-extended-attributes *filename* [Function]

This function returns an alist of the Emacs-recognized extended attributes of file *filename*. Currently, it serves as a convenient way to retrieve both the ACL and SELinux context; you can then call the function `set-file-extended-attributes`, with the returned alist as its second argument, to apply the same file access attributes to another file (see Section 26.7 [Changing Files], page 629).

One of the elements is `(acl . acl)`, where *acl* has the same form returned by `file-acl`.

Another element is `(selinux-context . context)`, where *context* is the SELinux context, in the same form returned by `file-selinux-context`.

26.6.6 Locating Files in Standard Places

This section explains how to search for a file in a list of directories (a *path*), or for an executable file in the standard list of executable file directories.

To search for a user-specific configuration file, See Section 26.9.7 [Standard File Names], page 645, for the `locate-user-emacs-file` function.

locate-file *filename path &optional suffixes predicate* [Function]

This function searches for a file whose name is *filename* in a list of directories given by *path*, trying the suffixes in *suffixes*. If it finds such a file, it returns the file's absolute file name (see Section 26.9.2 [Relative File Names], page 637); otherwise it returns `nil`.

The optional argument *suffixes* gives the list of file-name suffixes to append to *filename* when searching. `locate-file` tries each possible directory with each of these suffixes. If *suffixes* is `nil`, or `("")`, then there are no suffixes, and *filename* is used only as-is. Typical values of *suffixes* are `exec-suffixes` (see Section 40.1 [Subprocess Creation], page 1078), `load-suffixes`, `load-file-rep-suffixes` and the return value of the function `get-load-suffixes` (see Section 16.2 [Load Suffixes], page 300).

Typical values for *path* are `exec-path` (see Section 40.1 [Subprocess Creation], page 1078) when looking for executable programs, or `load-path` (see Section 16.3 [Library Search], page 301) when looking for Lisp files. If *filename* is absolute, *path* has no effect, but the suffixes in *suffixes* are still tried.

The optional argument *predicate*, if non-`nil`, specifies a predicate function for testing whether a candidate file is suitable. The predicate is passed the candidate file name as its single argument. If *predicate* is `nil` or omitted, `locate-file` uses `file-readable-p` as the predicate. See Section 26.6.2 [Kinds of Files], page 621, for other useful predicates, e.g., `file-executable-p` and `file-directory-p`.

This function will normally skip directories, so if you want it to find directories, make sure the *predicate* function returns `dir-ok` for them. For example:

```
(locate-file "html" '("/var/www" "/srv") nil)
```

```
(lambda (f) (if (file-directory-p f) 'dir-ok)))
```

For compatibility, *predicate* can also be one of the symbols `executable`, `readable`, `writable`, `exists`, or a list of one or more of these symbols.

executable-find program &optional remote [Function]

This function searches for the executable file of the named *program* and returns the absolute file name of the executable, including its file-name extensions, if any. It returns `nil` if the file is not found. The function searches in all the directories in `exec-path`, and tries all the file-name extensions in `exec-suffixes` (see Section 40.1 [Subprocess Creation], page 1078).

If *remote* is non-`nil`, and `default-directory` is a remote directory, *program* is searched on the respective remote host.

26.7 Changing File Names and Attributes

The functions in this section rename, copy, delete, link, and set the modes (permissions) of files. Typically, they signal a `file-error` error if they fail to perform their function, reporting the system-dependent error message that describes the reason for the failure. If they fail because a file is missing, they signal a `file-missing` error instead.

For performance, the operating system may cache or alias changes made by these functions instead of writing them immediately to secondary storage. See Section 26.8 [Files and Storage], page 634.

In the functions that have an argument *newname*, if this argument is a directory name it is treated as if the nondirectory part of the source name were appended. Typically, a directory name is one that ends in ‘/’ (see Section 26.9.3 [Directory Names], page 637). For example, if the old name is `a/b/c`, the *newname* `d/e/f/` is treated as if it were `d/e/f/c`. This special treatment does not apply if *newname* is not a directory name but names a file that is a directory; for example, the *newname* `d/e/f` is left as-is even if `d/e/f` happens to be a directory.

In the functions that have an argument *newname*, if a file by the name of *newname* already exists, the actions taken depend on the value of the argument `ok-if-already-exists`:

- Signal a `file-already-exists` error if `ok-if-already-exists` is `nil`.
- Request confirmation if `ok-if-already-exists` is a number.
- Replace the old file without confirmation if `ok-if-already-exists` is any other value.

add-name-to-file oldname newname &optional ok-if-already-exists [Command]

This function gives the file named *oldname* the additional name *newname*. This means that *newname* becomes a new hard link to *oldname*.

If *newname* is a symbolic link, its directory entry is replaced, not the directory entry it points to. If *oldname* is a symbolic link, this function might or might not follow the link; it does not follow the link on GNU platforms. If *oldname* is a directory, this function typically fails, although for the superuser on a few old-fashioned non-GNU platforms it can succeed and create a filesystem that is not tree-structured.

In the first part of the following example, we list two files, `foo` and `foo3`.

```
$ ls -li fo*
81908 -rw-rw-rw- 1 rms rms 29 Aug 18 20:32 foo
84302 -rw-rw-rw- 1 rms rms 24 Aug 18 20:31 foo3
```

Now we create a hard link, by calling `add-name-to-file`, then list the files again. This shows two names for one file, `foo` and `foo2`.

```
(add-name-to-file "foo" "foo2")
⇒ nil

$ ls -li fo*
81908 -rw-rw-rw- 2 rms rms 29 Aug 18 20:32 foo
81908 -rw-rw-rw- 2 rms rms 29 Aug 18 20:32 foo2
84302 -rw-rw-rw- 1 rms rms 24 Aug 18 20:31 foo3
```

Finally, we evaluate the following:

```
(add-name-to-file "foo" "foo3" t)
```

and list the files again. Now there are three names for one file: `foo`, `foo2`, and `foo3`. The old contents of `foo3` are lost.

```
(add-name-to-file "foo1" "foo3")
⇒ nil
```

```
$ ls -li fo*
81908 -rw-rw-rw- 3 rms rms 29 Aug 18 20:32 foo
81908 -rw-rw-rw- 3 rms rms 29 Aug 18 20:32 foo2
81908 -rw-rw-rw- 3 rms rms 29 Aug 18 20:32 foo3
```

This function is meaningless on operating systems where multiple names for one file are not allowed. Some systems implement multiple names by copying the file instead. See also `file-nlinks` in Section 26.6.4 [File Attributes], page 624.

rename-file *filename newname* &optional *ok-if-already-exists* [Command]

This command renames the file *filename* as *newname*.

If *filename* has additional names aside from *filename*, it continues to have those names. In fact, adding the name *newname* with `add-name-to-file` and then deleting *filename* has the same effect as renaming, aside from momentary intermediate states and treatment of errors, directories and symbolic links.

This command does not follow symbolic links. If *filename* is a symbolic link, this command renames the symbolic link, not the file it points to. If *newname* is a symbolic link, its directory entry is replaced, not the directory entry it points to.

This command does nothing if *filename* and *newname* are the same directory entry, i.e., if they refer to the same parent directory and give the same name within that directory. Otherwise, if *filename* and *newname* name the same file, this command does nothing on POSIX-conforming systems, and removes *filename* on some non-POSIX systems.

If *newname* exists, then it must be an empty directory if *oldname* is a directory and a non-directory otherwise.

copy-file *oldname newname* &optional *ok-if-already-exists time* [Command]
preserve-uid-gid *preserve-permissions*

This command copies the file *oldname* to *newname*. An error is signaled if *oldname* is not a regular file. If *newname* names a directory, it copies *oldname* into that directory, preserving its final name component.

This function follows symbolic links, except that it does not follow a dangling symbolic link to create *newname*.

If *time* is non-*nil*, then this function gives the new file the same last-modified time that the old one has. (This works on only some operating systems.) If setting the time gets an error, `copy-file` signals a `file-date-error` error. In an interactive call, a prefix argument specifies a non-*nil* value for *time*.

If argument *preserve-uid-gid* is *nil*, we let the operating system decide the user and group ownership of the new file (this is usually set to the user running Emacs). If *preserve-uid-gid* is non-*nil*, we attempt to copy the user and group ownership of the file. This works only on some operating systems, and only if you have the correct permissions to do so.

If the optional argument *preserve-permissions* is non-*nil*, this function copies the file modes (or “permissions”) of *oldname* to *newname*, as well as the Access Control List and SELinux context (if any). See Section 26.6 [Information about Files], page 619.

Otherwise, the file modes of *newname* are left unchanged if it is an existing file, and set to those of *oldname*, masked by the default file permissions (see `set-default-file-modes` below), if *newname* is to be newly created. The Access Control List or SELinux context are not copied over in either case.

make-symbolic-link target *linkname* &optional *ok-if-already-exists* [Command]

This command makes a symbolic link to *target*, named *linkname*. This is like the shell command ‘`ln -s target linkname`’. The *target* argument is treated only as a string; it need not name an existing file. If *ok-if-already-exists* is an integer, indicating interactive use, then leading ‘~’ is expanded and leading ‘:/’ is stripped in the *target* string.

If *target* is a relative file name, the resulting symbolic link is interpreted relative to the directory containing the symbolic link. See Section 26.9.2 [Relative File Names], page 637.

If both *target* and *linkname* have remote file name syntax, and if both remote identifications are equal, the symbolic link points to the local file name part of *target*.

This function is not available on systems that don’t support symbolic links.

delete-file *filename* &optional *trash* [Command]

This command deletes the file *filename*. If the file has multiple names, it continues to exist under the other names. If *filename* is a symbolic link, `delete-file` deletes only the symbolic link and not its target.

The command signals a suitable kind of `file-error` error if *filename* cannot be deleted. (On GNU and other POSIX-like systems, a file can be deleted if its directory is writable.) If the file does not exist, this command will not signal any error.

If the optional argument *trash* is non-*nil* and the variable `delete-by-moving-to-trash` is non-*nil*, this command moves the file into the system Trash instead of deleting it. See Section “Miscellaneous File Operations” in *The GNU Emacs Manual*. When called interactively, *trash* is `t` if no prefix argument is given, and `nil` otherwise.

See also `delete-directory` in Section 26.11 [Create/Delete Dirs], page 648.

set-file-modes *filename mode &optional flag* [Command]

This function sets the *file mode* (or *permissions*) of *filename* to *mode*.

By default this function follows symbolic links. However, if the optional argument *flag* is the symbol `nofollow`, this function does not follow *filename* if it is a symbolic link; this can help prevent inadvertently changing the mode bits of a file somewhere else. On platforms that do not support changing mode bits on a symbolic link, this function signals an error when *filename* is a symbolic link and *flag* is `nofollow`.

If called non-interactively, *mode* must be an integer. Only the lowest 12 bits of the integer are used; on most systems, only the lowest 9 bits are meaningful. You can use the Lisp construct for octal numbers to enter *mode*. For example,

```
(set-file-modes "myfile" #o644 'nofollow)
```

specifies that the file should be readable and writable for its owner, readable for group members, and readable for all other users. See Section “File permissions” in *The GNU Coreutils Manual*, for a description of mode bit specifications.

Interactively, *mode* is read from the minibuffer using `read-file-modes` (see below), which lets the user type in either an integer or a string representing the permissions symbolically.

See Section 26.6.1 [Testing Accessibility], page 619, for the function `file-modes`, which returns the permissions of a file.

set-default-file-modes *mode* [Function]

This function sets the default permissions for new files created by Emacs and its subprocesses. Every file created with Emacs initially has these permissions, or a subset of them (`write-region` will not grant execute permissions even if the default file permissions allow execution). On GNU and other POSIX-like systems, the default permissions are given by the bitwise complement of the ‘`umask`’ value, i.e. each bit that is set in the argument *mode* will be *reset* in the default permissions with which Emacs creates files.

The argument *mode* should be an integer which specifies the permissions, similar to `set-file-modes` above. Only the lowest 9 bits are meaningful.

The default file permissions have no effect when you save a modified version of an existing file; saving a file preserves its existing permissions.

with-file-modes *mode body...* [Macro]

This macro evaluates the *body* forms with the default permissions for new files temporarily set to *modes* (whose value is as for `set-file-modes` above). When finished, it restores the original default file permissions, and returns the value of the last form in *body*.

This is useful for creating private files, for example.

default-file-modes [Function]

This function returns the default file permissions, as an integer.

read-file-modes *&optional prompt base-file* [Function]

This function reads a set of file mode bits from the minibuffer. The first optional argument *prompt* specifies a non-default prompt. Second second optional argument

base-file is the name of a file on whose permissions to base the mode bits that this function returns, if what the user types specifies mode bits relative to permissions of an existing file.

If user input represents an octal number, this function returns that number. If it is a complete symbolic specification of mode bits, as in "`u=rwx`", the function converts it to the equivalent numeric value using `file-modes-symbolic-to-number` and returns the result. If the specification is relative, as in "`o+g`", then the permissions on which the specification is based are taken from the mode bits of *base-file*. If *base-file* is omitted or `nil`, the function uses 0 as the base mode bits. The complete and relative specifications can be combined, as in "`u+r,g+rx,o+r,g-w`". See Section "File permissions" in *The GNU Coreutils Manual*, for a description of file mode specifications.

file-modes-symbolic-to-number *modes* &**optional** *base-modes* [Function]

This function converts a symbolic file mode specification in *modes* into the equivalent integer. If the symbolic specification is based on an existing file, that file's mode bits are taken from the optional argument *base-modes*; if that argument is omitted or `nil`, it defaults to 0, i.e., no access rights at all.

file-modes-number-to-symbolic *modes* [Function]

This function converts a numeric file mode specification in *modes* into the equivalent string form. The string which this function returns is in the same format produced by the shell command `ls -l` and by `file-attributes`, *not* the symbolic form accepted by `file-modes-symbolic-to-number` and the `chmod` shell command.

set-file-times *filename* &**optional** *time flag* [Function]

This function sets the access and modification times of *filename* to *time*. The return value is `t` if the times are successfully set, otherwise it is `nil`. *time* defaults to the current time and must be a time value (see Section 42.5 [Time of Day], page 1270).

By default this function follows symbolic links. However, if the optional argument *flag* is the symbol `nofollow`, this function does not follow *filename* if it is a symbolic link; this can help prevent inadvertently changing the times of a file somewhere else. On platforms that do not support changing times on a symbolic link, this function signals an error when *filename* is a symbolic link and *flag* is `nofollow`.

set-file-extended-attributes *filename attribute-alist* [Function]

This function sets the Emacs-recognized extended file attributes for *filename*. The second argument *attribute-alist* should be an alist of the same form returned by `file-extended-attributes`. The return value is `t` if the attributes are successfully set, otherwise it is `nil`. See Section 26.6.5 [Extended Attributes], page 627.

set-file-selinux-context *filename context* [Function]

This function sets the SELinux security context for *filename* to *context*. The *context* argument should be a list (`user role type range`), where each element is a string. See Section 26.6.5 [Extended Attributes], page 627.

The function returns `t` if it succeeds in setting the SELinux context of *filename*. It returns `nil` if the context was not set (e.g., if SELinux is disabled, or if Emacs was compiled without SELinux support).

set-file-acl *filename acl* [Function]

This function sets the Access Control List for *filename* to *acl*. The *acl* argument should have the same form returned by the function `file-acl`. See Section 26.6.5 [Extended Attributes], page 627.

The function returns `t` if it successfully sets the ACL of *filename*, `nil` otherwise.

26.8 Files and Secondary Storage

After Emacs changes a file, there are two reasons the changes might not survive later failures of power or media, both having to do with efficiency. First, the operating system might alias written data with data already stored elsewhere on secondary storage until one file or the other is later modified; this will lose both files if the only copy on secondary storage is lost due to media failure. Second, the operating system might not write data to secondary storage immediately, which will lose the data if power is lost.

Although both sorts of failures can largely be avoided by a suitably configured file system, such systems are typically more expensive or less efficient. In more-typical systems, to survive media failure you can copy the file to a different device, and to survive a power failure you can use the `write-region` function with the `write-region-inhibit-fsync` variable set to `nil`. See Section 26.4 [Writing to Files], page 616.

26.9 File Names

Files are generally referred to by their names, in Emacs as elsewhere. File names in Emacs are represented as strings. The functions that operate on a file all expect a file name argument.

In addition to operating on files themselves, Emacs Lisp programs often need to operate on file names; i.e., to take them apart and to use part of a name to construct related file names. This section describes how to manipulate file names.

The functions in this section do not actually access files, so they can operate on file names that do not refer to an existing file or directory.

On MS-DOS and MS-Windows, these functions (like the function that actually operate on files) accept MS-DOS or MS-Windows file-name syntax, where backslashes separate the components, as well as POSIX syntax; but they always return POSIX syntax. This enables Lisp programs to specify file names in POSIX syntax and work properly on all systems without change.¹

26.9.1 File Name Components

The operating system groups files into directories. To specify a file, you must specify the directory and the file's name within that directory. Therefore, Emacs considers a file name as having two main parts: the *directory name* part, and the *nondirectory* part (or *file name within the directory*). Either part may be empty. Concatenating these two parts reproduces the original file name.²

¹ In MS-Windows versions of Emacs compiled for the Cygwin environment, you can use the functions `cygwin-convert-file-name-to-windows` and `cygwin-convert-file-name-from-windows` to convert between the two file-name syntaxes.

² Emacs follows the GNU convention to use the term *file name* instead of the term *pathname*. We use the term *path* only for search paths, which are lists of directory names.

On most systems, the directory part is everything up to and including the last slash (backslash is also allowed in input on MS-DOS or MS-Windows); the nondirectory part is the rest.

For some purposes, the nondirectory part is further subdivided into the name proper and the *version number*. On most systems, only backup files have version numbers in their names.

file-name-directory *filename* [Function]

This function returns the directory part of *filename*, as a directory name (see Section 26.9.3 [Directory Names], page 637), or `nil` if *filename* does not include a directory part.

On GNU and other POSIX-like systems, a string returned by this function always ends in a slash. On MS-DOS it can also end in a colon.

```
(file-name-directory "lewis/foo") ; GNU example
⇒ "lewis/"
(file-name-directory "foo")      ; GNU example
⇒ nil
```

file-name-nondirectory *filename* [Function]

This function returns the nondirectory part of *filename*.

```
(file-name-nondirectory "lewis/foo")
⇒ "foo"
(file-name-nondirectory "foo")
⇒ "foo"
(file-name-nondirectory "lewis/")
⇒ ""
```

file-name-sans-versions *filename* &optional *keep-backup-version* [Function]

This function returns *filename* with any file version numbers, backup version numbers, or trailing tildes discarded.

If *keep-backup-version* is non-`nil`, then true file version numbers understood as such by the file system are discarded from the return value, but backup version numbers are kept.

```
(file-name-sans-versions "~rms/foo.^1^")
⇒ "~rms/foo"
(file-name-sans-versions "~rms/foo~")
⇒ "~rms/foo"
(file-name-sans-versions "~rms/foo")
⇒ "~rms/foo"
```

file-name-extension *filename* &optional *period* [Function]

This function returns *filename*'s final extension, if any, after applying `file-name-sans-versions` to remove any version/backup part. The extension, in a file name, is the part that follows the last '.' in the last name component (minus any version/backup part).

This function returns `nil` for extensionless file names such as `foo`. It returns `" "` for null extensions, as in `foo..`. If the last component of a file name begins with a '.', that

'.' doesn't count as the beginning of an extension. Thus, `.emacs`'s extension is `nil`, not `'.emacs'`.

If `period` is non-`nil`, then the returned value includes the period that delimits the extension, and if `filename` has no extension, the value is `"."`.

file-name-with-extension *filename extension* [Function]

This function returns *filename* with its extension set to *extension*. A single leading dot in the extension will be stripped if there is one. For example:

```
(file-name-with-extension "file" "el")
  ⇒ "file.el"
(file-name-with-extension "file" ".el")
  ⇒ "file.el"
(file-name-with-extension "file.c" "el")
  ⇒ "file.el"
```

Note that this function will error if *filename* or *extension* are empty, or if the *filename* is shaped like a directory (i.e., if `directory-name-p` returns non-`nil`).

file-name-sans-extension *filename* [Function]

This function returns *filename* minus its extension, if any. The version/backup part, if present, is only removed if the file has an extension. For example,

```
(file-name-sans-extension "foo.lose.c")
  ⇒ "foo.lose"
(file-name-sans-extension "big.hack/foo")
  ⇒ "big.hack/foo"
(file-name-sans-extension "/my/home/.emacs")
  ⇒ "/my/home/.emacs"
(file-name-sans-extension "/my/home/.emacs.el")
  ⇒ "/my/home/.emacs"
(file-name-sans-extension "~/foo.el.~3~")
  ⇒ "~/foo"
(file-name-sans-extension "~/foo.~3~")
  ⇒ "~/foo.~3~"
```

Note that the `'~3~'` in the two last examples is the backup part, not an extension.

file-name-base *filename* [Function]

This function is the composition of `file-name-sans-extension` and `file-name-nondirectory`. For example,

```
(file-name-base "/my/home/foo.c")
  ⇒ "foo"
```

file-name-split *filename* [Function]

This function splits a file name into its components, and can be thought of as the inverse of `string-join` with the appropriate directory separator. For example,

```
(file-name-split "/tmp/foo.txt")
  ⇒ ("\" "tmp" "foo.txt")
(string-join (file-name-split "/tmp/foo.txt") "/")
  ⇒ "/tmp/foo.txt"
```

26.9.2 Absolute and Relative File Names

All the directories in the file system form a tree starting at the root directory. A file name can specify all the directory names starting from the root of the tree; then it is called an *absolute* file name. Or it can specify the position of the file in the tree relative to a default directory; then it is called a *relative* file name. On GNU and other POSIX-like systems, after any leading ‘~’ has been expanded, an absolute file name starts with a ‘/’ (see [abbreviate-file-name], page 639), and a relative one does not. On MS-DOS and MS-Windows, an absolute file name starts with a slash or a backslash, or with a drive specification ‘x:/’, where x is the *drive letter*.

file-name-absolute-p *filename* [Function]

This function returns t if file *filename* is an absolute file name, nil otherwise. A file name is considered to be absolute if its first component is ‘~’, or is ‘~*user*’ where *user* is a valid login name. In the following examples, assume that there is a user named ‘rms’ but no user named ‘nosuchuser’.

```
(file-name-absolute-p "~rms/foo")
⇒ t
(file-name-absolute-p "~nosuchuser/foo")
⇒ nil
(file-name-absolute-p "rms/foo")
⇒ nil
(file-name-absolute-p "/user/rms/foo")
⇒ t
```

Given a possibly relative file name, you can expand any leading ‘~’ and convert the result to an absolute name using **expand-file-name** (see Section 26.9.4 [File Name Expansion], page 639). This function converts absolute file names to relative names:

file-relative-name *filename* &**optional** *directory* [Function]

This function tries to return a relative name that is equivalent to *filename*, assuming the result will be interpreted relative to *directory* (an absolute directory name or directory file name). If *directory* is omitted or nil, it defaults to the current buffer’s default directory.

On some operating systems, an absolute file name begins with a device name. On such systems, *filename* has no relative equivalent based on *directory* if they start with two different device names. In this case, **file-relative-name** returns *filename* in absolute form.

```
(file-relative-name "/foo/bar" "/foo/")
⇒ "bar"
(file-relative-name "/foo/bar" "/hack/")
⇒ "../foo/bar"
```

A file name that is an empty string stands for the current buffer’s default directory.

26.9.3 Directory Names

A *directory name* is a string that must name a directory if it names any file at all. A directory is actually a kind of file, and it has a file name (called the *directory file name*),

which is related to the directory name but is typically not identical. (This is not quite the same as the usual POSIX terminology.) These two names for the same entity are related by a syntactic transformation. On GNU and other POSIX-like systems, this is simple: to obtain a directory name, append a ‘/’ to a directory file name that does not already end in ‘/’. On MS-DOS the relationship is more complicated.

The difference between a directory name and a directory file name is subtle but crucial. When an Emacs variable or function argument is described as being a directory name, a directory file name is not acceptable. When `file-name-directory` returns a string, that is always a directory name.

The following two functions convert between directory names and directory file names. They do nothing special with environment variable substitutions such as ‘\$HOME’, and the constructs ‘~’, ‘.’ and ‘...’.

file-name-as-directory *filename*

[Function]

This function returns a string representing *filename* in a form that the operating system will interpret as the name of a directory (a directory name). On most systems, this means appending a slash to the string (if it does not already end in one).

```
(file-name-as-directory "~rms/lewis")
⇒ "~rms/lewis/"
```

directory-name-p *filename*

[Function]

This function returns non-*nil* if *filename* ends with a directory separator character. This is the forward slash ‘/’ on GNU and other POSIX-like systems; MS-Windows and MS-DOS recognize both the forward slash and the backslash ‘\’ as directory separators.

directory-file-name *dirname*

[Function]

This function returns a string representing *dirname* in a form that the operating system will interpret as the name of a file (a directory file name). On most systems, this means removing the final directory separators from the string, unless the string consists entirely of directory separators.

```
(directory-file-name "~lewis/")
⇒ "~lewis"
```

file-name-concat *directory &rest components*

[Function]

Concatenate *components* to *directory*, inserting a slash before the components if *directory* or the preceding component didn’t end with a slash.

```
(file-name-concat "/tmp" "foo")
⇒ "/tmp/foo"
```

A *directory* or components that are *nil* or the empty string are ignored—they are filtered out first and do not affect the results in any way.

This is almost the same as using `concat`, but *dirname* (and the non-final components) may or may not end with slash characters, and this function will not double those characters.

To convert a directory name to its abbreviation, use this function:

abbreviate-file-name *filename* [Function]

This function returns an abbreviated form of *filename*. It applies the abbreviations specified in `directory-abbrev-alist` (see Section “File Aliases” in *The GNU Emacs Manual*), then substitutes ‘~’ for the user’s home directory if the argument names a file in the home directory or one of its subdirectories. If the home directory is a root directory, it is not replaced with ‘~’, because this does not make the result shorter on many systems.

You can use this function for directory names and for file names, because it recognizes abbreviations even as part of the name.

file-name-parent-directory *filename* [Function]

This function returns the directory name of the parent directory of *filename*. If *filename* is at the root directory of the filesystem, it returns `nil`. A relative *filename* is assumed to be relative to `default-directory`, and the return value will also be relative in that case. If the return value is non-`nil`, it ends in a slash.

26.9.4 Functions that Expand Filenames

Expanding a file name means converting a relative file name to an absolute one. Since this is done relative to a default directory, you must specify the default directory as well as the file name to be expanded. It also involves expanding abbreviations like `~/` and eliminating redundancies like `./` and `name/..`.

expand-file-name *filename* &*optional directory* [Function]

This function converts *filename* to an absolute file name. If *directory* is supplied, it is the default directory to start with if *filename* is relative and does not start with ‘~’. (The value of *directory* should itself be an absolute directory name or directory file name; it may start with ‘~’.) Otherwise, the current buffer’s value of `default-directory` is used. For example:

```
(expand-file-name "foo")
⇒ "/xcssun/users/rms/lewis/foo"
(expand-file-name "../foo")
⇒ "/xcssun/users/rms/foo"
(expand-file-name "foo" "/usr/spool/")
⇒ "/usr/spool/foo"
```

If the part of *filename* before the first slash is ‘~’, it expands to your home directory, which is typically specified by the value of the `HOME` environment variable (see Section “General Variables” in *The GNU Emacs Manual*). If the part before the first slash is ‘~*user*’ and if *user* is a valid login name, it expands to *user*’s home directory. If you do not want this expansion for a relative *filename* that might begin with a literal ‘~’, you can use `(concat (file-name-as-directory directory) filename)` instead of `(expand-file-name filename directory)`.

File names containing ‘.’ or ‘..’ are simplified to their canonical form:

```
(expand-file-name "bar/../../foo")
⇒ "/xcssun/users/rms/lewis/foo"
```

In some cases, a leading ‘..’ component can remain in the output:

```
(expand-file-name "../../home" "/")
⇒ "../../home"
```

This is for the sake of filesystems that have the concept of a superroot above the root directory /. On other filesystems, ./ is interpreted exactly the same as /.

Expanding . or the empty string returns the default directory:

```
(expand-file-name ". " "/usr/spool/")
  ⇒ "/usr/spool"
(expand-file-name "" "/usr/spool/")
  ⇒ "/usr/spool"
```

Note that `expand-file-name` does *not* expand environment variables; only `substitute-in-file-name` does that:

```
(expand-file-name "$HOME/foo")
  ⇒ "/xcsun/users/rms/lewis/$HOME/foo"
```

Note also that `expand-file-name` does not follow symbolic links at any level. This results in a difference between the way `file-truename` and `expand-file-name` treat ‘..’. Assuming that ‘/tmp/bar’ is a symbolic link to the directory ‘/tmp/foo/bar’ we get:

```
(file-truename "/tmp/bar/..myfile")
  ⇒ "/tmp/foo/myfile"
(expand-file-name "/tmp/bar/..myfile")
  ⇒ "/tmp/myfile"
```

If you may need to follow symbolic links preceding ‘..’, you should make sure to call `file-truename` without prior direct or indirect calls to `expand-file-name`. See Section 26.6.3 [Truenames], page 623.

`default-directory` [Variable]

The value of this buffer-local variable is the default directory for the current buffer. It should be an absolute directory name; it may start with ‘~’. This variable is buffer-local in every buffer.

`expand-file-name` uses the default directory when its second argument is `nil`.

The value is always a string ending with a slash.

```
default-directory
  ⇒ "/user/lewis/manual/"
```

`substitute-in-file-name filename` [Function]

This function replaces environment variable references in `filename` with the environment variable values. Following standard Unix shell syntax, ‘\$’ is the prefix to substitute an environment variable value. If the input contains ‘\$\$’, that is converted to ‘\$’; this gives the user a way to quote a ‘\$’.

The environment variable name is the series of alphanumeric characters (including underscores) that follow the ‘\$’. If the character following the ‘\$’ is a ‘{’, then the variable name is everything up to the matching ‘}’.

Calling `substitute-in-file-name` on output produced by `substitute-in-file-name` tends to give incorrect results. For instance, use of ‘\$\$’ to quote a single ‘\$’ won’t work properly, and ‘\$’ in an environment variable’s value could lead to repeated substitution. Therefore, programs that call this function and put the output where it

will be passed to this function need to double all ‘\$’ characters to prevent subsequent incorrect results.

Here we assume that the environment variable `HOME`, which holds the user’s home directory, has value ‘`/xcssun/users/rms`’.

```
(substitute-in-file-name "$HOME/foo")
⇒ "/xcssun/users/rms/foo"
```

After substitution, if a ‘`~`’ or a ‘`/`’ appears immediately after another ‘`/`’, the function discards everything before it (up through the immediately preceding ‘`/`’).

```
(substitute-in-file-name "bar/~/foo")
⇒ "~/foo"
(substitute-in-file-name "/usr/local/$HOME/foo")
⇒ "/xcssun/users/rms/foo"
;; /usr/local/ has been discarded.
```

Sometimes, it is not desired to expand file names. In such cases, the file name can be quoted to suppress the expansion, and to handle the file name literally. Quoting happens by prefixing the file name with ‘`/:`’.

`file-name-quote name`

[Macro]

This macro adds the quotation prefix ‘`/:`’ to the file *name*. For a local file *name*, it prefixes *name* with ‘`/:`’. If *name* is a remote file name, the local part of *name* (see Section 26.12 [Magic File Names], page 649) is quoted. If *name* is already a quoted file name, *name* is returned unchanged.

```
(substitute-in-file-name (file-name-quote "bar/~/foo"))
⇒ "/:bar/~/foo"

(substitute-in-file-name (file-name-quote "/ssh:host:bar/~/foo"))
⇒ "/ssh:host:/:bar/~/foo"
```

The macro cannot be used to suppress file name handlers from magic file names (see Section 26.12 [Magic File Names], page 649).

`file-name-unquote name`

[Macro]

This macro removes the quotation prefix ‘`/:`’ from the file *name*, if any. If *name* is a remote file name, the local part of *name* is unquoted.

`file-name-quoted-p name`

[Macro]

This macro returns non-nil, when *name* is quoted with the prefix ‘`/:`’. If *name* is a remote file name, the local part of *name* is checked.

26.9.5 Generating Unique File Names

Some programs need to write temporary files. Here is the usual way to construct a name for such a file:

```
(make-temp-file name-of-application)
```

The job of `make-temp-file` is to prevent two different users or two different jobs from trying to use the exact same file name.

make-temp-file *prefix* &**optional** *dir-flag* *suffix* *text* [Function]

This function creates a temporary file and returns its name. Emacs creates the temporary file's name by adding to *prefix* some random characters that are different in each Emacs job. The result is guaranteed to be a newly created file, containing *text* if that's given as a string and empty otherwise. On MS-DOS, this function can truncate *prefix* to fit into the 8+3 file-name limits. If *prefix* is a relative file name, it is expanded against **temporary-file-directory**.

```
(make-temp-file "foo")
⇒ "/tmp/foo232J6v"
```

When **make-temp-file** returns, the file has been created and is empty. At that point, you should write the intended contents into the file.

If *dir-flag* is non-*nil*, **make-temp-file** creates an empty directory instead of an empty file. It returns the file name, not the directory name, of that directory. See Section 26.9.3 [Directory Names], page 637.

If *suffix* is non-*nil*, **make-temp-file** adds it at the end of the file name.

If *text* is a string, **make-temp-file** inserts it in the file.

To prevent conflicts among different libraries running in the same Emacs, each Lisp program that uses **make-temp-file** should have its own *prefix*. The number added to the end of *prefix* distinguishes between the same application running in different Emacs jobs. Additional added characters permit a large number of distinct names even in one Emacs job.

The default directory for temporary files is controlled by the variable **temporary-file-directory**. This variable gives the user a uniform way to specify the directory for all temporary files. Some programs use **small-temporary-file-directory** instead, if that is non-*nil*. To use it, you should expand the prefix against the proper directory before calling **make-temp-file**.

temporary-file-directory [User Option]

This variable specifies the directory name for creating temporary files. Its value should be a directory name (see Section 26.9.3 [Directory Names], page 637), but it is good for Lisp programs to cope if the value is a directory's file name instead. Using the value as the second argument to **expand-file-name** is a good way to achieve that.

The default value is determined in a reasonable way for your operating system; it is based on the TMPDIR, TMP and TEMP environment variables, with a fall-back to a system-dependent name if none of these variables is defined.

Even if you do not use **make-temp-file** to create the temporary file, you should still use this variable to decide which directory to put the file in. However, if you expect the file to be small, you should use **small-temporary-file-directory** first if that is non-*nil*.

small-temporary-file-directory [User Option]

This variable specifies the directory name for creating certain temporary files, which are likely to be small.

If you want to write a temporary file which is likely to be small, you should compute the directory like this:

```
(make-temp-file
```

```
(expand-file-name prefix
  (or small-temporary-file-directory
      temporary-file-directory)))
```

make-temp-name *base-name*

[Function]

This function generates a string that might be a unique file name. The name starts with *base-name*, and has several random characters appended to it, which are different in each Emacs job. It is like **make-temp-file** except that (i) it just constructs a name and does not create a file, (ii) *base-name* should be an absolute file name that is not magic, and (iii) if the returned file name is magic, it might name an existing file. See Section 26.12 [Magic File Names], page 649.

Warning: In most cases, you should not use this function; use **make-temp-file** instead! This function is susceptible to a race condition, between the **make-temp-name** call and the creation of the file, which in some cases may cause a security hole.

Sometimes, it is necessary to create a temporary file on a remote host or a mounted directory. The following two functions support this.

make-nearby-temp-file *prefix* &**optional** *dir-flag suffix*

[Function]

This function is similar to **make-temp-file**, but it creates a temporary file as close as possible to **default-directory**. If *prefix* is a relative file name, and **default-directory** is a remote file name or located on a mounted file system, the temporary file is created in the directory returned by the function **temporary-file-directory**. Otherwise, the function **make-temp-file** is used. *prefix*, *dir-flag* and *suffix* have the same meaning as in **make-temp-file**.

```
(let ((default-directory "/ssh:remotehost:"))
  (make-nearby-temp-file "foo"))
  ⇒ "/ssh:remotehost:/tmp/foo232J6v"
```

temporary-file-directory

[Function]

The directory for writing temporary files via **make-nearby-temp-file**. In case of a remote **default-directory**, this is a directory for temporary files on that remote host. If such a directory does not exist, or **default-directory** ought to be located on a mounted file system (see **mounted-file-systems**), the function returns **default-directory**. For a non-remote and non-mounted **default-directory**, the value of the variable **temporary-file-directory** is returned.

In order to extract the local part of the file's name of a temporary file, use **file-local-name** (see Section 26.12 [Magic File Names], page 649).

26.9.6 File Name Completion

This section describes low-level subroutines for completing a file name. For higher level functions, see Section 21.6.5 [Reading File Names], page 404.

file-name-all-completions *partial-filename directory*

[Function]

This function returns a list of all possible completions for a file whose name starts with *partial-filename* in directory *directory*. The order of the completions is the order of the files in the directory, which is unpredictable and conveys no useful information.

The argument *partial-filename* must be a file name containing no directory part and no slash (or backslash on some systems). The current buffer's default directory is prepended to *directory*, if *directory* is not absolute.

In the following example, suppose that `~rms/lewis` is the current default directory, and has five files whose names begin with 'f': `foo`, `file~`, `file.c`, `file.c.~1~`, and `file.c.~2~`.

```
(file-name-all-completions "f" "")
  ⇒ ("foo" "file~" "file.c.~2~"
      "file.c.~1~" "file.c")

(file-name-all-completions "fo" "")
  ⇒ ("foo")
```

file-name-completion *filename* *directory* &**optional** *predicate* [Function]

This function completes the file name *filename* in directory *directory*. It returns the longest prefix common to all file names in directory *directory* that start with *filename*. If *predicate* is non-nil then it ignores possible completions that don't satisfy *predicate*, after calling that function with one argument, the expanded absolute file name.

If only one match exists and *filename* matches it exactly, the function returns t. The function returns nil if directory *directory* contains no name starting with *filename*.

In the following example, suppose that the current default directory has five files whose names begin with 'f': `foo`, `file~`, `file.c`, `file.c.~1~`, and `file.c.~2~`.

```
(file-name-completion "fi" "")
  ⇒ "file"

(file-name-completion "file.c.~1" "")
  ⇒ "file.c.~1~"

(file-name-completion "file.c.~1~" "")
  ⇒ t

(file-name-completion "file.c.~3" "")
  ⇒ nil
```

completion-ignored-extensions [User Option]

`file-name-completion` usually ignores file names that end in any string in this list. It does not ignore them when all the possible completions end in one of these suffixes. This variable has no effect on `file-name-all-completions`.

A typical value might look like this:

```
completion-ignored-extensions
  ⇒ ("."o" ".elc" "~" ".dvi")
```

If an element of `completion-ignored-extensions` ends in a slash '/', it signals a directory. The elements which do *not* end in a slash will never match a directory; thus, the above value will not filter out a directory named `foo.elc`.

26.9.7 Standard File Names

Sometimes, an Emacs Lisp program needs to specify a standard file name for a particular use—typically, to hold configuration data specified by the current user. Usually, such files should be located in the directory specified by `user-emacs-directory`, which is typically `~/.config/emacs/` or `~/.emacs.d/` by default (see Section “How Emacs Finds Your Init File” in *The GNU Emacs Manual*). For example, abbrev definitions are stored by default in `~/.config/emacs/abbrev_defs` or `~/.emacs.d/abbrev_defs`. The easiest way to specify such a file name is to use the function `locate-user-emacs-file`.

`locate-user-emacs-file base-name &optional old-name` [Function]

This function returns an absolute file name for an Emacs-specific configuration or data file. The argument `base-name` should be a relative file name. The return value is the absolute name of a file in the directory specified by `user-emacs-directory`; if that directory does not exist, this function creates it.

If the optional argument `old-name` is non-`nil`, it specifies a file in the user’s home directory, `~/old-name`. If such a file exists, the return value is the absolute name of that file, instead of the file specified by `base-name`. This argument is intended to be used by Emacs packages to provide backward compatibility. For instance, prior to the introduction of `user-emacs-directory`, the abbrev file was located in `~/.abbrev_defs`. Here is the definition of `abbrev-file-name`:

```
(defcustom abbrev-file-name
  (locate-user-emacs-file "abbrev_defs" ".abbrev_defs")
  "Default name of file from which to read abbrevs."
  ...
  :type 'file)
```

A lower-level function for standardizing file names, which `locate-user-emacs-file` uses as a subroutine, is `convert-standard-filename`.

`convert-standard-filename filename` [Function]

This function returns a file name based on `filename`, which fits the conventions of the current operating system.

On GNU and other POSIX-like systems, this simply returns `filename`. On other operating systems, it may enforce system-specific file name conventions; for example, on MS-DOS this function performs a variety of changes to enforce MS-DOS file name limitations, including converting any leading ‘.’ to ‘_’ and truncating to three characters after the ‘.’.

The recommended way to use this function is to specify a name which fits the conventions of GNU and Unix systems, and pass it to `convert-standard-filename`.

26.10 Contents of Directories

A directory is a kind of file that contains other files entered under various names. Directories are a feature of the file system.

Emacs can list the names of the files in a directory as a Lisp list, or display the names in a buffer using the `ls` shell command. In the latter case, it can optionally display information about each file, depending on the options passed to the `ls` command.

directory-files *directory* &**optional** *full-name* *match-regexp* *nosort* [Function]
count

This function returns a list of the names of the files in the directory *directory*. By default, the list is in alphabetical order.

If *full-name* is non-*nil*, the function returns the files' absolute file names. Otherwise, it returns the names relative to the specified directory.

If *match-regexp* is non-*nil*, this function returns only those file names whose non-directory part contain a match for that regular expression—the other file names are excluded from the list. On case-insensitive filesystems, the regular expression matching is case-insensitive.

If *nosort* is non-*nil*, **directory-files** does not sort the list, so you get the file names in no particular order. Use this if you want the utmost possible speed and don't care what order the files are processed in. If the order of processing is visible to the user, then the user will probably be happier if you do sort the names.

If *count* is non-*nil*, the function will return names of first *count* number of files, or names of all files, whichever occurs first. *count* has to be an integer greater than zero.

```
(directory-files "~lewis")
  ⇒ ("#foo#" "#foo.el#" "." ".."
      "dired-mods.el" "files.texi"
      "files.texi.^1^")
```

An error is signaled if *directory* is not the name of a directory that can be read.

directory-empty-p *directory* [Function]

This utility function returns *t* if given *directory* is an accessible directory and it does not contain any files, i.e., is an empty directory. It will ignore ‘.’ and ‘..’ on systems that return them as files in a directory.

Symbolic links to directories count as directories. See *file-symlink-p* to distinguish symlinks.

directory-files-recursively *directory* *regexp* &**optional** [Function]
include-directories *predicate* *follow-symlinks*

Return all files under *directory* whose names match *regexp*. This function searches the specified *directory* and its sub-directories, recursively, for files whose basenames (i.e., without the leading directories) match the specified *regexp*, and returns a list of the absolute file names of the matching files (see Section 26.9.2 [Relative File Names], page 637). The file names are returned in depth-first order, meaning that files in some sub-directory are returned before the files in its parent directory. In addition, matching files found in each subdirectory are sorted alphabetically by their basenames. By default, directories whose names match *regexp* are omitted from the list, but if the optional argument *include-directories* is non-*nil*, they are included.

By default, all subdirectories are descended into. If *predicate* is *t*, errors when trying to descend into a subdirectory (for instance, if it's not readable by this user) are ignored. If it's neither *nil* nor *t*, it should be a function that takes one parameter (the subdirectory name) and should return non-*nil* if the directory is to be descended into.

Symbolic links to subdirectories are not followed by default, but if *follow-symlinks* is non-*nil*, they are followed.

locate-dominating-file *file name* [Function]

Starting at *file*, go up the directory tree hierarchy looking for the first directory where *name*, a string, exists, and return that directory. If *file* is a file, its directory will serve as the starting point for the search; otherwise *file* should be a directory from which to start. The function looks in the starting directory, then in its parent, then in its parent's parent, etc., until it either finds a directory with *name* or reaches the root directory of the filesystem without finding *name* – in the latter case the function returns *nil*.

The argument *name* can also be a predicate function. The predicate is called for every directory examined by the function, starting from *file* (even if *file* is not a directory). It is called with one argument (the file or directory) and should return non-*nil* if that directory is the one it is looking for.

file-in-directory-p *file dir* [Function]

This function returns *t* if *file* is a file in directory *dir*, or in a subdirectory of *dir*. It also returns *t* if *file* and *dir* are the same directory. It compares the truenames of the two directories. If *dir* does not name an existing directory, the return value is *nil*.

directory-files-and-attributes *directory &optional full-name
match-regexp nosort id-format count* [Function]

This is similar to **directory-files** in deciding which files to report on and how to report their names. However, instead of returning a list of file names, it returns for each file a list (*filename . attributes*), where *attributes* is what **file-attributes** returns for that file. The optional argument *id-format* has the same meaning as the corresponding argument to **file-attributes** (see [Definition of file-attributes], page 625).

directory-files-no-dot-files-regexp [Constant]

This regular expression matches any file name except ‘.’ and ‘..’. More precisely, it matches parts of any nonempty string except those two. It is useful as the *match-regexp* argument to **directory-files** and **directory-files-and-attributes**:

```
(directory-files "/foo" nil directory-files-no-dot-files-regexp)
returns nil, if directory '/foo' is empty.
```

file-expand-wildcards *pattern &optional full regexp* [Function]

This function expands the wildcard pattern *pattern*, returning a list of file names that match it.

pattern is, by default, a “glob”/wildcard string, e.g., “/tmp/*.*.png” or “/*/*/*/*.*.png”, but can also be a regular expression if the optional *regexp* parameter is non-*nil*. In any case, the matches are applied per sub-directory, so a match can't span a parent/sub directory.

If *pattern* is written as an absolute file name, the values are absolute also.

If *pattern* is written as a relative file name, it is interpreted relative to the current default directory. The file names returned are normally also relative to the current default directory. However, if *full* is non-*nil*, they are absolute.

insert-directory *file* **switches** &**optional** *wildcard* *full-directory-p* [Function]

This function inserts (in the current buffer) a directory listing for directory *file*, formatted with `ls` according to *switches*. It leaves point after the inserted text. *switches* may be a string of options, or a list of strings representing individual options.

The argument *file* may be either a directory or a file specification including wildcard characters. If *wildcard* is non-*nil*, that means treat *file* as a file specification with wildcards.

If *full-directory-p* is non-*nil*, that means the directory listing is expected to show the full contents of a directory. You should specify `t` when *file* is a directory and *switches* do not contain ‘`-d`’. (The ‘`-d`’ option to `ls` says to describe a directory itself as a file, rather than showing its contents.)

On most systems, this function works by running a directory listing program whose name is in the variable `insert-directory-program`. If *wildcard* is non-*nil*, it also runs the shell specified by `shell-file-name`, to expand the wildcards.

MS-DOS and MS-Windows systems usually lack the standard Unix program `ls`, so this function emulates the standard Unix program `ls` with Lisp code.

As a technical detail, when *switches* contains the long ‘`--dired`’ option, `insert-directory` treats it specially, for the sake of `dired`. However, the normally equivalent short ‘`-D`’ option is just passed on to `insert-directory-program`, as any other option.

insert-directory-program [Variable]

This variable’s value is the program to run to generate a directory listing for the function `insert-directory`. It is ignored on systems which generate the listing with Lisp code.

26.11 Creating, Copying and Deleting Directories

Most Emacs Lisp file-manipulation functions get errors when used on files that are directories. For example, you cannot delete a directory with `delete-file`. These special functions exist to create and delete directories.

make-directory *dirname* &**optional** *parents* [Command]

This command creates a directory named *dirname*. If *parents* is non-*nil*, as is always the case in an interactive call, that means to create the parent directories first, if they don’t already exist. As a function, `make-directory` returns non-*nil* if *dirname* already exists as a directory and *parents* is non-*nil*, and returns *nil* if it successfully created *dirname*. `mkdir` is an alias for this.

make-empty-file *filename* &**optional** *parents* [Command]

This command creates an empty file named *filename*. As `make-directory`, this command creates parent directories if *parents* is non-*nil*. If *filename* already exists, this command signals an error.

copy-directory *dirname newname &optional keep-time parents [Command]*
copy-contents

This command copies the directory named *dirname* to *newname*. If *newname* is a directory name, *dirname* will be copied to a subdirectory there. See Section 26.9.3 [Directory Names], page 637.

It always sets the file modes of the copied files to match the corresponding original file.

The third argument *keep-time non-nil* means to preserve the modification time of the copied files. A prefix arg makes *keep-time non-nil*.

The fourth argument *parents* says whether to create parent directories if they don't exist. Interactively, this happens by default.

The fifth argument *copy-contents*, if non-*nil*, means to copy the contents of *dirname* directly into *newname* if the latter is a directory name, instead of copying *dirname* into it as a subdirectory.

delete-directory *dirname &optional recursive trash [Command]*

This command deletes the directory named *dirname*. The function **delete-file** does not work for files that are directories; you must use **delete-directory** for them. If *recursive* is *nil*, and the directory contains any files, **delete-directory** signals an error. If *recursive* is non-*nil*, there is no error merely because the directory or its files are deleted by some other process before **delete-directory** gets to them.

delete-directory only follows symbolic links at the level of parent directories.

If the optional argument *trash* is non-*nil* and the variable **delete-by-moving-to-trash** is non-*nil*, this command moves the file into the system Trash instead of deleting it. See Section “Miscellaneous File Operations” in *The GNU Emacs Manual*. When called interactively, *trash* is *t* if no prefix argument is given, and *nil* otherwise.

26.12 Making Certain File Names “Magic”

You can implement special handling for certain file names. This is called making those names *magic*. The principal use for this feature is in implementing access to remote files (see Section “Remote Files” in *The GNU Emacs Manual*).

To define a kind of magic file name, you must supply a regular expression to define the class of names (all those that match the regular expression), plus a handler that implements all the primitive Emacs file operations for file names that match.

The variable **file-name-handler-alist** holds a list of handlers, together with regular expressions that determine when to apply each handler. Each element has this form:

(regexp . handler)

All the Emacs primitives for file access and file name transformation check the given file name against **file-name-handler-alist**. If the file name matches *regexp*, the primitives handle that file by calling *handler*.

The first argument given to *handler* is the name of the primitive, as a symbol; the remaining arguments are the arguments that were passed to that primitive. (The first of these arguments is most often the file name itself.) For example, if you do this:

(file-exists-p filename)

and *filename* has handler *handler*, then *handler* is called like this:

```
(funcall handler 'file-exists-p filename)
```

When a function takes two or more arguments that must be file names, it checks each of those names for a handler. For example, if you do this:

```
(expand-file-name filename dirname)
```

then it checks for a handler for *filename* and then for a handler for *dirname*. In either case, the *handler* is called like this:

```
(funcall handler 'expand-file-name filename dirname)
```

The *handler* then needs to figure out whether to handle *filename* or *dirname*.

If the specified file name matches more than one handler, the one whose match starts last in the file name gets precedence. This rule is chosen so that handlers for jobs such as uncompression are handled first, before handlers for jobs such as remote file access.

Here are the operations that a magic file name handler gets to handle:

```
abbreviate-file-name, access-file,  
add-name-to-file,  
byte-compiler-base-file-name,  
copy-directory, copy-file,  
delete-directory, delete-file,  
diff-latest-backup-file,  
directory-file-name,  
directory-files,  
directory-files-and-attributes,  
dired-compress-file, dired-uncache,  
exec-path, expand-file-name,  
file-accessible-directory-p,  
file-acl,  
file-attributes,  
file-directory-p,  
file-equal-p,  
file-executable-p, file-exists-p,  
file-in-directory-p,  
file-local-copy, file-locked-p,  
file-modes, file-name-all-completions,  
file-name-as-directory,  
file-name-case-insensitive-p,  
file-name-completion,  
file-name-directory,  
file-name-nondirectory,  
file-name-sans-versions, file-newer-than-file-p,  
file-notify-add-watch, file-notify-rm-watch,  
file-notify-valid-p,  
file-ownership-preserved-p,  
file-readable-p, file-regular-p,  
file-remote-p, file-selinux-context,  
file-symlink-p, file-system-info,
```

```
file-truename, file-writable-p,
find-backup-file-name,
get-file-buffer,
insert-directory,
insert-file-contents,
list-system-processes,
load, lock-file,
make-auto-save-file-name,
make-directory,
make-lock-file-name,
make-nearby-temp-file,
make-process,
make-symbolic-link,
memory-info, process-attributes, process-file,
rename-file, set-file-acl, set-file-modes,
set-file-selinux-context, set-file-times,
set-visited-file-modtime, shell-command,
start-file-process,
substitute-in-file-name,
temporary-file-directory,
unhandled-file-name-directory,
unlock-file,
vc-registered,
verify-visited-file-modtime,
write-region.
```

Handlers for `insert-file-contents` typically need to clear the buffer's modified flag, with `(set-buffer-modified-p nil)`, if the `visit` argument is non-`nil`. This also has the effect of unlocking the buffer if it is locked.

The handler function must handle all of the above operations, and possibly others to be added in the future. It need not implement all these operations itself—when it has nothing special to do for a certain operation, it can reinvoke the primitive, to handle the operation in the usual way. It should always reinvoke the primitive for an operation it does not recognize. Here's one way to do this:

```
(defun my-file-handler (operation &rest args)
  ;; First check for the specific operations
  ;; that we have special handling for.
  (cond ((eq operation 'insert-file-contents) ...)
        ((eq operation 'write-region) ...)

        ...
        ;; Handle any operation we don't know about.
        (t (let ((inhibit-file-name-handlers
                  (cons 'my-file-handler
                        (and (eq inhibit-file-name-operation operation)
                             inhibit-file-name-handlers)))
                (inhibit-file-name-operation operation))
             (apply operation args)))))
```

When a handler function decides to call the ordinary Emacs primitive for the operation at hand, it needs to prevent the primitive from calling the same handler once again, thus leading to an infinite recursion. The example above shows how to do this, with the variables

`inhibit-file-name-handlers` and `inhibit-file-name-operation`. Be careful to use them exactly as shown above; the details are crucial for proper behavior in the case of multiple handlers, and for operations that have two file names that may each have handlers.

Handlers that don't really do anything special for actual access to the file—such as the ones that implement completion of host names for remote file names—should have a non-`nil` `safe-magic` property. For instance, Emacs normally protects directory names it finds in `PATH` from becoming magic, if they look like magic file names, by prefixing them with `'/:'`. But if the handler that would be used for them has a non-`nil` `safe-magic` property, the `'/:'` is not added.

A file name handler can have an `operations` property to declare which operations it handles in a nontrivial way. If this property has a non-`nil` value, it should be a list of operations; then only those operations will call the handler. This avoids inefficiency, but its main purpose is for autoloaded handler functions, so that they won't be loaded except when they have real work to do.

Simply deferring all operations to the usual primitives does not work. For instance, if the file name handler applies to `file-exists-p`, then it must handle `load` itself, because the usual `load` code won't work properly in that case. However, if the handler uses the `operations` property to say it doesn't handle `file-exists-p`, then it need not handle `load` nontrivially.

`inhibit-file-name-handlers`

[Variable]

This variable holds a list of handlers whose use is presently inhibited for a certain operation.

`inhibit-file-name-operation`

[Variable]

The operation for which certain handlers are presently inhibited.

`find-file-name-handler file operation`

[Function]

This function returns the handler function for file name `file`, or `nil` if there is none. The argument `operation` should be the operation to be performed on the file—the value you will pass to the handler as its first argument when you call it. If `operation` equals `inhibit-file-name-operation`, or if it is not found in the `operations` property of the handler, this function returns `nil`.

`file-local-copy filename`

[Function]

This function copies file `filename` to an ordinary non-magic file on the local machine, if it isn't on the local machine already. Magic file names should handle the `file-local-copy` operation if they refer to files on other machines. A magic file name that is used for other purposes than remote file access should not handle `file-local-copy`; then this function will treat the file as local.

If `filename` is local, whether magic or not, this function does nothing and returns `nil`. Otherwise it returns the file name of the local copy file.

`file-remote-p filename &optional identification connected`

[Function]

This function tests whether `filename` is a remote file. If `filename` is local (not remote), the return value is `nil`. If `filename` is indeed remote, the return value is a string that identifies the remote system.

This identifier string can include a host name and a user name, as well as characters designating the method used to access the remote system. For example, the remote identifier string for the file name `/sudo:::/some/file` is `/sudo:root@localhost::`.

If `file-remote-p` returns the same identifier for two different file names, that means they are stored on the same file system and can be accessed locally with respect to each other. This means, for example, that it is possible to start a remote process accessing both files at the same time. Implementers of file name handlers need to ensure this principle is valid.

`identification` specifies which part of the identifier shall be returned as string. `identification` can be the symbol `method`, `user` or `host`; any other value is handled like `nil` and means to return the complete identifier string. In the example above, the remote `user` identifier string would be `root`.

If `connected` is non-`nil`, this function returns `nil` even if `filename` is remote, if Emacs has no network connection to its host. This is useful when you want to avoid the delay of making connections when they don't exist.

`unhandled-file-name-directory filename`

[Function]

This function returns the name of a directory that is not magic. For a non-magic `filename` it returns the corresponding directory name (see Section 26.9.3 [Directory Names], page 637). For a magic `filename`, it invokes the file name handler, which therefore decides what value to return. If `filename` is not accessible from a local process, then the file name handler should indicate that by returning `nil`.

This is useful for running a subprocess; every subprocess must have a non-magic directory to serve as its current directory, and this function is a good way to come up with one.

`file-local-name filename`

[Function]

This function returns the *local part* of `filename`. This is the part of the file's name that identifies it on the remote host, and is typically obtained by removing from the remote file name the parts that specify the remote host and the method of accessing it. For example:

```
(file-local-name "/ssh:user@host:/foo/bar")
⇒ "/foo/bar"
```

For a remote `filename`, this function returns a file name which could be used directly as an argument of a remote process (see Section 40.4 [Asynchronous Processes], page 1086, and see Section 40.3 [Synchronous Processes], page 1081), and as the program to run on the remote host. If `filename` is local, this function returns it unchanged.

`remote-file-name-inhibit-cache`

[User Option]

The attributes of remote files can be cached for better performance. If they are changed outside of Emacs's control, the cached values become invalid, and must be reread.

When this variable is set to `nil`, cached values are never expired. Use this setting with caution, only if you are sure nothing other than Emacs ever changes the remote files. If it is set to `t`, cached values are never used. This is the safest value, but could result in performance degradation.

A compromise is to set it to a positive number. This means that cached values are used for that amount of seconds since they were cached. If a remote file is checked regularly, it might be a good idea to let-bind this variable to a value less than the time period between consecutive checks. For example:

```
(defun display-time-file-nonempty-p (file)
  (let ((remote-file-name-inhibit-cache
         (- display-time-interval 5)))
    (and (file-exists-p file)
         (< 0 (file-attribute-size
                  (file-attributes
                    (file-chase-links file)))))))
```

26.13 File Format Conversion

Emacs performs several steps to convert the data in a buffer (text, text properties, and possibly other information) to and from a representation suitable for storing into a file. This section describes the fundamental functions that perform this *format conversion*, namely `insert-file-contents` for reading a file into a buffer, and `write-region` for writing a buffer into a file.

26.13.1 Overview

The function `insert-file-contents`:

- initially, inserts bytes from the file into the buffer;
- decodes bytes to characters as appropriate;
- processes formats as defined by entries in `format-alist`; and
- calls functions in `after-insert-file-functions`.

The function `write-region`:

- initially, calls functions in `write-region-annotate-functions`;
- processes formats as defined by entries in `format-alist`;
- encodes characters to bytes as appropriate; and
- modifies the file with the bytes.

This shows the symmetry of the lowest-level operations; reading and writing handle things in opposite order. The rest of this section describes the two facilities surrounding the three variables named above, as well as some related functions. Section 34.10 [Coding Systems], page 976, for details on character encoding and decoding.

26.13.2 Round-Trip Specification

The most general of the two facilities is controlled by the variable `format-alist`, a list of *file format* specifications, which describe textual representations used in files for the data in an Emacs buffer. The descriptions for reading and writing are paired, which is why we call this “round-trip” specification (see Section 26.13.3 [Format Conversion Piecemeal], page 657, for non-paired specification).

format-alist [Variable]

This list contains one format definition for each defined file format. Each format definition is a list of this form:

`(name doc-string regexp from-fn to-fn modify mode-fn preserve)`

Here is what the elements in a format definition mean:

name The name of this format.

doc-string A documentation string for the format.

regexp A regular expression which is used to recognize files represented in this format. If `nil`, the format is never applied automatically.

from-fn A shell command or function to decode data in this format (to convert file data into the usual Emacs data representation).

A shell command is represented as a string; Emacs runs the command as a filter to perform the conversion.

If *from-fn* is a function, it is called with two arguments, *begin* and *end*, which specify the part of the buffer it should convert. It should convert the text by editing it in place. Since this can change the length of the text, *from-fn* should return the modified end position.

One responsibility of *from-fn* is to make sure that the beginning of the file no longer matches *regexp*. Otherwise it is likely to get called again. Also, *from-fn* must not involve buffers or files other than the one being decoded, otherwise the internal buffer used for formatting might be overwritten.

to-fn A shell command or function to encode data in this format—that is, to convert the usual Emacs data representation into this format.

If *to-fn* is a string, it is a shell command; Emacs runs the command as a filter to perform the conversion.

If *to-fn* is a function, it is called with three arguments: *begin* and *end*, which specify the part of the buffer it should convert, and *buffer*, which specifies which buffer. There are two ways it can do the conversion:

- By editing the buffer in place. In this case, *to-fn* should return the end-position of the range of text, as modified.
- By returning a list of annotations. This is a list of elements of the form `(position . string)`, where *position* is an integer specifying the relative position in the text to be written, and *string* is the annotation to add there. The list must be sorted in order of position when *to-fn* returns it.

When `write-region` actually writes the text from the buffer to the file, it intermixes the specified annotations at the corresponding positions. All this takes place without modifying the buffer.

to-fn must not involve buffers or files other than the one being encoded, otherwise the internal buffer used for formatting might be overwritten.

modify A flag, `t` if the encoding function modifies the buffer, and `nil` if it works by returning a list of annotations.

- mode-fn** A minor-mode function to call after visiting a file converted from this format. The function is called with one argument, the integer 1; that tells a minor-mode function to enable the mode.
- preserve** A flag, `t` if `format-write-file` should not remove this format from `buffer-file-format`.

The function `insert-file-contents` automatically recognizes file formats when it reads the specified file. It checks the text of the beginning of the file against the regular expressions of the format definitions, and if it finds a match, it calls the decoding function for that format. Then it checks all the known formats over again. It keeps checking them until none of them is applicable.

Visiting a file, with `find-file-noselect` or the commands that use it, performs conversion likewise (because it calls `insert-file-contents`); it also calls the mode function for each format that it decodes. It stores a list of the format names in the buffer-local variable `buffer-file-format`.

buffer-file-format [Variable]
 This variable states the format of the visited file. More precisely, this is a list of the file format names that were decoded in the course of visiting the current buffer's file. It is always buffer-local in all buffers.

When `write-region` writes data into a file, it first calls the encoding functions for the formats listed in `buffer-file-format`, in the order of appearance in the list.

format-write-file *file format &optional confirm* [Command]
 This command writes the current buffer contents into the file *file* in a format based on *format*, which is a list of format names. It constructs the actual format starting from *format*, then appending any elements from the value of `buffer-file-format` with a non-`nil` *preserve* flag (see above), if they are not already present in *format*. It then updates `buffer-file-format` with this format, making it the default for future saves. Except for the *format* argument, this command is similar to `write-file`. In particular, *confirm* has the same meaning and interactive treatment as the corresponding argument to `write-file`. See [Definition of write-file], page 612.

format-find-file *file format* [Command]
 This command finds the file *file*, converting it according to format *format*. It also makes *format* the default if the buffer is saved later.

The argument *format* is a list of format names. If *format* is `nil`, no conversion takes place. Interactively, typing just RET for *format* specifies `nil`.

format-insert-file *file format &optional beg end* [Command]
 This command inserts the contents of file *file*, converting it according to format *format*. If *beg* and *end* are non-`nil`, they specify which part of the file to read, as in `insert-file-contents` (see Section 26.3 [Reading from Files], page 614).

The return value is like what `insert-file-contents` returns: a list of the absolute file name and the length of the data inserted (after conversion).

The argument *format* is a list of format names. If *format* is `nil`, no conversion takes place. Interactively, typing just RET for *format* specifies `nil`.

buffer-auto-save-file-format

[Variable]

This variable specifies the format to use for auto-saving. Its value is a list of format names, just like the value of **buffer-file-format**; however, it is used instead of **buffer-file-format** for writing auto-save files. If the value is `t`, the default, auto-saving uses the same format as a regular save in the same buffer. This variable is always buffer-local in all buffers.

26.13.3 Piecemeal Specification

In contrast to the round-trip specification described in the previous subsection (see Section 26.13.2 [Format Conversion Round-Trip], page 654), you can use the variables **after-insert-file-functions** and **write-region-annotate-functions** to separately control the respective reading and writing conversions.

Conversion starts with one representation and produces another representation. When there is only one conversion to do, there is no conflict about what to start with. However, when there are multiple conversions involved, conflict may arise when two conversions need to start with the same data.

This situation is best understood in the context of converting text properties during **write-region**. For example, the character at position 42 in a buffer is ‘X’ with a text property `foo`. If the conversion for `foo` is done by inserting into the buffer, say, ‘FOO:’, then that changes the character at position 42 from ‘X’ to ‘F’. The next conversion will start with the wrong data straight away.

To avoid conflict, cooperative conversions do not modify the buffer, but instead specify *annotations*, a list of elements of the form (*position . string*), sorted in order of increasing *position*.

If there is more than one conversion, **write-region** merges their annotations destructively into one sorted list. Later, when the text from the buffer is actually written to the file, it intermixes the specified annotations at the corresponding positions. All this takes place without modifying the buffer.

In contrast, when reading, the annotations intermixed with the text are handled immediately. **insert-file-contents** sets point to the beginning of some text to be converted, then calls the conversion functions with the length of that text. These functions should always return with point at the beginning of the inserted text. This approach makes sense for reading because annotations removed by the first converter can’t be mistakenly processed by a later converter. Each conversion function should scan for the annotations it recognizes, remove the annotation, modify the buffer text (to set a text property, for example), and return the updated length of the text, as it stands after those changes. The value returned by one function becomes the argument to the next function.

write-region-annotate-functions

[Variable]

A list of functions for **write-region** to call. Each function in the list is called with two arguments: the start and end of the region to be written. These functions should not alter the contents of the buffer. Instead, they should return annotations.

As a special case, a function may return with a different buffer current. Emacs takes this to mean that the current buffer contains altered text to be output. It therefore changes the *start* and *end* arguments of the **write-region** call, giving them the values

of `point-min` and `point-max` in the new buffer, respectively. It also discards all previous annotations, because they should have been dealt with by this function.

write-region-post-annotation-function [Variable]

The value of this variable, if non-`nil`, should be a function. This function is called, with no arguments, after `write-region` has completed.

If any function in `write-region-annotate-functions` returns with a different buffer current, Emacs calls `write-region-post-annotation-function` more than once. Emacs calls it with the last buffer that was current, and again with the buffer before that, and so on back to the original buffer.

Thus, a function in `write-region-annotate-functions` can create a buffer, give this variable the local value of `kill-buffer` in that buffer, set up the buffer with altered text, and make the buffer current. The buffer will be killed after `write-region` is done.

after-insert-file-functions [Variable]

Each function in this list is called by `insert-file-contents` with one argument, the number of characters inserted, and with point at the beginning of the inserted text. Each function should leave point unchanged, and return the new character count describing the inserted text as modified by the function.

We invite users to write Lisp programs to store and retrieve text properties in files, using these hooks, and thus to experiment with various data formats and find good ones. Eventually we hope users will produce good, general extensions we can install in Emacs.

We suggest not trying to handle arbitrary Lisp objects as text property names or values—because a program that general is probably difficult to write, and slow. Instead, choose a set of possible data types that are reasonably flexible, and not too hard to encode.

27 Backups and Auto-Saving

Backup files and auto-save files are two methods by which Emacs tries to protect the user from the consequences of crashes or of the user's own errors. Auto-saving preserves the text from earlier in the current editing session; backup files preserve file contents prior to the current session.

27.1 Backup Files

A *backup file* is a copy of the old contents of a file you are editing. Emacs makes a backup file the first time you save a buffer into its visited file. Thus, normally, the backup file contains the contents of the file as it was before the current editing session. The contents of the backup file normally remain unchanged once it exists.

Backups are usually made by renaming the visited file to a new name. Optionally, you can specify that backup files should be made by copying the visited file. This choice makes a difference for files with multiple names; it also can affect whether the edited file remains owned by the original owner or becomes owned by the user editing it.

By default, Emacs makes a single backup file for each file edited. You can alternatively request numbered backups; then each new backup file gets a new name. You can delete old numbered backups when you don't want them any more, or Emacs can delete them automatically.

For performance, the operating system may not write the backup file's contents to secondary storage immediately, or may alias the backup data with the original until one or the other is later modified. See Section 26.8 [Files and Storage], page 634.

27.1.1 Making Backup Files

`backup-buffer`

[Function]

This function makes a backup of the file visited by the current buffer, if appropriate. It is called by `save-buffer` before saving the buffer the first time.

If a backup was made by renaming, the return value is a cons cell of the form (*modes extra-alist backupname*), where *modes* are the mode bits of the original file, as returned by `file-modes` (see Section 26.6.1 [Testing Accessibility], page 619), *extra-alist* is an alist describing the original file's extended attributes, as returned by `file-extended-attributes` (see Section 26.6.5 [Extended Attributes], page 627), and *backupname* is the name of the backup.

In all other cases (i.e., if a backup was made by copying or if no backup was made), this function returns `nil`.

`buffer-backed-up`

[Variable]

This buffer-local variable says whether this buffer's file has been backed up on account of this buffer. If it is `non-nil`, the backup file has been written. Otherwise, the file should be backed up when it is next saved (if backups are enabled). This is a permanent local; `kill-all-local-variables` does not alter it.

make-backup-files

[User Option]

This variable determines whether or not to make backup files. If it is non-*nil*, then Emacs creates a backup of each file when it is saved for the first time—provided that **backup-inhibited** is *nil* (see below).

The following example shows how to change the **make-backup-files** variable only in the Rmail buffers and not elsewhere. Setting it *nil* stops Emacs from making backups of these files, which may save disk space. (You would put this code in your init file.)

```
(add-hook 'rmail-mode-hook
          (lambda () (setq-local make-backup-files nil)))
```

backup-enable-predicate

[Variable]

This variable's value is a function to be called on certain occasions to decide whether a file should have backup files. The function receives one argument, an absolute file name to consider. If the function returns *nil*, backups are disabled for that file. Otherwise, the other variables in this section say whether and how to make backups. The default value is **normal-backup-enable-predicate**, which checks for files in **temporary-file-directory** and **small-temporary-file-directory**.

backup-inhibited

[Variable]

If this variable is non-*nil*, backups are inhibited. It records the result of testing **backup-enable-predicate** on the visited file name. It can also coherently be used by other mechanisms that inhibit backups based on which file is visited. For example, VC sets this variable non-*nil* to prevent making backups for files managed with a version control system.

This is a permanent local, so that changing the major mode does not lose its value. Major modes should not set this variable—they should set **make-backup-files** instead.

backup-directory-alist

[User Option]

This variable's value is an alist of filename patterns and backup directories. Each element looks like

```
(regexp . directory)
```

Backups of files with names matching *regexp* will be made in *directory*. *directory* may be relative or absolute. If it is absolute, so that all matching files are backed up into the same directory, the file names in this directory will be the full name of the file backed up with all directory separators changed to ‘!’ to prevent clashes. This will not work correctly if your filesystem truncates the resulting name.

For the common case of all backups going into one directory, the alist should contain a single element pairing ““.”” with the appropriate directory.

If this variable is *nil* (the default), or it fails to match a filename, the backup is made in the original file's directory.

On MS-DOS filesystems without long names this variable is always ignored.

make-backup-file-name-function

[User Option]

This variable's value is a function to use for making backup file names. The function **make-backup-file-name** calls it. See Section 27.1.4 [Naming Backup Files], page 662.

This could be buffer-local to do something special for specific files. If you change it, you may need to change **backup-file-name-p** and **file-name-sans-versions** too.

27.1.2 Backup by Renaming or by Copying?

There are two ways that Emacs can make a backup file:

- Emacs can rename the original file so that it becomes a backup file, and then write the buffer being saved into a new file. After this procedure, any other names (i.e., hard links) of the original file now refer to the backup file. The new file is owned by the user doing the editing, and its group is the default for new files written by the user in that directory.
- Emacs can copy the original file into a backup file, and then overwrite the original file with new contents. After this procedure, any other names (i.e., hard links) of the original file continue to refer to the current (updated) version of the file. The file's owner and group will be unchanged.

The first method, renaming, is the default.

The variable `backup-by-copying`, if non-`nil`, says to use the second method, which is to copy the original file and overwrite it with the new buffer contents. The variable `file-precious-flag`, if non-`nil`, also has this effect (as a sideline of its main significance). See Section 26.2 [Saving Buffers], page 612.

backup-by-copying [User Option]

If this variable is non-`nil`, Emacs always makes backup files by copying. The default is `nil`.

The following three variables, when non-`nil`, cause the second method to be used in certain special cases. They have no effect on the treatment of files that don't fall into the special cases.

backup-by-copying-when-linked [User Option]

If this variable is non-`nil`, Emacs makes backups by copying for files with multiple names (hard links). The default is `nil`.

This variable is significant only if `backup-by-copying` is `nil`, since copying is always used when that variable is non-`nil`.

backup-by-copying-when-mismatch [User Option]

If this variable is non-`nil` (the default), Emacs makes backups by copying in cases where renaming would change either the owner or the group of the file.

The value has no effect when renaming would not alter the owner or group of the file; that is, for files which are owned by the user and whose group matches the default for a new file created there by the user.

This variable is significant only if `backup-by-copying` is `nil`, since copying is always used when that variable is non-`nil`.

backup-by-copying-when-privileged-mismatch [User Option]

This variable, if non-`nil`, specifies the same behavior as `backup-by-copying-when-mismatch`, but only for certain user-id and group-id values: namely, those less than or equal to a certain number. You set this variable to that number.

Thus, if you set `backup-by-copying-when-privileged-mismatch` to 0, backup by copying is done for the superuser and group 0 only, when necessary to prevent a change in the owner of the file.

The default is 200.

27.1.3 Making and Deleting Numbered Backup Files

If a file's name is `foo`, the names of its numbered backup versions are `foo.~v~`, for various integers `v`, like this: `foo.~1~`, `foo.~2~`, `foo.~3~`, ..., `foo.~259~`, and so on.

version-control [User Option]

This variable controls whether to make a single non-numbered backup file or multiple numbered backups.

`nil` Make numbered backups if the visited file already has numbered backups; otherwise, do not. This is the default.

`never` Do not make numbered backups.

`anything else` Make numbered backups.

The use of numbered backups ultimately leads to a large number of backup versions, which must then be deleted. Emacs can do this automatically or it can ask the user whether to delete them.

kept-new-versions [User Option]

The value of this variable is the number of newest versions to keep when a new numbered backup is made. The newly made backup is included in the count. The default value is 2.

kept-old-versions [User Option]

The value of this variable is the number of oldest versions to keep when a new numbered backup is made. The default value is 2.

If there are backups numbered 1, 2, 3, 5, and 7, and both of these variables have the value 2, then the backups numbered 1 and 2 are kept as old versions and those numbered 5 and 7 are kept as new versions; backup version 3 is excess. The function `find-backup-file-name` (see Section 27.1.4 [Backup Names], page 662) is responsible for determining which backup versions to delete, but does not delete them itself.

delete-old-versions [User Option]

If this variable is `t`, then saving a file deletes excess backup versions silently. If it is `nil`, that means to ask for confirmation before deleting excess backups. Otherwise, they are not deleted at all.

dired-kept-versions [User Option]

This variable specifies how many of the newest backup versions to keep in the Dired command `.` (`dired-clean-directory`). That's the same thing `kept-new-versions` specifies when you make a new backup file. The default is 2.

27.1.4 Naming Backup Files

The functions in this section are documented mainly because you can customize the naming conventions for backup files by redefining them. If you change one, you probably need to change the rest.

backup-file-name-p *filename* [Function]

This function returns a non-*nil* value if *filename* is a possible name for a backup file. It just checks the name, not whether a file with the name *filename* exists.

```
(backup-file-name-p "foo")
  ⇒ nil
(backup-file-name-p "foo~")
  ⇒ 3
```

The standard definition of this function is as follows:

```
(defun backup-file-name-p (file)
  "Return non-nil if FILE is a backup file \
name (numeric or not)..."'
  (string-match "~\\\" file))
```

Thus, the function returns a non-*nil* value if the file name ends with a ‘~’. (We use a backslash to split the documentation string’s first line into two lines in the text, but produce just one line in the string itself.)

This simple expression is placed in a separate function to make it easy to redefine for customization.

make-backup-file-name *filename* [Function]

This function returns a string that is the name to use for a non-numbered backup file for file *filename*. On Unix, this is just *filename* with a tilde appended.

The standard definition of this function, on most operating systems, is as follows:

```
(defun make-backup-file-name (file)
  "Create the non-numeric backup file name for FILE..."
  (concat file "~"))
```

You can change the backup-file naming convention by redefining this function. The following example redefines **make-backup-file-name** to prepend a ‘.’ in addition to appending a tilde:

```
(defun make-backup-file-name (filename)
  (expand-file-name
   (concat "." (file-name-nondirectory filename) "~")
   (file-name-directory filename)))

(make-backup-file-name "backups.texi")
  ⇒ ".backups.texi~"
```

Some parts of Emacs, including some **Dired** commands, assume that backup file names end with ‘~’. If you do not follow that convention, it will not cause serious problems, but these commands may give less-than-desirable results.

find-backup-file-name *filename* [Function]

This function computes the file name for a new backup file for *filename*. It may also propose certain existing backup files for deletion. **find-backup-file-name** returns a list whose CAR is the name for the new backup file and whose CDR is a list of backup files whose deletion is proposed. The value can also be *nil*, which means not to make a backup.

Two variables, **kept-old-versions** and **kept-new-versions**, determine which backup versions should be kept. This function keeps those versions by excluding them from the CDR of the value. See Section 27.1.3 [Numbered Backups], page 662.

In this example, the value says that `~rms/foo.~5~` is the name to use for the new backup file, and `~rms/foo.~3~` is an excess version that the caller should consider deleting now.

```
(find-backup-file-name "~rms/foo")
⇒ ("~rms/foo.~5~" "~rms/foo.~3~")
```

file-backup-file-names *filename*

[Function]

This function returns a list of all the backup file names for *filename*, or `nil` if there are none. The files are sorted by modification time, descending, so that the most recent files are first.

file-newest-backup *filename*

[Function]

This function returns the first element of the list returned by `file-backup-file-names`.

Some file comparison commands use this function so that they can automatically compare a file with its most recent backup.

27.2 Auto-Saving

Emacs periodically saves all files that you are visiting; this is called *auto-saving*. Auto-saving prevents you from losing more than a limited amount of work if the system crashes. By default, auto-saves happen every 300 keystrokes, or after around 30 seconds of idle time. See Section “Auto-Saving: Protection Against Disasters” in *The GNU Emacs Manual*, for information on auto-save for users. Here we describe the functions used to implement auto-saving and the variables that control them.

buffer-auto-save-file-name

[Variable]

This buffer-local variable is the name of the file used for auto-saving the current buffer. It is `nil` if the buffer should not be auto-saved.

```
buffer-auto-save-file-name
⇒ "/xcssun/users/rms/lewis/#backups.texi#"
```

auto-save-mode *arg*

[Command]

This is the mode command for Auto Save mode, a buffer-local minor mode. When Auto Save mode is enabled, auto-saving is enabled in the buffer. The calling convention is the same as for other minor mode commands (see Section 24.3.1 [Minor Mode Conventions], page 544).

Unlike most minor modes, there is no `auto-save-mode` variable. Auto Save mode is enabled if `buffer-auto-save-file-name` is non-`nil` and `buffer-saved-size` (see below) is non-zero.

auto-save-file-name-transforms

[Variable]

This variable lists transforms to apply to buffer’s file name before making the auto-save file name.

Each transform is a list of the form `(regexp replacement [uniquify])`. `regexp` is a regular expression to match against the file name; if it matches, `replace-match` is used to replace the matching part with `replacement`. If the optional element `uniquify` is non-`nil`, the auto-save file name is constructed by concatenating the directory

part of the transformed file name with the buffer's file name in which all directory separators were changed to '!' to prevent clashes. (This will not work correctly if your filesystem truncates the resulting name.)

If *uniquify* is one of the members of `secure-hash-algorithms`, Emacs constructs the nondirectory part of the auto-save file name by applying that `secure-hash` to the buffer file name. This avoids any risk of excessively long file names.

All the transforms in the list are tried, in the order they are listed. When one transform applies, its result is final; no further transforms are tried.

The default value is set up to put the auto-save files of remote files into the temporary directory (see Section 26.9.5 [Unique File Names], page 641).

On MS-DOS filesystems without long names this variable is always ignored.

auto-save-file-name-p *filename* [Function]

This function returns a non-`nil` value if *filename* is a string that could be the name of an auto-save file. It assumes the usual naming convention for auto-save files: a name that begins and ends with hash marks ('#') is a possible auto-save file name. The argument *filename* should not contain a directory part.

```
(make-auto-save-file-name)
  ⇒ "/xcssun/users/rms/lewis/#backups.texi#"
(auto-save-file-name-p "#backups.texi#")
  ⇒ 0
(auto-save-file-name-p "backups.texi")
  ⇒ nil
```

make-auto-save-file-name [Function]

This function returns the file name to use for auto-saving the current buffer. This is just the file name with hash marks ('#') prepended and appended to it. This function does not look at the variable `auto-save-visited-file-name` (described below); callers of this function should check that variable first.

```
(make-auto-save-file-name)
  ⇒ "/xcssun/users/rms/lewis/#backups.texi#"
```

auto-save-visited-file-name [User Option]

If this variable is non-`nil`, Emacs auto-saves buffers in the files they are visiting. That is, the auto-save is done in the same file that you are editing. Normally, this variable is `nil`, so auto-save files have distinct names that are created by `make-auto-save-file-name`.

When you change the value of this variable, the new value does not take effect in an existing buffer until the next time auto-save mode is reenabled in it. If auto-save mode is already enabled, auto-saves continue to go in the same file name until `auto-save-mode` is called again.

Note that setting this variable to a non-`nil` value does not change the fact that auto-saving is different from saving the buffer; e.g., the hooks described in Section 26.2 [Saving Buffers], page 612, are *not* run when a buffer is auto-saved.

recent-auto-save-p [Function]

This function returns `t` if the current buffer has been auto-saved since the last time it was read in or saved.

set-buffer-auto-saved [Function]

This function marks the current buffer as auto-saved. The buffer will not be auto-saved again until the buffer text is changed again. The function returns `nil`.

auto-save-interval [User Option]

The value of this variable specifies how often to do auto-saving, in terms of number of input events. Each time this many additional input events are read, Emacs does auto-saving for all buffers in which that is enabled. Setting this to zero disables autosaving based on the number of characters typed.

auto-save-timeout [User Option]

The value of this variable is the number of seconds of idle time that should cause auto-saving. Each time the user pauses for this long, Emacs does auto-saving for all buffers in which that is enabled. (If the current buffer is large, the specified timeout is multiplied by a factor that increases as the size increases; for a million-byte buffer, the factor is almost 4.)

If the value is zero or `nil`, then auto-saving is not done as a result of idleness, only after a certain number of input events as specified by `auto-save-interval`.

auto-save-hook [Variable]

This normal hook is run whenever an auto-save is about to happen.

auto-save-default [User Option]

If this variable is non-`nil`, buffers that are visiting files have auto-saving enabled by default. Otherwise, they do not.

do-auto-save &optional no-message current-only [Command]

This function auto-saves all buffers that need to be auto-saved. It saves all buffers for which auto-saving is enabled and that have been changed since the previous auto-save.

If any buffers are auto-saved, `do-auto-save` normally displays a message saying ‘Auto-saving...’ in the echo area while auto-saving is going on. However, if `no-message` is non-`nil`, the message is inhibited.

If `current-only` is non-`nil`, only the current buffer is auto-saved.

delete-auto-save-file-if-necessary &optional force [Function]

This function deletes the current buffer’s auto-save file if `delete-auto-save-files` is non-`nil`. It is called every time a buffer is saved.

Unless `force` is non-`nil`, this function only deletes the file if it was written by the current Emacs session since the last true save.

delete-auto-save-files [User Option]

This variable is used by the function `delete-auto-save-file-if-necessary`. If it is non-`nil`, Emacs deletes auto-save files when a true save is done (in the visited file). This saves disk space and unclutters your directory.

rename-auto-save-file

[Function]

This function adjusts the current buffer's auto-save file name if the visited file name has changed. It also renames an existing auto-save file, if it was made in the current Emacs session. If the visited file name has not changed, this function does nothing.

buffer-saved-size

[Variable]

The value of this buffer-local variable is the length of the current buffer, when it was last read in, saved, or auto-saved. This is used to detect a substantial decrease in size, and turn off auto-saving in response.

If it is `-1`, that means auto-saving is temporarily shut off in this buffer due to a substantial decrease in size. Explicitly saving the buffer stores a positive value in this variable, thus reenabling auto-saving. Turning auto-save mode off or on also updates this variable, so that the substantial decrease in size is forgotten.

If it is `-2`, that means this buffer should disregard changes in buffer size; in particular, it should not shut off auto-saving temporarily due to changes in buffer size.

auto-save-list-file-name

[Variable]

This variable (if non-`nil`) specifies a file for recording the names of all the auto-save files. Each time Emacs does auto-saving, it writes two lines into this file for each buffer that has auto-saving enabled. The first line gives the name of the visited file (it's empty if the buffer has none), and the second gives the name of the auto-save file.

When Emacs exits normally, it deletes this file; if Emacs crashes, you can look in the file to find all the auto-save files that might contain work that was otherwise lost. The `recover-session` command uses this file to find them.

The default name for this file specifies your home directory and starts with '`.saves-`'. It also contains the Emacs process ID and the host name.

auto-save-list-file-prefix

[User Option]

After Emacs reads your init file, it initializes `auto-save-list-file-name` (if you have not already set it non-`nil`) based on this prefix, adding the host name and process ID. If you set this to `nil` in your init file, then Emacs does not initialize `auto-save-list-file-name`.

27.3 Reverting

If you have made extensive changes to a file and then change your mind about them, you can get rid of them by reading in the previous version of the file with the `revert-buffer` command. See Section “Reverting a Buffer” in *The GNU Emacs Manual*.

revert-buffer &optional ignore-auto noconfirm preserve-modes

[Command]

This command replaces the buffer text with the text of the visited file on disk. This action undoes all changes since the file was visited or saved.

By default, if the latest auto-save file is more recent than the visited file, and the argument `ignore-auto` is `nil`, `revert-buffer` asks the user whether to use that auto-save instead. When you invoke this command interactively, `ignore-auto` is `t` if there is no numeric prefix argument; thus, the interactive default is not to check the auto-save file.

Normally, `revert-buffer` asks for confirmation before it changes the buffer; but if the argument `noconfirm` is non-`nil`, `revert-buffer` does not ask for confirmation.

Normally, this command reinitializes the buffer's major and minor modes using `normal-mode`. But if `preserve-modes` is non-`nil`, the modes remain unchanged.

Reverting tries to preserve marker positions in the buffer by using the replacement feature of `insert-file-contents`. If the buffer contents and the file contents are identical before the revert operation, reverting preserves all the markers. If they are not identical, reverting does change the buffer; in that case, it preserves the markers in the unchanged text (if any) at the beginning and end of the buffer. Preserving any additional markers would be problematic.

When reverting from non-file sources, markers are usually not preserved, but this is up to the specific `revert-buffer-function` implementation.

revert-buffer-in-progress-p [Variable]
`revert-buffer` binds this variable to a non-`nil` value while it is working.

You can customize how `revert-buffer` does its work by setting the variables described in the rest of this section.

revert-without-query [User Option]
This variable holds a list of files that should be reverted without query. The value is a list of regular expressions. If the visited file name matches one of these regular expressions, and the file has changed on disk but the buffer is not modified, then `revert-buffer` reverts the file without asking the user for confirmation.

Some major modes customize `revert-buffer` by making buffer-local bindings for these variables:

revert-buffer-function [Variable]
The value of this variable is the function to use to revert this buffer. It should be a function with two optional arguments to do the work of reverting. The two optional arguments, `ignore-auto` and `noconfirm`, are the arguments that `revert-buffer` received.

Modes such as `Dired` mode, in which the text being edited does not consist of a file's contents but can be regenerated in some other fashion, can give this variable a buffer-local value that is a special function to regenerate the contents.

revert-buffer-insert-file-contents-function [Variable]
The value of this variable specifies the function to use to insert the updated contents when reverting this buffer. The function receives two arguments: first the file name to use; second, `t` if the user has asked to read the auto-save file.

The reason for a mode to change this variable instead of `revert-buffer-function` is to avoid duplicating or replacing the rest of what `revert-buffer` does: asking for confirmation, clearing the undo list, deciding the proper major mode, and running the hooks listed below.

before-revert-hook [Variable]
This normal hook is run by the default `revert-buffer-function` before inserting the modified contents. A custom `revert-buffer-function` may or may not run this hook.

after-revert-hook

[Variable]

This normal hook is run by the default **revert-buffer-function** after inserting the modified contents. A custom **revert-buffer-function** may or may not run this hook.

Emacs can revert buffers automatically. It does that by default for buffers visiting files. The following describes how to add support for auto-reverting new types of buffers.

First, such buffers must have a suitable **revert-buffer-function** and **buffer-stale-function** defined.

buffer-stale-function

[Variable]

The value of this variable specifies a function to call to check whether a buffer needs reverting. The default value only handles buffers that are visiting files, by checking their modification time. Buffers that are not visiting files require a custom function of one optional argument *noconfirm*. The function should return *non-nil* if the buffer should be reverted. The buffer is current when this function is called.

While this function is mainly intended for use in auto-reverting, it could be used for other purposes as well. For instance, if auto-reverting is not enabled, it could be used to warn the user that the buffer needs reverting. The idea behind the *noconfirm* argument is that it should be *t* if the buffer is going to be reverted without asking the user and *nil* if the function is just going to be used to warn the user that the buffer is out of date. In particular, for use in auto-reverting, *noconfirm* is *t*. If the function is only going to be used for auto-reverting, you can ignore the *noconfirm* argument.

If you just want to automatically auto-revert every **auto-revert-interval** seconds (like the Buffer Menu), use:

```
(setq-local buffer-stale-function
           (lambda (&optional noconfirm) 'fast))
```

in the buffer's mode function.

The special return value '**fast**' tells the caller that the need for reverting was not checked, but that reverting the buffer is fast. It also tells Auto Revert not to print any revert messages, even if **auto-revert-verbose** is *non-nil*. This is important, as getting revert messages every **auto-revert-interval** seconds can be very annoying. The information provided by this return value could also be useful if the function is consulted for purposes other than auto-reverting.

Once the buffer has a suitable **revert-buffer-function** and **buffer-stale-function**, several problems usually remain.

The buffer will only auto-revert if it is marked unmodified. Hence, you will have to make sure that various functions mark the buffer modified if and only if either the buffer contains information that might be lost by reverting, or there is reason to believe that the user might be inconvenienced by auto-reverting, because he is actively working on the buffer. The user can always override this by manually adjusting the modified status of the buffer. To support this, calling the **revert-buffer-function** on a buffer that is marked unmodified should always keep the buffer marked unmodified.

It is important to assure that point does not continuously jump around as a consequence of auto-reverting. Of course, moving point might be inevitable if the buffer radically changes.

You should make sure that the `revert-buffer-function` does not print messages that unnecessarily duplicate Auto Revert's own messages, displayed if `auto-revert-verbose` is `t`, and effectively override a `nil` value for `auto-revert-verbose`. Hence, adapting a mode for auto-reverting often involves getting rid of such messages. This is especially important for buffers that automatically revert every `auto-revert-interval` seconds.

If the new auto-reverting is part of Emacs, you should mention it in the documentation string of `global-auto-revert-non-file-buffers`.

Similarly, you should document the additions in the Emacs manual.

28 Buffers

A *buffer* is a Lisp object containing text to be edited. Buffers are used to hold the contents of files that are being visited; there may also be buffers that are not visiting files. While several buffers may exist at one time, only one buffer is designated the *current buffer* at any time. Most editing commands act on the contents of the current buffer. Each buffer, including the current buffer, may or may not be displayed in any windows.

28.1 Buffer Basics

Buffers in Emacs editing are objects that have distinct names and hold text that can be edited. Buffers appear to Lisp programs as a special data type. You can think of the contents of a buffer as a string that you can extend; insertions and deletions may occur in any part of the buffer. See Chapter 33 [Text], page 878.

A Lisp buffer object contains numerous pieces of information. Some of this information is directly accessible to the programmer through variables, while other information is accessible only through special-purpose functions. For example, the visited file name is directly accessible through a variable, while the value of point is accessible only through a primitive function.

Buffer-specific information that is directly accessible is stored in *buffer-local* variable bindings, which are variable values that are effective only in a particular buffer. This feature allows each buffer to override the values of certain variables. Most major modes override variables such as `fill-column` or `comment-column` in this way. For more information about buffer-local variables and functions related to them, see Section 12.11 [Buffer-Local Variables], page 207.

For functions and variables related to visiting files in buffers, see Section 26.1 [Visiting Files], page 608, and Section 26.2 [Saving Buffers], page 612. For functions and variables related to the display of buffers in windows, see Section 29.11 [Buffers and Windows], page 720.

bufferp *object* [Function]

This function returns `t` if *object* is a buffer, `nil` otherwise.

28.2 The Current Buffer

There are, in general, many buffers in an Emacs session. At any time, one of them is designated the *current buffer*—the buffer in which most editing takes place. Most of the primitives for examining or changing text operate implicitly on the current buffer (see Chapter 33 [Text], page 878).

Normally, the buffer displayed in the selected window (see Section 29.3 [Selecting Windows], page 696) is the current buffer, but this is not always so: a Lisp program can temporarily designate any buffer as current in order to operate on its contents, without changing what is displayed on the screen. The most basic function for designating a current buffer is `set-buffer`.

current-buffer [Function]

This function returns the current buffer.

```
(current-buffer)
⇒ #<buffer buffers.texi>

set-buffer buffer-or-name [Function]
```

This function makes *buffer-or-name* the current buffer. *buffer-or-name* must be an existing buffer or the name of an existing buffer. The return value is the buffer made current.

This function does not display the buffer in any window, so the user cannot necessarily see the buffer. But Lisp programs will now operate on it.

When an editing command returns to the editor command loop, Emacs automatically calls **set-buffer** on the buffer shown in the selected window (see Section 29.3 [Selecting Windows], page 696). This is to prevent confusion: it ensures that the buffer that the cursor is in, when Emacs reads a command, is the buffer to which that command applies (see Chapter 22 [Command Loop], page 423). Thus, you should not use **set-buffer** to switch visibly to a different buffer; for that, use the functions described in Section 29.12 [Switching Buffers], page 721.

When writing a Lisp function, do *not* rely on this behavior of the command loop to restore the current buffer after an operation. Editing commands can also be called as Lisp functions by other programs, not just from the command loop; it is convenient for the caller if the subroutine does not change which buffer is current (unless, of course, that is the subroutine's purpose).

To operate temporarily on another buffer, put the **set-buffer** within a **save-current-buffer** form. Here, as an example, is a simplified version of the command **append-to-buffer**:

```
(defun append-to-buffer (buffer start end)
  "Append the text of the region to BUFFER."
  (interactive "BAppend to buffer: \nr")
  (let ((oldbuf (current-buffer)))
    (save-current-buffer
      (set-buffer (get-buffer-create buffer))
      (insert-buffer-substring oldbuf start end))))
```

Here, we bind a local variable to record the current buffer, and then **save-current-buffer** arranges to make it current again later. Next, **set-buffer** makes the specified buffer current, and **insert-buffer-substring** copies the string from the original buffer to the specified (and now current) buffer.

Alternatively, we can use the **with-current-buffer** macro:

```
(defun append-to-buffer (buffer start end)
  "Append the text of the region to BUFFER."
  (interactive "BAppend to buffer: \nr")
  (let ((oldbuf (current-buffer)))
    (with-current-buffer (get-buffer-create buffer)
      (insert-buffer-substring oldbuf start end))))
```

In either case, if the buffer appended to happens to be displayed in some window, the next redisplay will show how its text has changed. If it is not displayed in any window,

you will not see the change immediately on the screen. The command causes the buffer to become current temporarily, but does not cause it to be displayed.

If you make local bindings (with `let` or function arguments) for a variable that may also have buffer-local bindings, make sure that the same buffer is current at the beginning and at the end of the local binding's scope. Otherwise you might bind it in one buffer and unbind it in another!

Do not rely on using `set-buffer` to change the current buffer back, because that won't do the job if a quit happens while the wrong buffer is current. For instance, in the previous example, it would have been wrong to do this:

```
(let ((oldbuf (current-buffer)))
  (set-buffer (get-buffer-create buffer))
  (insert-buffer-substring oldbuf start end)
  (set-buffer oldbuf))
```

Using `save-current-buffer` or `with-current-buffer`, as we did, correctly handles quitting, errors, and `throw`, as well as ordinary evaluation.

`save-current-buffer body...`

[Special Form]

The `save-current-buffer` special form saves the identity of the current buffer, evaluates the *body* forms, and finally restores that buffer as current. The return value is the value of the last form in *body*. The current buffer is restored even in case of an abnormal exit via `throw` or `error` (see Section 11.7 [Nonlocal Exits], page 177).

If the buffer that used to be current has been killed by the time of exit from `save-current-buffer`, then it is not made current again, of course. Instead, whichever buffer was current just before exit remains current.

`with-current-buffer buffer-or-name body...`

[Macro]

The `with-current-buffer` macro saves the identity of the current buffer, makes *buffer-or-name* current, evaluates the *body* forms, and finally restores the current buffer. *buffer-or-name* must specify an existing buffer or the name of an existing buffer.

The return value is the value of the last form in *body*. The current buffer is restored even in case of an abnormal exit via `throw` or `error` (see Section 11.7 [Nonlocal Exits], page 177).

`with-temp-buffer body...`

[Macro]

The `with-temp-buffer` macro evaluates the *body* forms with a temporary buffer as the current buffer. It saves the identity of the current buffer, creates a temporary buffer and makes it current, evaluates the *body* forms, and finally restores the previous current buffer while killing the temporary buffer.

By default, undo information (see Section 33.9 [Undo], page 895) is not recorded in the buffer created by this macro (but *body* can enable that, if needed). The temporary buffer also does not run the hooks `kill-buffer-hook`, `kill-buffer-query-functions` (see Section 28.10 [Killing Buffers], page 685), and `buffer-list-update-hook` (see Section 28.8 [Buffer List], page 681).

The return value is the value of the last form in *body*. You can return the contents of the temporary buffer by using `(buffer-string)` as the last form.

The current buffer is restored even in case of an abnormal exit via `throw` or error (see Section 11.7 [Nonlocal Exits], page 177).

See also `with-temp-file` in [Writing to Files], page 617.

28.3 Buffer Names

Each buffer has a unique name, which is a string. Many of the functions that work on buffers accept either a buffer or a buffer name as an argument. Any argument called *buffer-or-name* is of this sort, and an error is signaled if it is neither a string nor a buffer. Any argument called *buffer* must be an actual buffer object, not a name.

Buffers that are ephemeral and generally uninteresting to the user have names starting with a space, so that the `list-buffers` and `buffer-menu` commands don't mention them (but if such a buffer visits a file, it is mentioned). A name starting with space also initially disables recording undo information; see Section 33.9 [Undo], page 895.

buffer-name &**optional** *buffer* [Function]

This function returns the name of *buffer* as a string. *buffer* defaults to the current buffer.

If `buffer-name` returns `nil`, it means that *buffer* has been killed. See Section 28.10 [Killing Buffers], page 685.

```
(buffer-name)
  ⇒ "buffers.texi"

(setq foo (get-buffer "temp"))
  ⇒ #<buffer temp>
(kill-buffer foo)
  ⇒ nil
(buffer-name foo)
  ⇒ nil
foo
  ⇒ #<killed buffer>
```

rename-buffer *newname* &**optional** *unique* [Command]

This function renames the current buffer to *newname*. An error is signaled if *newname* is not a string.

Ordinarily, `rename-buffer` signals an error if *newname* is already in use. However, if *unique* is non-`nil`, it modifies *newname* to make a name that is not in use. Interactively, you can make *unique* non-`nil` with a numeric prefix argument. (This is how the command `rename-uniquely` is implemented.)

This function returns the name actually given to the buffer.

get-buffer *buffer-or-name* [Function]

This function returns the buffer specified by *buffer-or-name*. If *buffer-or-name* is a string and there is no buffer with that name, the value is `nil`. If *buffer-or-name* is a buffer, it is returned as given; that is not very useful, so the argument is usually a name. For example:

```
(setq b (get-buffer "lewis"))
  ⇒ #<buffer lewis>
```

```
(get-buffer b)
  ⇒ #<buffer lewis>
(get-buffer "Frazzle-nots")
  ⇒ nil
```

See also the function `get-buffer-create` in Section 28.9 [Creating Buffers], page 684.

generate-new-buffer-name *starting-name* &*optional ignore* [Function]

This function returns a name that would be unique for a new buffer—but does not create the buffer. It starts with *starting-name*, and produces a name not currently in use for any buffer by appending a number inside of ‘`<...>`’. It starts at 2 and keeps incrementing the number until it is not the name of an existing buffer.

If the optional second argument *ignore* is non-`nil`, it should be a string, a potential buffer name. It means to consider that potential buffer acceptable, if it is tried, even if it is the name of an existing buffer (which would normally be rejected). Thus, if buffers named ‘`foo`’, ‘`foo<2>`’, ‘`foo<3>`’ and ‘`foo<4>`’ exist,

```
(generate-new-buffer-name "foo")
  ⇒ "foo<5>"
(generate-new-buffer-name "foo" "foo<3>")
  ⇒ "foo<3>"
(generate-new-buffer-name "foo" "foo<6>")
  ⇒ "foo<5>"
```

See the related function `generate-new-buffer` in Section 28.9 [Creating Buffers], page 684.

28.4 Buffer File Name

The *buffer file name* is the name of the file that is visited in that buffer. When a buffer is not visiting a file, its buffer file name is `nil`. Most of the time, the buffer name is the same as the nondirectory part of the buffer file name, but the buffer file name and the buffer name are distinct and can be set independently. See Section 26.1 [Visiting Files], page 608.

buffer-file-name &*optional buffer* [Function]

This function returns the absolute file name of the file that *buffer* is visiting. If *buffer* is not visiting any file, `buffer-file-name` returns `nil`. If *buffer* is not supplied, it defaults to the current buffer.

```
(buffer-file-name (other-buffer))
  ⇒ "/usr/user/lewis/manual/files.texi"
```

buffer-file-name [Variable]

This buffer-local variable contains the name of the file being visited in the current buffer, or `nil` if it is not visiting a file. It is a permanent local variable, unaffected by `kill-all-local-variables`.

```
buffer-file-name
  ⇒ "/usr/user/lewis/manual/buffers.texi"
```

It is risky to change this variable’s value without doing various other things. Normally it is better to use `set-visited-file-name` (see below); some of the things done there, such as changing the buffer name, are not strictly necessary, but others are essential to avoid confusing Emacs.

buffer-file-truename

[Variable]

This buffer-local variable holds the abbreviated truename of the file visited in the current buffer, or `nil` if no file is visited. It is a permanent local, unaffected by `kill-all-local-variables`. See Section 26.6.3 [Truenames], page 623, and [abbreviate-filename], page 639.

buffer-file-number

[Variable]

This buffer-local variable holds the inode number and device identifier of the file visited in the current buffer, or `nil` if no file or a nonexistent file is visited. It is a permanent local, unaffected by `kill-all-local-variables`.

The value is normally a list of the form `(inodenum device)`. This tuple uniquely identifies the file among all files accessible on the system. See the function `file-attributes`, in Section 26.6.4 [File Attributes], page 624, for more information about them.

If `buffer-file-name` is the name of a symbolic link, then both `inodenum` and `device` refer to the recursive target of the link.

get-file-buffer filename

[Function]

This function returns the buffer visiting file `filename`. If there is no such buffer, it returns `nil`. The argument `filename`, which must be a string, is expanded (see Section 26.9.4 [File Name Expansion], page 639), then compared against the visited file names of all live buffers. Note that the buffer's `buffer-file-name` must match the expansion of `filename` exactly. This function will not recognize other names for the same file.

```
(get-file-buffer "buffers.texi")
⇒ #<buffer buffers.texi>
```

In unusual circumstances, there can be more than one buffer visiting the same file name. In such cases, this function returns the first such buffer in the buffer list.

find-buffer-visiting filename &optional predicate

[Function]

This is like `get-file-buffer`, except that it can return any buffer visiting the file *possibly under a different name*. That is, the buffer's `buffer-file-name` does not need to match the expansion of `filename` exactly, it only needs to refer to the same file. If `predicate` is non-`nil`, it should be a function of one argument, a buffer visiting `filename`. The buffer is only considered a suitable return value if `predicate` returns non-`nil`. If it can not find a suitable buffer to return, `find-buffer-visiting` returns `nil`.

set-visited-file-name filename &optional no-query along-with-file

[Command]

If `filename` is a non-empty string, this function changes the name of the file visited in the current buffer to `filename`. (If the buffer had no visited file, this gives it one.) The *next time* the buffer is saved it will go in the newly-specified file.

This command marks the buffer as modified, since it does not (as far as Emacs knows) match the contents of `filename`, even if it matched the former visited file. It also renames the buffer to correspond to the new file name, unless the new name is already in use.

If *filename* is `nil` or the empty string, that stands for “no visited file”. In this case, `set-visited-file-name` marks the buffer as having no visited file, without changing the buffer’s modified flag.

Normally, this function asks the user for confirmation if there already is a buffer visiting *filename*. If *no-query* is non-`nil`, that prevents asking this question. If there already is a buffer visiting *filename*, and the user confirms or *no-query* is non-`nil`, this function makes the new buffer name unique by appending a number inside of ‘`<...>`’ to *filename*.

If *along-with-file* is non-`nil`, that means to assume that the former visited file has been renamed to *filename*. In this case, the command does not change the buffer’s modified flag, nor the buffer’s recorded last file modification time as reported by `visited-file-modtime` (see Section 28.6 [Modification Time], page 678). If *along-with-file* is `nil`, this function clears the recorded last file modification time, after which `visited-file-modtime` returns zero.

When the function `set-visited-file-name` is called interactively, it prompts for *filename* in the minibuffer.

`list-buffers-directory`

[Variable]

This buffer-local variable specifies a string to display in a buffer listing where the visited file name would go, for buffers that don’t have a visited file name. Dired buffers use this variable.

28.5 Buffer Modification

Emacs keeps a flag called the *modified flag* for each buffer, to record whether you have changed the text of the buffer. This flag is set to `t` whenever you alter the contents of the buffer, and cleared to `nil` when you save it. Thus, the flag shows whether there are unsaved changes. The flag value is normally shown in the mode line (see Section 24.4.4 [Mode Line Variables], page 554), and controls saving (see Section 26.2 [Saving Buffers], page 612) and auto-saving (see Section 27.2 [Auto-Saving], page 664).

Some Lisp programs set the flag explicitly. For example, the function `set-visited-file-name` sets the flag to `t`, because the text does not match the newly-visited file, even if it is unchanged from the file formerly visited.

The functions that modify the contents of buffers are described in Chapter 33 [Text], page 878.

`buffer-modified-p &optional buffer`

[Function]

This function returns non-`nil` if *buffer* has been modified since it was last read in from a file or saved, or `nil` otherwise. If *buffer* has been auto-saved since the time it was last modified, this function returns the symbol `autosaved`. If *buffer* is `nil` or omitted, it defaults to the current buffer.

`set-buffer-modified-p flag`

[Function]

This function marks the current buffer as modified if *flag* is non-`nil`, or as unmodified if the flag is `nil`.

Another effect of calling this function is to cause unconditional redisplay of the mode line for the current buffer. In fact, the function `force-mode-line-update` works by doing this:

```
(set-buffer-modified-p (buffer-modified-p))
```

`restore-buffer-modified-p flag` [Function]

Like `set-buffer-modified-p`, but does not force redisplay of mode lines. This function also allows `flag`'s value to be the symbol `autosaved`, which marks the buffer as modified and auto-saved after the last modification.

`not-modified &optional arg` [Command]

This command marks the current buffer as unmodified, and not needing to be saved. If `arg` is non-`nil`, it marks the buffer as modified, so that it will be saved at the next suitable occasion. Interactively, `arg` is the prefix argument.

Don't use this function in programs, since it prints a message in the echo area; use `set-buffer-modified-p` (above) instead.

`buffer-modified-tick &optional buffer` [Function]

This function returns `buffer`'s modification-count. This is a counter that increments every time the buffer is modified. If `buffer` is `nil` (or omitted), the current buffer is used.

`buffer-chars-modified-tick &optional buffer` [Function]

This function returns `buffer`'s character-change modification-count. Changes to text properties leave this counter unchanged; however, each time text is inserted or removed from the buffer, the counter is reset to the value that would be returned by `buffer-modified-tick`. By comparing the values returned by two `buffer-chars-modified-tick` calls, you can tell whether a character change occurred in that buffer in between the calls. If `buffer` is `nil` (or omitted), the current buffer is used.

Sometimes there's a need for modifying buffer in a way that doesn't really change its text, like if only its text properties are changed. If your program needs to modify a buffer without triggering any hooks and features that react to buffer modifications, use the `with-silent-modifications` macro.

`with-silent-modifications body...` [Macro]

Execute `body` pretending it does not modify the buffer. This includes checking whether the buffer's file is locked (see Section 26.5 [File Locks], page 617), running buffer modification hooks (see Section 33.34 [Change Hooks], page 961), etc. Note that if `body` actually modifies the buffer text (as opposed to its text properties), its undo data may become corrupted.

28.6 Buffer Modification Time

Suppose that you visit a file and make changes in its buffer, and meanwhile the file itself is changed on disk. At this point, saving the buffer would overwrite the changes in the file. Occasionally this may be what you want, but usually it would lose valuable information. Emacs therefore checks the file's modification time using the functions described below before saving the file. (See Section 26.6.4 [File Attributes], page 624, for how to examine a file's modification time.)

verify-visited-file-modtime &optional buffer [Function]

This function compares what *buffer* (by default, the current-buffer) has recorded for the modification time of its visited file against the actual modification time of the file as recorded by the operating system. The two should be the same unless some other process has written the file since Emacs visited or saved it.

The function returns **t** if the last actual modification time and Emacs's recorded modification time are the same, **nil** otherwise. It also returns **t** if the buffer has no recorded last modification time, that is if **visited-file-modtime** would return zero.

It always returns **t** for buffers that are not visiting a file, even if **visited-file-modtime** returns a non-zero value. For instance, it always returns **t** for dired buffers. It returns **t** for buffers that are visiting a file that does not exist and never existed, but **nil** for file-visiting buffers whose file has been deleted.

clear-visited-file-modtime [Function]

This function clears out the record of the last modification time of the file being visited by the current buffer. As a result, the next attempt to save this buffer will not complain of a discrepancy in file modification times.

This function is called in **set-visited-file-name** and other exceptional places where the usual test to avoid overwriting a changed file should not be done.

visited-file-modtime [Function]

This function returns the current buffer's recorded last file modification time, as a Lisp timestamp (see Section 42.5 [Time of Day], page 1270).

If the buffer has no recorded last modification time, this function returns zero. This case occurs, for instance, if the buffer is not visiting a file or if the time has been explicitly cleared by **clear-visited-file-modtime**. Note, however, that **visited-file-modtime** returns a timestamp for some non-file buffers too. For instance, in a Dired buffer listing a directory, it returns the last modification time of that directory, as recorded by Dired.

If the buffer is visiting a file that doesn't exist, this function returns **-1**.

set-visited-file-modtime &optional time [Function]

This function updates the buffer's record of the last modification time of the visited file, to the value specified by *time* if *time* is not **nil**, and otherwise to the last modification time of the visited file.

If *time* is neither **nil** nor an integer flag returned by **visited-file-modtime**, it should be a Lisp time value (see Section 42.5 [Time of Day], page 1270).

This function is useful if the buffer was not read from the file normally, or if the file itself has been changed for some known benign reason.

ask-user-about-supersession-threat filename [Function]

This function is used to ask a user how to proceed after an attempt to modify a buffer visiting file *filename* when the file is newer than the buffer text. Emacs detects this because the modification time of the file on disk is newer than the last save-time and its contents have changed. This means some other program has probably altered the file.

Depending on the user's answer, the function may return normally, in which case the modification of the buffer proceeds, or it may signal a `file-supersession` error with data (`filename`), in which case the proposed buffer modification is not allowed.

This function is called automatically by Emacs on the proper occasions. It exists so you can customize Emacs by redefining it. See the file `userlock.el` for the standard definition.

See also the file locking mechanism in Section 26.5 [File Locks], page 617.

28.7 Read-Only Buffers

If a buffer is *read-only*, then you cannot change its contents, although you may change your view of the contents by scrolling and narrowing.

Read-only buffers are used in two kinds of situations:

- A buffer visiting a write-protected file is normally read-only.

Here, the purpose is to inform the user that editing the buffer with the aim of saving it in the file may be futile or undesirable. The user who wants to change the buffer text despite this can do so after clearing the read-only flag with `C-x C-q`.

- Modes such as `Dired` and `Rmail` make buffers read-only when altering the contents with the usual editing commands would probably be a mistake.

The special commands of these modes bind `buffer-read-only` to `nil` (with `let`) or bind `inhibit-read-only` to `t` around the places where they themselves change the text.

`buffer-read-only`

[Variable]

This buffer-local variable specifies whether the buffer is read-only. The buffer is read-only if this variable is non-`nil`. However, characters that have the `inhibit-read-only` text property can still be modified. See Section 33.19.4 [Special Properties], page 924.

`inhibit-read-only`

[Variable]

If this variable is non-`nil`, then read-only buffers and, depending on the actual value, some or all read-only characters may be modified. Read-only characters in a buffer are those that have a non-`nil` `read-only` text property. See Section 33.19.4 [Special Properties], page 924, for more information about text properties.

If `inhibit-read-only` is `t`, all `read-only` character properties have no effect. If `inhibit-read-only` is a list, then `read-only` character properties have no effect if they are members of the list (comparison is done with `eq`).

`read-only-mode &optional arg`

[Command]

This is the mode command for `Read Only` minor mode, a buffer-local minor mode. When the mode is enabled, `buffer-read-only` is non-`nil` in the buffer; when disabled, `buffer-read-only` is `nil` in the buffer. The calling convention is the same as for other minor mode commands (see Section 24.3.1 [Minor Mode Conventions], page 544).

This minor mode mainly serves as a wrapper for `buffer-read-only`; unlike most minor modes, there is no separate `read-only-mode` variable. Even when `Read Only` mode is disabled, characters with non-`nil` `read-only` text properties remain read-only. To temporarily ignore all read-only states, bind `inhibit-read-only`, as described above.

When enabling Read Only mode, this mode command also enables View mode if the option `view-read-only` is non-`nil`. See Section “Miscellaneous Buffer Operations” in *The GNU Emacs Manual*. When disabling Read Only mode, it disables View mode if View mode was enabled.

barf-if-buffer-read-only &optional position [Function]

This function signals a `buffer-read-only` error if the current buffer is read-only. If the text at *position* (which defaults to point) has the `inhibit-read-only` text property set, the error will not be raised.

See Section 22.2.1 [Using Interactive], page 424, for another way to signal an error if the current buffer is read-only.

28.8 The Buffer List

The *buffer list* is a list of all live buffers. The order of the buffers in this list is based primarily on how recently each buffer has been displayed in a window. Several functions, notably `other-buffer`, use this ordering. A buffer list displayed for the user also follows this order.

Creating a buffer adds it to the end of the buffer list, and killing a buffer removes it from that list. A buffer moves to the front of this list whenever it is chosen for display in a window (see Section 29.12 [Switching Buffers], page 721) or a window displaying it is selected (see Section 29.3 [Selecting Windows], page 696). A buffer moves to the end of the list when it is buried (see `bury-buffer`, below). There are no functions available to the Lisp programmer which directly manipulate the buffer list.

In addition to the fundamental buffer list just described, Emacs maintains a local buffer list for each frame, in which the buffers that have been displayed (or had their windows selected) in that frame come first. (This order is recorded in the frame’s `buffer-list` frame parameter; see Section 30.4.3.5 [Buffer Parameters], page 812.) Buffers never displayed in that frame come afterward, ordered according to the fundamental buffer list.

buffer-list &optional frame [Function]

This function returns the buffer list, including all buffers, even those whose names begin with a space. The elements are actual buffers, not their names.

If *frame* is a frame, this returns *frame*’s local buffer list. If *frame* is `nil` or omitted, the fundamental buffer list is used: the buffers appear in order of most recent display or selection, regardless of which frames they were displayed on.

```
(buffer-list)
  ⇒ (#<buffer buffers.texi>
      #<buffer *Minibuf-1*> #<buffer buffer.c>
      #<buffer *Help*> #<buffer TAGS>

;; Note that the name of the minibuffer
;; begins with a space!
(mapcar #'buffer-name (buffer-list))
  ⇒ ("buffers.texi" " *Minibuf-1*"
      "buffer.c" "*Help*" "TAGS")
```

The list returned by `buffer-list` is constructed specifically; it is not an internal Emacs data structure, and modifying it has no effect on the order of buffers. If you want to change the order of buffers in the fundamental buffer list, here is an easy way:

```
(defun reorder-buffer-list (new-list)
  (while new-list
    (bury-buffer (car new-list))
    (setq new-list (cdr new-list))))
```

With this method, you can specify any order for the list, but there is no danger of losing a buffer or adding something that is not a valid live buffer.

To change the order or value of a specific frame's buffer list, set that frame's `buffer-list` parameter with `modify-frame-parameters` (see Section 30.4.1 [Parameter Access], page 803).

other-buffer &optional buffer visible-ok frame [Function]

This function returns the first buffer in the buffer list other than `buffer`. Usually, this is the buffer appearing in the most recently selected window (in frame `frame` or else the selected frame, see Section 30.10 [Input Focus], page 824), aside from `buffer`. Buffers whose names start with a space are not considered at all.

If `buffer` is not supplied (or if it is not a live buffer), then `other-buffer` returns the first buffer in the selected frame's local buffer list. (If `frame` is non-`nil`, it returns the first buffer in `frame`'s local buffer list instead.)

If `frame` has a non-`nil` `buffer-predicate` parameter, then `other-buffer` uses that predicate to decide which buffers to consider. It calls the predicate once for each buffer, and if the value is `nil`, that buffer is ignored. See Section 30.4.3.5 [Buffer Parameters], page 812.

If `visible-ok` is `nil`, `other-buffer` avoids returning a buffer visible in any window on any visible frame, except as a last resort. If `visible-ok` is non-`nil`, then it does not matter whether a buffer is displayed somewhere or not.

If no suitable buffer exists, the buffer `*scratch*` is returned (and created, if necessary).

last-buffer &optional buffer visible-ok frame [Function]

This function returns the last buffer in `frame`'s buffer list other than `buffer`. If `frame` is omitted or `nil`, it uses the selected frame's buffer list.

The argument `visible-ok` is handled as with `other-buffer`, see above. If no suitable buffer can be found, the buffer `*scratch*` is returned.

bury-buffer &optional buffer-or-name [Command]

This command puts `buffer-or-name` at the end of the buffer list, without changing the order of any of the other buffers on the list. This buffer therefore becomes the least desirable candidate for `other-buffer` to return. The argument can be either a buffer itself or the name of one.

This function operates on each frame's `buffer-list` parameter as well as the fundamental buffer list; therefore, the buffer that you bury will come last in the value of `(buffer-list frame)` and in the value of `(buffer-list)`. In addition, it also puts the buffer at the end of the list of buffers of the selected window (see Section 29.14 [Window History], page 746) provided it is shown in that window.

If `buffer-or-name` is `nil` or omitted, this means to bury the current buffer. In addition, if the current buffer is displayed in the selected window (see Section 29.3 [Selecting Windows], page 696), this makes sure that the window is either deleted or another buffer is shown in it. More precisely, if the selected window is dedicated (see Section 29.15 [Dedicated Windows], page 749) and there are other windows on its frame, the window is deleted. If it is the only window on its frame and that frame is not the only frame on its terminal, the frame is dismissed by calling the function specified by `frame-auto-hide-function` (see Section 29.16 [Quitting Windows], page 749). Otherwise, it calls `switch-to-prev-buffer` (see Section 29.14 [Window History], page 746) to show another buffer in that window. If `buffer-or-name` is displayed in some other window, it remains displayed there.

To replace a buffer in all the windows that display it, use `replace-buffer-in-windows`. See Section 29.11 [Buffers and Windows], page 720.

unbury-buffer

[Command]

This command switches to the last buffer in the local buffer list of the selected frame. More precisely, it calls the function `switch-to-buffer` (see Section 29.12 [Switching Buffers], page 721), to display the buffer returned by `last-buffer` (see above), in the selected window.

buffer-list-update-hook

[Variable]

This is a normal hook run whenever the buffer list changes. Functions (implicitly) running this hook are `get-buffer-create` (see Section 28.9 [Creating Buffers], page 684), `rename-buffer` (see Section 28.3 [Buffer Names], page 674), `kill-buffer` (see Section 28.10 [Killing Buffers], page 685), `bury-buffer` (see above), and `select-window` (see Section 29.3 [Selecting Windows], page 696). This hook is not run for internal or temporary buffers created by `get-buffer-create` or `generate-new-buffer` with a non-`nil` argument `inhibit-buffer-hooks`.

Functions run by this hook should avoid calling `select-window` with a `nil norecord` argument since this may lead to infinite recursion.

buffer-match-p condition buffer-or-name &optional arg

[Function]

This function checks if a buffer designated by `buffer-or-name` satisfies the specified `condition`. Optional third argument `arg` is passed to the predicate function in `condition`. A valid `condition` can be one of the following:

- A string, interpreted as a regular expression. The buffer satisfies the condition if the regular expression matches the buffer name.
- A predicate function, which should return `non-nil` if the buffer matches. If the function expects one argument, it is called with `buffer-or-name` as the argument; if it expects 2 arguments, the first argument is `buffer-or-name` and the second is `arg` (or `nil` if `arg` is omitted).
- A cons-cell (`oper . expr`) where `oper` is one of

`(not cond)`

Satisfied if `cond` doesn't satisfy `buffer-match-p` with the same buffer and `arg`.

(or *conds...*)

Satisfied if *any* condition in *conds* satisfies `buffer-match-p`, with the same buffer and `arg`.

(and *conds...*)

Satisfied if *all* the conditions in *conds* satisfy `buffer-match-p`, with the same buffer and `arg`.

`derived-mode`

Satisfied if the buffer's major mode derives from `expr`. Note that this condition might fail to report a match if `buffer-match-p` is invoked before the major mode of the buffer has been established.

`major-mode`

Satisfied if the buffer's major mode is equal to `expr`. Prefer using `derived-mode` instead, when both can work. Note that this condition might fail to report a match if `buffer-match-p` is invoked before the major mode of the buffer has been established.

- `t` Satisfied by any buffer. A convenient alternative to "" (empty string) or (and) (empty conjunction).

`match-buffers` *condition* &optional *buffer-list arg*

[Function]

This function returns a list of all buffers that satisfy the *condition*. If no buffers match, the function returns `nil`. The argument *condition* is as defined in `buffer-match-p` above. By default, all the buffers are considered, but this can be restricted via the optional argument `buffer-list`, which should be a list of buffers to consider. Optional third argument `arg` will be passed to *condition* in the same way as `buffer-match-p` does.

28.9 Creating Buffers

This section describes the two primitives for creating buffers. `get-buffer-create` creates a buffer if it finds no existing buffer with the specified name; `generate-new-buffer` always creates a new buffer and gives it a unique name.

Both functions accept an optional argument `inhibit-buffer-hooks`. If it is non-`nil`, the buffer they create does not run the hooks `kill-buffer-hook`, `kill-buffer-query-functions` (see Section 28.10 [Killing Buffers], page 685), and `buffer-list-update-hook` (see Section 28.8 [Buffer List], page 681). This avoids slowing down internal or temporary buffers that are never presented to users or passed on to other applications.

Other functions you can use to create buffers include `with-output-to-temp-buffer` (see Section 41.8 [Temporary Displays], page 1146) and `create-file-buffer` (see Section 26.1 [Visiting Files], page 608). Starting a subprocess can also create a buffer (see Chapter 40 [Processes], page 1078).

`get-buffer-create` *buffer-or-name* &optional *inhibit-buffer-hooks*

[Function]

This function returns a buffer named *buffer-or-name*. The buffer returned does not become the current buffer—this function does not change which buffer is current.

buffer-or-name must be either a string or an existing buffer. If it is a string and a live buffer with that name already exists, `get-buffer-create` returns that buffer. If no

such buffer exists, it creates a new buffer. If *buffer-or-name* is a buffer instead of a string, it is returned as given, even if it is dead.

```
(get-buffer-create "foo")
⇒ #<buffer foo>
```

The major mode for a newly created buffer is set to Fundamental mode. (The default value of the variable `major-mode` is handled at a higher level; see Section 24.2.2 [Auto Major Mode], page 531.) If the name begins with a space, the buffer initially disables undo information recording (see Section 33.9 [Undo], page 895).

generate-new-buffer *name* &*optional inhibit-buffer-hooks* [Function]

This function returns a newly created, empty buffer, but does not make it current. The name of the buffer is generated by passing *name* to the function `generate-new-buffer-name` (see Section 28.3 [Buffer Names], page 674). Thus, if there is no buffer named *name*, then that is the name of the new buffer; if that name is in use, a suffix of the form ‘*<n>*’, where *n* is an integer, is appended to *name*.

An error is signaled if *name* is not a string.

```
(generate-new-buffer "bar")
⇒ #<buffer bar>
(generate-new-buffer "bar")
⇒ #<buffer bar<2>>
(generate-new-buffer "bar")
⇒ #<buffer bar<3>>
```

The major mode for the new buffer is set to Fundamental mode. The default value of the variable `major-mode` is handled at a higher level. See Section 24.2.2 [Auto Major Mode], page 531.

28.10 Killing Buffers

Killing a buffer makes its name unknown to Emacs and makes the memory space it occupied available for other use.

The buffer object for the buffer that has been killed remains in existence as long as anything refers to it, but it is specially marked so that you cannot make it current or display it. Killed buffers retain their identity, however; if you kill two distinct buffers, they remain distinct according to `eq` although both are dead.

If you kill a buffer that is current or displayed in a window, Emacs automatically selects or displays some other buffer instead. This means that killing a buffer can change the current buffer. Therefore, when you kill a buffer, you should also take the precautions associated with changing the current buffer (unless you happen to know that the buffer being killed isn't current). See Section 28.2 [Current Buffer], page 671.

If you kill a buffer that is the base buffer of one or more indirect buffers, the indirect buffers are automatically killed as well.

The `buffer-name` of a buffer is `nil` if, and only if, the buffer is killed. A buffer that has not been killed is called a *live* buffer. To test whether a buffer is live or killed, use the function `buffer-live-p` (see below).

kill-buffer &optional *buffer-or-name* [Command]

This function kills the buffer *buffer-or-name*, freeing all its memory for other uses or to be returned to the operating system. If *buffer-or-name* is `nil` or omitted, it kills the current buffer.

Any processes that have this buffer as the `process-buffer` are sent the `SIGHUP` (hangup) signal, which normally causes them to terminate. See Section 40.8 [Signals to Processes], page 1097.

If the buffer is visiting a file and contains unsaved changes, `kill-buffer` asks the user to confirm before the buffer is killed. It does this even if not called interactively. To prevent the request for confirmation, clear the modified flag before calling `kill-buffer`. See Section 28.5 [Buffer Modification], page 677.

This function calls `replace-buffer-in-windows` for cleaning up all windows currently displaying the buffer to be killed.

Killing a buffer that is already dead has no effect.

This function returns `t` if it actually killed the buffer. It returns `nil` if the user refuses to confirm or if *buffer-or-name* was already dead.

```
(kill-buffer "foo.unchanged")
⇒ t
(kill-buffer "foo.changed")

----- Buffer: Minibuffer -----
Buffer foo.changed modified; kill anyway? (yes or no) yes
----- Buffer: Minibuffer -----

⇒ t
```

kill-buffer-query-functions [Variable]

Before confirming unsaved changes, `kill-buffer` calls the functions in the list `kill-buffer-query-functions`, in order of appearance, with no arguments. The buffer being killed is the current buffer when they are called. The idea of this feature is that these functions will ask for confirmation from the user. If any of them returns `nil`, `kill-buffer` spares the buffer's life.

This hook is not run for internal or temporary buffers created by `get-buffer-create` or `generate-new-buffer` with a non-`nil` argument `inhibit-buffer-hooks`.

kill-buffer-hook [Variable]

This is a normal hook run by `kill-buffer` after asking all the questions it is going to ask, just before actually killing the buffer. The buffer to be killed is current when the hook functions run. See Section 24.1 [Hooks], page 524. This variable is a permanent local, so its local binding is not cleared by changing major modes.

This hook is not run for internal or temporary buffers created by `get-buffer-create` or `generate-new-buffer` with a non-`nil` argument `inhibit-buffer-hooks`.

buffer-offer-save [User Option]

This variable, if non-`nil` in a particular buffer, tells `save-buffers-kill-emacs` to offer to save that buffer, just as it offers to save file-visiting buffers. If `save-some-buffers` is called with the second optional argument set to `t`, it will also offer to save the buffer. Lastly, if this variable is set to the symbol `always`, both `save-buffers-kill-emacs`

and `save-some-buffers` will always offer to save. See [Definition of save-some-buffers], page 612. The variable `buffer-offer-save` automatically becomes buffer-local when set for any reason. See Section 12.11 [Buffer-Local Variables], page 207.

buffer-save-without-query [Variable]

This variable, if non-`nil` in a particular buffer, tells `save-buffers-kill-emacs` and `save-some-buffers` to save this buffer (if it's modified) without asking the user. The variable automatically becomes buffer-local when set for any reason.

buffer-live-p object [Function]

This function returns `t` if *object* is a live buffer (a buffer which has not been killed), `nil` otherwise.

28.11 Indirect Buffers

An *indirect buffer* shares the text of some other buffer, which is called the *base buffer* of the indirect buffer. In some ways it is the analogue, for buffers, of a symbolic link among files. The base buffer may not itself be an indirect buffer.

The text of the indirect buffer is always identical to the text of its base buffer; changes made by editing either one are visible immediately in the other. This includes the text properties as well as the characters themselves.

In all other respects, the indirect buffer and its base buffer are completely separate. They have different names, independent values of point, independent narrowing, independent markers and overlays (though inserting or deleting text in either buffer relocates the markers and overlays for both), independent major modes, and independent buffer-local variable bindings.

An indirect buffer cannot visit a file, but its base buffer can. If you try to save the indirect buffer, that actually saves the base buffer.

Killing an indirect buffer has no effect on its base buffer. Killing the base buffer effectively kills the indirect buffer in that it cannot ever again be the current buffer.

make-indirect-buffer base-buffer name &optional clone [Command]
inhibit-buffer-hooks

This creates and returns an indirect buffer named *name* whose base buffer is *base-buffer*. The argument *base-buffer* may be a live buffer or the name (a string) of an existing buffer. If *name* is the name of an existing buffer, an error is signaled.

If *clone* is non-`nil`, then the indirect buffer originally shares the state of *base-buffer* such as major mode, minor modes, buffer local variables and so on. If *clone* is omitted or `nil` the indirect buffer's state is set to the default state for new buffers.

If *base-buffer* is an indirect buffer, its base buffer is used as the base for the new buffer. If, in addition, *clone* is non-`nil`, the initial state is copied from the actual base buffer, not from *base-buffer*.

See Section 28.9 [Creating Buffers], page 684, for the meaning of *inhibit-buffer-hooks*.

clone-indirect-buffer newname display-flag &optional norecord [Command]

This function creates and returns a new indirect buffer that shares the current buffer's base buffer and copies the rest of the current buffer's attributes. (If the current buffer is not indirect, it is used as the base buffer.)

If *display-flag* is non-`nil`, as it always is in interactive calls, that means to display the new buffer by calling `pop-to-buffer`. If *norecord* is non-`nil`, that means not to put the new buffer to the front of the buffer list.

buffer-base-buffer &optional buffer [Function]

This function returns the base buffer of *buffer*, which defaults to the current buffer. If *buffer* is not indirect, the value is `nil`. Otherwise, the value is another buffer, which is never an indirect buffer.

28.12 Swapping Text Between Two Buffers

Specialized modes sometimes need to let the user access from the same buffer several vastly different types of text. For example, you may need to display a summary of the buffer text, in addition to letting the user access the text itself.

This could be implemented with multiple buffers (kept in sync when the user edits the text), or with narrowing (see Section 31.4 [Narrowing], page 865). But these alternatives might sometimes become tedious or prohibitively expensive, especially if each type of text requires expensive buffer-global operations in order to provide correct display and editing commands.

Emacs provides another facility for such modes: you can quickly swap buffer text between two buffers with `buffer-swap-text`. This function is very fast because it doesn't move any text, it only changes the internal data structures of the buffer object to point to a different chunk of text. Using it, you can pretend that a group of two or more buffers are actually a single virtual buffer that holds the contents of all the individual buffers together.

buffer-swap-text buffer [Function]

This function swaps the text of the current buffer and that of its argument *buffer*. It signals an error if one of the two buffers is an indirect buffer (see Section 28.11 [Indirect Buffers], page 687) or is a base buffer of an indirect buffer.

All the buffer properties that are related to the buffer text are swapped as well: the positions of point and mark, all the markers, the overlays, the text properties, the undo list, the value of the `enable-multibyte-characters` flag (see Section 34.1 [Text Representations], page 963), etc.

Warning: If this function is called from within a `save-excursion` form, the current buffer will be set to *buffer* upon leaving the form, since the marker used by `save-excursion` to save the position and buffer will be swapped as well.

If you use `buffer-swap-text` on a file-visiting buffer, you should set up a hook to save the buffer's original text rather than what it was swapped with. `write-region-annotate-functions` works for this purpose. You should probably set `buffer-saved-size` to `-2` in the buffer, so that changes in the text it is swapped with will not interfere with auto-saving.

28.13 The Buffer Gap

Emacs buffers are implemented using an invisible gap to make insertion and deletion faster. Insertion works by filling in part of the gap, and deletion adds to the gap. Of course, this means that the gap must first be moved to the locus of the insertion or deletion. Emacs moves the gap only when you try to insert or delete. This is why your first editing command

in one part of a large buffer, after previously editing in another far-away part, sometimes involves a noticeable delay.

This mechanism works invisibly, and Lisp code should never be affected by the gap's current location, but these functions are available for getting information about the gap status.

gap-position

[Function]

This function returns the current gap position in the current buffer.

gap-size

[Function]

This function returns the current gap size of the current buffer.

29 Windows

This chapter describes the functions and variables related to Emacs windows. See Chapter 30 [Frames], page 785, for how windows are assigned an area of screen available for Emacs to use. See Chapter 41 [Display], page 1129, for information on how text is displayed in windows.

29.1 Basic Concepts of Emacs Windows

A *window* is an area of the screen that can be used to display a buffer (see Chapter 28 [Buffers], page 671). Windows are grouped into frames (see Chapter 30 [Frames], page 785). Each frame contains at least one window; the user can subdivide a frame into multiple, non-overlapping windows to view several buffers at once. Lisp programs can use multiple windows for a variety of purposes. In Rmail, for example, you can view a summary of message titles in one window, and the contents of the selected message in another window.

Emacs uses the term “window” with a different meaning than in graphical desktop environments and window systems, such as the X Window System. When Emacs is run on X, each graphical X window owned by the Emacs process corresponds to one Emacs frame. When Emacs is run on a text terminal, each Emacs frame fills the entire terminal screen. In either case, the frame may contain one or more Emacs windows. For disambiguation, we use the term *window-system window* when we mean the window-system window corresponding to an Emacs frame.

Unlike X windows, Emacs windows are *tiled*; they never overlap within the area of their frame. When a window is created, resized, or deleted, the change in window space is taken from or given to other windows on the same frame, so that the total area of the frame is unchanged.

In Emacs Lisp, windows are represented by a special Lisp object type (see Section 2.5.3 [Window Type], page 27).

windowp *object* [Function]
 This function returns `t` if *object* is a window (whether or not it displays a buffer). Otherwise, it returns `nil`.

A *live window* is one that is actually displaying a buffer in a frame.

window-live-p *object* [Function]
 This function returns `t` if *object* is a live window and `nil` otherwise. A live window is one that displays a buffer.

The windows in each frame are organized into a *window tree*. See Section 29.2 [Windows and Frames], page 692. The leaf nodes of each window tree are live windows—the ones actually displaying buffers. The internal nodes of the window tree are *internal windows*, which are not live.

A *valid window* is one that is either live or internal. A valid window can be *deleted*, i.e., removed from its frame (see Section 29.8 [Deleting Windows], page 711); then it is no longer valid, but the Lisp object representing it might be still referenced from other Lisp objects. A deleted window may be made valid again by restoring a saved window configuration (see Section 29.26 [Window Configurations], page 774).

You can distinguish valid windows from deleted windows with `window-valid-p`.

window-valid-p object

[Function]

This function returns `t` if *object* is a live window, or an internal window in a window tree. Otherwise, it returns `nil`, including for the case where *object* is a deleted window.

The following schematic shows the structure of a live window:

At the center of that window is the *body*, where the buffer text is displayed. The body can be surrounded by a series of optional areas which we will call *window decorations*. On the left and right, from innermost to outermost, these are the left and right fringes, denoted by LF and RF (see Section 41.13 [Fringes], page 1189); the left and right margins, denoted by LM and RM in the schematic (see Section 41.16.5 [Display Margins], page 1205); the left or right vertical scroll bar, only one of which is present at any time, denoted by LS and RS (see Section 41.14 [Scroll Bars], page 1195); and the right divider, denoted by RD (see Section 41.15 [Window Dividers], page 1198). Together these are the window's *left and right decorations*.

At the top of the window are the tab line and the header line (see Section 24.4.7 [Header Lines], page 559). The *text area* of the window includes the header line and the tab line, if they are present in the window. At the bottom of the window are the horizontal scroll bar (see Section 41.14 [Scroll Bars], page 1195); the mode line (see Section 24.4 [Mode Line Format], page 550); and the bottom divider (see Section 41.15 [Window Dividers], page 1198). Together these form the window's *top and bottom decorations*.

There are two special areas omitted in the schematic:

- When any of the fringes is missing, the display engine may use one character cell in its place for showing a continuation or truncation glyph provided a text line doesn't fit in a window.
- When both, the vertical scroll bar and the right divider are missing, the display engine usurps one pixel for drawing a vertical divider line between this window and the window on its right, provided such a window exists. On a text terminal, this divider always occupies an entire character cell.

In either case, the resulting artifact is considered part of the window's body although its screen space cannot be used for displaying buffer text.

Note also, that line numbers (and their surrounding whitespace) as displayed by `display-line-numbers-mode` (see Section “Display Custom” in *The GNU Emacs Manual*) do not count as decorations either; they are part of the window's body too.

Internal windows neither show any text nor do they have decorations. Hence, the concept of “body” does not make sense for them. In fact, most functions operating on the body of a window will yield an error when applied to an internal window.

By default, an Emacs frame exhibits one special live window that is used for displaying messages and accepting user input—the *minibuffer window* (see Section 21.11 [Minibuffer Windows], page 418). Since the minibuffer window is used for displaying text, it has a body but it does not have a tab or header line or any margins. Finally, a *tooltip window* which is used for displaying a tooltip in a tooltip frame (see Section 41.26 [Tooltips], page 1249) has a body too but no decorations at all.

29.2 Windows and Frames

Each window belongs to exactly one frame (see Chapter 30 [Frames], page 785). For all windows belonging to a specific frame, we sometimes also say that these windows are *owned* by that frame or simply that they are on that frame.

window-frame &optional window

[Function]

This function returns the specified *window*’s frame—the frame that *window* belongs to. If *window* is omitted or `nil`, it defaults to the selected window (see Section 29.3 [Selecting Windows], page 696).

window-list &optional frame minibuffer window

[Function]

This function returns a list of all live windows owned by the specified *frame*. If *frame* is omitted or `nil`, it defaults to the selected frame (see Section 30.10 [Input Focus], page 824).

The optional argument *minibuffer* specifies whether to include the minibuffer window (see Section 21.11 [Minibuffer Windows], page 418) in that list. If *minibuffer* is `t`, the minibuffer window is included. If `nil` or omitted, the minibuffer window is included only if it is active. If *minibuffer* is neither `nil` nor `t`, the minibuffer window is never included.

The optional argument *window*, if non-`nil`, must be a live window on the specified frame; then *window* will be the first element in the returned list. If *window* is omitted or `nil`, the window selected within *frame* (see Section 29.3 [Selecting Windows], page 696) is the first element.

Windows on the same frame are organized into a *window tree*, whose leaf nodes are the live windows. The internal nodes of a window tree are not live; they exist for the purpose of organizing the relationships between live windows. The root node of a window tree is called the *root window*. It is either a live window or an internal window. If it is a live window, then the frame has just one window besides the minibuffer window, or the frame is a minibuffer-only frame, see Section 30.3.1 [Frame Layout], page 791.

A minibuffer window (see Section 21.11 [Minibuffer Windows], page 418) that is not alone on its frame does not have a parent window, so it strictly speaking is not part of its frame’s window tree. Nonetheless, it is a sibling window of the frame’s root window, and thus can be reached from the root window via `window-next-sibling`, see below. Also, the function `window-tree` described at the end of this section lists the minibuffer window alongside the actual window tree.

frame-root-window &optional *frame-or-window* [Function]

This function returns the root window for *frame-or-window*. The argument *frame-or-window* should be either a window or a frame; if omitted or `nil`, it defaults to the selected frame. If *frame-or-window* is a window, the return value is the root window of that window's frame.

When a live window is split (see Section 29.7 [Splitting Windows], page 708), there are two live windows where previously there was one. One of these is represented by the same Lisp window object as the original window, and the other is represented by a newly-created Lisp window object. Both of these live windows become leaf nodes of the window tree, as *child windows* of a single internal window. If necessary, Emacs automatically creates this internal window, which is also called the *parent window*, and assigns it to the appropriate position in the window tree. The set of windows that share the same parent are called *siblings*.

window-parent &optional *window* [Function]

This function returns the parent window of `window`. If `window` is omitted or `nil`, it defaults to the selected window. The return value is `nil` if `window` has no parent (i.e., it is a minibuffer window or the root window of its frame).

A parent window always has at least two child windows. If this number were to fall to one as a result of window deletion (see Section 29.8 [Deleting Windows], page 711), Emacs automatically deletes the parent window too, and its sole remaining child window takes its place in the window tree.

A child window can be either a live window, or an internal window (which in turn would have its own child windows). Therefore, each internal window can be thought of as occupying a certain rectangular *screen area*—the union of the areas occupied by the live windows that are ultimately descended from it.

For each internal window, the screen areas of the immediate children are arranged either vertically or horizontally (never both). If the child windows are arranged one above the other, they are said to form a *vertical combination*; if they are arranged side by side, they are said to form a *horizontal combination*. Consider the following example:

The root window of this frame is an internal window, W_1 . Its child windows form a horizontal combination, consisting of the live window W_2 and the internal window W_3 . The child windows of W_3 form a vertical combination, consisting of the live windows W_4 and W_5 . Hence, the live windows in this window tree are W_2 , W_4 , and W_5 .

The following functions can be used to retrieve a child window of an internal window, and the siblings of a child window. Their *window* argument always defaults to the selected window (see Section 29.3 [Selecting Windows], page 696).

window-top-child &optional window

[Function]

This function returns the topmost child window of *window*, if *window* is an internal window whose children form a vertical combination. For any other type of window, the return value is `nil`.

window-left-child &optional window

[Function]

This function returns the leftmost child window of *window*, if *window* is an internal window whose children form a horizontal combination. For any other type of window, the return value is `nil`.

window-child window

[Function]

This function returns the first child window of the internal window *window*—the topmost child window for a vertical combination, or the leftmost child window for a horizontal combination. If *window* is a live window, the return value is `nil`.

window-combined-p &optional window horizontal

[Function]

This function returns a non-`nil` value if and only if *window* is part of a vertical combination.

If the optional argument *horizontal* is non-`nil`, this means to return non-`nil` if and only if *window* is part of a horizontal combination.

window-next-sibling &optional window

[Function]

This function returns the next sibling of the specified *window*. The return value is `nil` if *window* is the last child of its parent.

window-prev-sibling &optional window

[Function]

This function returns the previous sibling of the specified *window*. The return value is `nil` if *window* is the first child of its parent.

The functions `window-next-sibling` and `window-prev-sibling` should not be confused with the functions `next-window` and `previous-window`, which return the next and previous window in the cyclic ordering of windows (see Section 29.10 [Cyclic Window Ordering], page 717).

The following functions can be useful to locate a window within its frame.

frame-first-window &optional frame-or-window

[Function]

This function returns the live window at the upper left corner of the frame specified by *frame-or-window*. The argument *frame-or-window* must denote a window or a live frame and defaults to the selected frame. If *frame-or-window* specifies a window, this function returns the first window on that window's frame. Under the assumption that the frame from our canonical example is selected (`frame-first-window`) returns W2.

window-at-side-p &optional window side

[Function]

This function returns `t` if *window* is located at *side* of its containing frame. The argument *window* must be a valid window and defaults to the selected one. The

argument *side* can be any of the symbols `left`, `top`, `right` or `bottom`. The default value `nil` is handled like `bottom`.

Note that this function disregards the minibuffer window (see Section 21.11 [Minibuffer Windows], page 418). Hence, with *side* equal to `bottom` it may return `t` also when the minibuffer window appears right below *window*.

window-in-direction *direction* &optional *window* *ignore* *sign* *wrap* [Function]
minibuf

This function returns the nearest live window in direction *direction* as seen from the position of `window-point` in window *window*. The argument *direction* must be one of `above`, `below`, `left` or `right`. The optional argument *window* must denote a live window and defaults to the selected one.

This function does not return a window whose `no-other-window` parameter is non-`nil` (see Section 29.27 [Window Parameters], page 776). If the nearest window's `no-other-window` parameter is non-`nil`, this function tries to find another window in the indicated direction whose `no-other-window` parameter is `nil`. If the optional argument *ignore* is non-`nil`, a window may be returned even if its `no-other-window` parameter is non-`nil`.

If the optional argument *sign* is a negative number, it means to use the right or bottom edge of *window* as reference position instead of `window-point`. If *sign* is a positive number, it means to use the left or top edge of *window* as reference position.

If the optional argument *wrap* is non-`nil`, this means to wrap *direction* around frame borders. For example, if *window* is at the top of the frame and *direction* is `above`, then this function usually returns the frame's minibuffer window if it's active and a window at the bottom of the frame otherwise.

If the optional argument *minibuf* is `t`, this function may return the minibuffer window even when it's not active. If the optional argument *minibuf* is `nil`, this means to return the minibuffer window if and only if it is currently active. If *minibuf* is neither `nil` nor `t`, this function never returns the minibuffer window. However, if *wrap* is non-`nil`, it always acts as if *minibuf* were `nil`.

If it doesn't find a suitable window, this function returns `nil`.

Don't use this function to check whether there is *no* window in *direction*. Calling `window-at-side-p` described above is a much more efficient way to do that.

The following function retrieves the entire window tree of a frame:

window-tree &optional *frame* [Function]

This function returns a list representing the window tree for frame *frame*. If *frame* is omitted or `nil`, it defaults to the selected frame.

The return value is a list of the form `(root mini)`, where *root* represents the window tree of the frame's root window, and *mini* is the frame's minibuffer window.

If the root window is live, *root* is that window itself. Otherwise, *root* is a list `(dir edges w1 w2 ...)` where *dir* is `nil` for a horizontal combination and `t` for a vertical combination, *edges* gives the size and position of the combination, and the remaining elements are the child windows. Each child window may again be a window object (for a live window) or a list with the same format as above (for an internal window).

The `edges` element is a list (`left top right bottom`), similar to the value returned by `window-edges` (see Section 29.24 [Coordinates and Windows], page 769).

29.3 Selecting Windows

In each frame, at any time, exactly one Emacs window is designated as *selected within the frame*. For the selected frame, that window is called the *selected window*—the one in which most editing takes place, and in which the cursor for selected windows appears (see Section 30.4.3.9 [Cursor Parameters], page 817). Keyboard input that inserts or deletes text is also normally directed to this window. The selected window’s buffer is usually also the current buffer, except when `set-buffer` has been used (see Section 28.2 [Current Buffer], page 671). As for non-selected frames, the window selected within the frame becomes the selected window if the frame is ever selected.

selected-window [Function]

This function returns the selected window (which is always a live window).

The following function explicitly selects a window and its frame.

select-window window &optional norecord [Function]

This function makes `window` the selected window and the window selected within its frame, and selects that frame. It also makes `window`’s buffer (see Section 29.11 [Buffers and Windows], page 720) current and sets that buffer’s value of `point` to the value of `window-point` (see Section 29.19 [Window Point], page 758) in `window`. `window` must be a live window. The return value is `window`.

By default, this function also moves `window`’s buffer to the front of the buffer list (see Section 28.8 [Buffer List], page 681) and makes `window` the most recently selected window. If the optional argument `norecord` is non-`nil`, these additional actions are omitted.

In addition, this function by default also tells the display engine to update the display of `window` when its frame gets redisplayed the next time. If `norecord` is non-`nil`, such updates are usually not performed. If, however, `norecord` equals the special symbol `mark-for-redisplay`, the additional actions mentioned above are omitted but `window`’s display will be nevertheless updated.

Note that sometimes selecting a window is not enough to show it, or make its frame the top-most frame on display: you may also need to raise the frame or make sure input focus is directed to that frame. See Section 30.10 [Input Focus], page 824.

For historical reasons, Emacs does not run a separate hook whenever a window gets selected. Applications and internal routines often temporarily select a window to perform a few actions on it. They do that either to simplify coding—because many functions by default operate on the selected window when no `window` argument is specified—or because some functions did not (and still do not) take a window as argument and always operate(d) on the selected window instead. Running a hook every time a window gets selected for a short time and once more when the previously selected window gets restored is not useful.

However, when its `norecord` argument is `nil`, `select-window` updates the buffer list and thus indirectly runs the normal hook `buffer-list-update-hook` (see Section 28.8 [Buffer

List], page 681). Consequently, that hook provides one way to run a function whenever a window gets selected more “permanently”.

Since `buffer-list-update-hook` is also run by functions that are not related to window management, it will usually make sense to save the value of the selected window somewhere and compare it with the value of `selected-window` while running that hook. Also, to avoid false positives when using `buffer-list-update-hook`, it is good practice that every `select-window` call supposed to select a window only temporarily passes a non-`nil` `norecord` argument. If possible, the macro `with-selected-window` (see below) should be used in such cases.

Emacs also runs the hook `window-selection-change-functions` whenever the redisplay routine detects that another window has been selected since last redisplay. See Section 29.28 [Window Hooks], page 779, for a detailed explanation. `window-state-change-functions` (described in the same section) is another abnormal hook run after a different window has been selected but is triggered by other window changes as well.

The sequence of calls to `select-window` with a non-`nil` `norecord` argument determines an ordering of windows by their selection or use time, see below. The function `get-lru-window`, for example, can then be used to retrieve the least recently selected window (see Section 29.10 [Cyclic Window Ordering], page 717).

`frame-selected-window` &optional `frame`

[Function]

This function returns the window on `frame` that is selected within that frame. `frame` should be a live frame; if omitted or `nil`, it defaults to the selected frame.

`set-frame-selected-window` `frame` `window` &optional `norecord`

[Function]

This function makes `window` the window selected within the frame `frame`. `frame` should be a live frame; if `nil`, it defaults to the selected frame. `window` must denote a live window.

If `frame` is the selected frame, this makes `window` the selected window.

If the optional argument `norecord` is non-`nil`, this function does not alter the ordering of the most recently selected windows, nor the buffer list.

The following macros are useful to temporarily select a window without affecting the ordering of recently selected windows or the buffer list.

`save-selected-window` `forms`...

[Macro]

This macro records the selected frame, as well as the selected window of each frame, executes `forms` in sequence, then restores the earlier selected frame and windows. It also saves and restores the current buffer. It returns the value of the last form in `forms`.

This macro does not save or restore anything about the sizes, arrangement or contents of windows; therefore, if `forms` change them, the change persists. If the previously selected window of some frame is no longer live at the time of exit from `forms`, that frame’s selected window is left alone. If the previously selected window is no longer live, then whatever window is selected at the end of `forms` remains selected. The current buffer is restored if and only if it is still live when exiting `forms`.

This macro changes neither the ordering of recently selected windows nor the buffer list.

with-selected-window *window forms...*

[Macro]

This macro selects *window*, executes *forms* in sequence, then restores the previously selected window and current buffer. The ordering of recently selected windows and the buffer list remain unchanged unless you deliberately change them within *forms*; for example, by calling **select-window** with argument *norecord nil*. Hence, this macro is the preferred way to temporarily work with *window* as the selected window without needlessly running **buffer-list-update-hook**.

Note that this macro temporarily puts the window management code in an unstable state. In particular, the most recently used window (see below) will not necessarily match the selected one. Hence, functions like **get-lru-window** and **get-mru-window** may return unexpected results when called from the body of this macro.

with-selected-frame *frame forms...*

[Macro]

This macro executes *forms* with *frame* as the selected frame. The value returned is the value of the last form in *forms*. This macro saves and restores the selected frame, and changes the order of neither the recently selected windows nor the buffers in the buffer list.

window-use-time &optional *window*

[Function]

This function returns the use time of window *window*. *window* must be a live window and defaults to the selected one.

The use time of a window is not really a time value, but an integer that does increase monotonically with each call of **select-window** with a *nil norecord* argument. The window with the lowest use time is usually called the least recently used window. The window with the highest use time is called the most recently used one (see Section 29.10 [Cyclic Window Ordering], page 717) and is usually the selected window unless **with-selected-window** has been used.

window-bump-use-time &optional *window*

[Function]

This function marks *window* as being the second most recently used one (after the selected window). It does nothing if *window* is the selected window or the selected window does not have the highest use time among all windows which may happen within the scope of **with-selected-window**.

Sometimes several windows collectively and cooperatively display a buffer, for example, under the management of Follow Mode (see Section “Follow Mode” in **emacs**), where the windows together display a bigger portion of the buffer than one window could alone. It is often useful to consider such a *window group* as a single entity. Several functions such as **window-group-start** (see Section 29.20 [Window Start and End], page 759) allow you to do this by supplying, as an argument, one of the windows as a stand-in for the whole group.

selected-window-group

[Function]

When the selected window is a member of a group of windows, this function returns a list of the windows in the group, ordered such that the first window in the list is displaying the earliest part of the buffer, and so on. Otherwise the function returns a list containing just the selected window.

The selected window is considered part of a group when the buffer local variable **selected-window-group-function** is set to a function. In this case,

`selected-window-group` calls it with no arguments and returns its result (which should be the list of windows in the group).

29.4 Window Sizes

Emacs provides miscellaneous functions for finding the height and width of a window. The return value of many of these functions can be specified either in units of pixels or in units of lines and columns. On a graphical display, the latter actually correspond to the height and width of a default character specified by the frame's default font as returned by `frame-char-height` and `frame-char-width` (see Section 30.3.2 [Frame Font], page 797). Thus, if a window is displaying text with a different font or size, the reported line height and column width for that window may differ from the actual number of text lines or columns displayed within it.

The *total height* of a window is the number of lines comprising its body and its top and bottom decorations (see Section 29.1 [Basic Windows], page 690).

window-total-height &optional `window` `round` [Function]

This function returns the total height, in lines, of the window `window`. If `window` is omitted or `nil`, it defaults to the selected window. If `window` is an internal window, the return value is the total height occupied by its descendant windows.

If a window's pixel height is not an integral multiple of its frame's default character height, the number of lines occupied by the window is rounded internally. This is done in a way such that, if the window is a parent window, the sum of the total heights of all its child windows internally equals the total height of their parent. This means that although two windows have the same pixel height, their internal total heights may differ by one line. This means also, that if `window` is vertically combined and has a next sibling, the topmost row of that sibling can be calculated as the sum of this window's topmost row and total height (see Section 29.24 [Coordinates and Windows], page 769)

If the optional argument `round` is `ceiling`, this function returns the smallest integer larger than `window`'s pixel height divided by the character height of its frame; if it is `floor`, it returns the largest integer smaller than said value; with any other `round` it returns the internal value of `window`'s total height.

The *total width* of a window is the number of columns comprising its body and its left and right decorations (see Section 29.1 [Basic Windows], page 690).

window-total-width &optional `window` `round` [Function]

This function returns the total width, in columns, of the window `window`. If `window` is omitted or `nil`, it defaults to the selected window. If `window` is internal, the return value is the total width occupied by its descendant windows.

If a window's pixel width is not an integral multiple of its frame's character width, the number of columns occupied by the window is rounded internally. This is done in a way such that, if the window is a parent window, the sum of the total widths of all its children internally equals the total width of their parent. This means that although two windows have the same pixel width, their internal total widths may differ by one column. This means also, that if this window is horizontally combined

and has a next sibling, the leftmost column of that sibling can be calculated as the sum of this window's leftmost column and total width (see Section 29.24 [Coordinates and Windows], page 769). The optional argument *round* behaves as it does for `window-total-height`.

window-total-size &optional window horizontal round [Function]

This function returns either the total height in lines or the total width in columns of the window *window*. If *horizontal* is omitted or `nil`, this is equivalent to calling `window-total-height` for *window*; otherwise it is equivalent to calling `window-total-width` for *window*. The optional argument *round* behaves as it does for `window-total-height`.

The following two functions can be used to return the total size of a window in units of pixels.

window-pixel-height &optional window [Function]

This function returns the total height of window *window* in pixels. *window* must be a valid window and defaults to the selected one.

The return value includes the heights of *window*'s top and bottom decorations. If *window* is an internal window, its pixel height is the pixel height of the screen areas spanned by its children.

window-pixel-width &optional window [Function]

This function returns the width of window *window* in pixels. *window* must be a valid window and defaults to the selected one.

The return value includes the widths of *window*'s left and right decorations. If *window* is an internal window, its pixel width is the width of the screen areas spanned by its children.

The following functions can be used to determine whether a given window has any adjacent windows.

window-full-height-p &optional window [Function]

This function returns non-`nil` if *window* has no other window above or below it in its frame. More precisely, this means that the total height of *window* equals the total height of the root window on that frame. The minibuffer window does not count in this regard. If *window* is omitted or `nil`, it defaults to the selected window.

window-full-width-p &optional window [Function]

This function returns non-`nil` if *window* has no other window to the left or right in its frame, i.e., its total width equals that of the root window on that frame. If *window* is omitted or `nil`, it defaults to the selected window.

The *body height* of a window is the height of its body, which does not include any of its top or bottom decorations (see Section 29.1 [Basic Windows], page 690).

window-body-height &optional window pixelwise [Function]

This function returns the height, in lines, of the body of window *window*. If *window* is omitted or `nil`, it defaults to the selected window; otherwise it must be a live window.

The optional argument *pixelwise* defines the units to use for the height. If `nil`, return the body height of *window* in characters, rounded down to the nearest integer, if necessary. This means that if a line at the bottom of the text area is only partially visible, that line is not counted. It also means that the height of a window's body can never exceed its total height as returned by `window-total-height`.

If *pixelwise* is `remap` and the default face is remapped (see Section 41.12.5 [Face Remapping], page 1175), use the remapped face to determine the character height. For any other non-`nil` value, return the height in pixels.

The *body width* of a window is the width of its body and of the text area, which does not include any of its left or right decorations (see Section 29.1 [Basic Windows], page 690).

Note that when one or both fringes are removed (by setting their width to zero), the display engine reserves two character cells, one on each side of the window, for displaying the continuation and truncation glyphs, which leaves 2 columns less for text display. (The function `window-max-chars-per-line`, described below, takes this peculiarity into account.)

window-body-width &optional window pixelwise [Function]

This function returns the width, in columns, of the body of window *window*. If *window* is omitted or `nil`, it defaults to the selected window; otherwise it must be a live window.

The optional argument *pixelwise* defines the units to use for the width. If `nil`, return the body width of *window* in characters, rounded down to the nearest integer, if necessary. This means that if a column on the right of the text area is only partially visible, that column is not counted. It also means that the width of a window's body can never exceed its total width as returned by `window-total-width`.

If *pixelwise* is `remap` and the default face is remapped (see Section 41.12.5 [Face Remapping], page 1175), use the remapped face to determine the character width. For any other non-`nil` value, return the width in pixels.

window-body-size &optional window horizontal pixelwise [Function]

This function returns the body height or body width of *window*. If *horizontal* is omitted or `nil`, it is equivalent to calling `window-body-height` for *window*; otherwise it is equivalent to calling `window-body-width`. In either case, the optional argument *pixelwise* is passed to the function called.

The pixel heights of a window's mode, tab and header line can be retrieved with the functions given below. Their return value is usually accurate unless the window has not been displayed before: In that case, the return value is based on an estimate of the font used for the window's frame.

window-mode-line-height &optional window [Function]

This function returns the height in pixels of *window*'s mode line. *window* must be a live window and defaults to the selected one. If *window* has no mode line, the return value is zero.

window-tab-line-height &optional window [Function]

This function returns the height in pixels of *window*'s tab line. *window* must be a live window and defaults to the selected one. If *window* has no tab line, the return value is zero.

window-header-line-height &optional window [Function]

This function returns the height in pixels of *window*'s header line. *window* must be a live window and defaults to the selected one. If *window* has no header line, the return value is zero.

Functions for retrieving the height and/or width of window dividers (see Section 41.15 [Window Dividers], page 1198), fringes (see Section 41.13 [Fringes], page 1189), scroll bars (see Section 41.14 [Scroll Bars], page 1195), and display margins (see Section 41.16.5 [Display Margins], page 1205) are described in the corresponding sections.

If your Lisp program needs to make layout decisions, you will find the following function useful:

window-max-chars-per-line &optional window face [Function]

This function returns the number of characters displayed in the specified face *face* in the specified window *window* (which must be a live window). If *face* was remapped (see Section 41.12.5 [Face Remapping], page 1175), the information is returned for the remapped face. If omitted or *nil*, *face* defaults to the default face, and *window* defaults to the selected window.

Unlike **window-body-width**, this function accounts for the actual size of *face*'s font, instead of working in units of the canonical character width of *window*'s frame (see Section 30.3.2 [Frame Font], page 797). It also accounts for space used by the continuation glyph, if *window* lacks one or both of its fringes.

Commands that change the size of windows (see Section 29.5 [Resizing Windows], page 703), or split them (see Section 29.7 [Splitting Windows], page 708), obey the variables **window-min-height** and **window-min-width**, which specify the smallest allowable window height and width. They also obey the variable **window-size-fixed**, with which a window can be fixed in size (see Section 29.6 [Preserving Window Sizes], page 707).

window-min-height [User Option]

This option specifies the minimum total height, in lines, of any window. Its value has to accommodate at least one text line and any top or bottom decorations.

window-min-width [User Option]

This option specifies the minimum total width, in columns, of any window. Its value has to accommodate at least two text columns and any left or right decorations.

The following function tells how small a specific window can get taking into account the sizes of its areas and the values of **window-min-height**, **window-min-width** and **window-size-fixed** (see Section 29.6 [Preserving Window Sizes], page 707).

window-min-size &optional window horizontal ignore pixelwise [Function]

This function returns the minimum size of *window*. *window* must be a valid window and defaults to the selected one. The optional argument *horizontal non-nil* means to return the minimum number of columns of *window*; otherwise return the minimum number of *window*'s lines.

The return value makes sure that all components of *window* remain fully visible if *window*'s size were actually set to it. With *horizontal nil* it includes any top or

bottom decorations. With *horizontal* non-*nil* it includes any left or right decorations of *window*.

The optional argument *ignore*, if non-*nil*, means ignore restrictions imposed by fixed size windows, `window-min-height` or `window-min-width` settings. If *ignore* equals `safe`, live windows may get as small as `window-safe-min-height` lines and `window-safe-min-width` columns. If *ignore* is a window, ignore restrictions for that window only. Any other non-*nil* value means ignore all of the above restrictions for all windows.

The optional argument *pixelwise* non-*nil* means to return the minimum size of *window* counted in pixels.

29.5 Resizing Windows

This section describes functions for resizing a window without changing the size of its frame. Because live windows do not overlap, these functions are meaningful only on frames that contain two or more windows: resizing a window also changes the size of at least one other window. If there is just one window on a frame, its size cannot be changed except by resizing the frame (see Section 30.3.4 [Frame Size], page 799).

Except where noted, these functions also accept internal windows as arguments. Resizing an internal window causes its child windows to be resized to fit the same space.

window-resizable *window delta &optional horizontal ignore pixelwise* [Function]

This function returns *delta* if the size of *window* can be changed vertically by *delta* lines. If the optional argument *horizontal* is non-*nil*, it instead returns *delta* if *window* can be resized horizontally by *delta* columns. It does not actually change the window size.

If *window* is `nil`, it defaults to the selected window.

A positive value of *delta* means to check whether the window can be enlarged by that number of lines or columns; a negative value of *delta* means to check whether the window can be shrunk by that many lines or columns. If *delta* is non-zero, a return value of 0 means that the window cannot be resized.

Normally, the variables `window-min-height` and `window-min-width` specify the smallest allowable window size (see Section 29.4 [Window Sizes], page 699). However, if the optional argument *ignore* is non-*nil*, this function ignores `window-min-height` and `window-min-width`, as well as `window-size-fixed`. Instead, it considers the minimum height of a window as the sum of its top and bottom decorations plus the text of one line; and its minimum width as the sum of its left and right decorations plus text that takes two columns.

If the optional argument *pixelwise* is non-*nil*, *delta* is interpreted as pixels.

window-resize *window delta &optional horizontal ignore pixelwise* [Function]

This function resizes *window* by *delta* increments. If *horizontal* is `nil`, it changes the height by *delta* lines; otherwise, it changes the width by *delta* columns. A positive *delta* means to enlarge the window, and a negative *delta* means to shrink it.

If *window* is `nil`, it defaults to the selected window. If the window cannot be resized as demanded, an error is signaled.

The optional argument *ignore* has the same meaning as for the function `window-resizable` above.

If the optional argument *pixelwise* is non-`nil`, *delta* will be interpreted as pixels.

The choice of which window edges this function alters depends on the values of the option `window-combination-resize` and the combination limits of the involved windows; in some cases, it may alter both edges. See Section 29.9 [Recombining Windows], page 712. To resize by moving only the bottom or right edge of a window, use the function `adjust-window-trailing-edge`.

adjust-window-trailing-edge *window delta &optional horizontal pixelwise* [Function]

This function moves *window*'s bottom edge by *delta* lines. If optional argument *horizontal* is non-`nil`, it instead moves the right edge by *delta* columns. If *window* is `nil`, it defaults to the selected window.

If the optional argument *pixelwise* is non-`nil`, *delta* is interpreted as pixels.

A positive *delta* moves the edge downwards or to the right; a negative *delta* moves it upwards or to the left. If the edge cannot be moved as far as specified by *delta*, this function moves it as far as possible but does not signal an error.

This function tries to resize windows adjacent to the edge that is moved. If this is not possible for some reason (e.g., if that adjacent window is fixed-size), it may resize other windows.

window-resize-pixelwise [User Option]

If the value of this option is non-`nil`, Emacs resizes windows in units of pixels. This currently affects functions like `split-window` (see Section 29.7 [Splitting Windows], page 708), `maximize-window`, `minimize-window`, `fit-window-to-buffer`, `fit-frame-to-buffer` and `shrink-window-if-larger-than-buffer` (all listed below).

Note that when a frame's pixel size is not a multiple of its character size, at least one window may get resized pixelwise even if this option is `nil`. The default value is `nil`.

The following commands resize windows in more specific ways. When called interactively, they act on the selected window.

fit-window-to-buffer *&optional window max-height min-height max-width min-width preserve-size* [Command]

This command adjusts the height or width of *window* to fit the text in it. It returns non-`nil` if it was able to resize *window*, and `nil` otherwise. If *window* is omitted or `nil`, it defaults to the selected window. Otherwise, it should be a live window.

If *window* is part of a vertical combination, this function adjusts *window*'s height. The new height is calculated from the actual height of the accessible portion of its buffer. The optional argument *max-height*, if non-`nil`, specifies the maximum total height that this function can give *window*. The optional argument *min-height*, if non-`nil`, specifies the minimum total height that it can give, which overrides the variable `window-min-height`. Both *max-height* and *min-height* are specified in lines and include any top or bottom decorations of *window*.

If *window* is part of a horizontal combination and the value of the option **fit-window-to-buffer-horizontally** (see below) is non-*nil*, this function adjusts *window*'s width. The new width of *window* is calculated from the maximum length of its buffer's lines that follow the current start position of *window*. The optional argument *max-width* specifies a maximum width and defaults to the width of *window*'s frame. The optional argument *min-width* specifies a minimum width and defaults to **window-min-width**. Both *max-width* and *min-width* are specified in columns and include any left or right decorations of *window*.

The optional argument *preserve-size*, if non-*nil*, will install a parameter to preserve the size of *window* during future resize operations (see Section 29.6 [Preserving Window Sizes], page 707).

If the option **fit-frame-to-buffer** (see below) is non-*nil*, this function will try to resize the frame of *window* to fit its contents by calling **fit-frame-to-buffer** (see below).

fit-window-to-buffer-horizontally

[User Option]

If this is non-*nil*, **fit-window-to-buffer** can resize windows horizontally. If this is *nil* (the default) **fit-window-to-buffer** never resizes windows horizontally. If this is **only**, it can resize windows horizontally only. Any other value means **fit-window-to-buffer** can resize windows in both dimensions.

fit-frame-to-buffer

[User Option]

If this option is non-*nil*, **fit-window-to-buffer** can fit a frame to its buffer. A frame is fit if and only if its root window is a live window and this option is non-*nil*. If this is **horizontally**, frames are fit horizontally only. If this is **vertically**, frames are fit vertically only. Any other non-*nil* value means frames can be resized in both dimensions.

If you have a frame that displays only one window, you can fit that frame to its buffer using the command **fit-frame-to-buffer**.

fit-frame-to-buffer &optional *frame max-height min-height*

[Command]

max-width min-width only

This command adjusts the size of *frame* to display the contents of its buffer exactly. *frame* can be any live frame and defaults to the selected one. Fitting is done only if *frame*'s root window is live.

The arguments *max-height*, *min-height*, *max-width* and *min-width*, if non-*nil*, specify bounds on the new body size of *frame*'s root window. A non-*nil* value specified by any of these arguments overrides the corresponding value specified by the option **fit-frame-to-buffer-sizes** described below.

If the optional argument *only* is **vertically**, this function may resize the frame vertically only. If *only* is **horizontally**, it may resize the frame horizontally only.

The behavior of **fit-frame-to-buffer** can be controlled with the help of the two options listed next.

fit-frame-to-buffer-margins

[User Option]

This option can be used to specify margins around frames to be fit by **fit-frame-to-buffer**. Such margins can be useful to avoid, for example, that the resized frame overlaps the taskbar or parts of its parent frame.

It specifies the numbers of pixels to be left free on the left, above, the right, and below a frame that shall be fit. The default specifies **nil** for each which means to use no margins. The value specified here can be overridden for a specific frame by that frame's **fit-frame-to-buffer-margins** parameter, if present.

fit-frame-to-buffer-sizes

[User Option]

This option specifies size boundaries for **fit-frame-to-buffer**. It specifies the maximum and minimum lines and maximum and minimum columns of the root window's body of any frame that shall be fit to its buffer. Any value this option specifies will be overridden by the corresponding argument of **fit-frame-to-buffer**, if non-**nil**.

shrink-window-if-larger-than-buffer &optional window

[Command]

This command attempts to reduce **window**'s height as much as possible while still showing its full buffer, but no less than **window-min-height** lines. The return value is **non-nil** if the window was resized, and **nil** otherwise. If **window** is omitted or **nil**, it defaults to the selected window. Otherwise, it should be a live window.

This command does nothing if the window is already too short to display all of its buffer, or if any of the buffer is scrolled off-screen, or if the window is the only live window in its frame.

This command calls **fit-window-to-buffer** (see above) to do its work.

balance-windows &optional window-or-frame

[Command]

This function balances windows in a way that gives more space to full-width and/or full-height windows. If **window-or-frame** specifies a frame, it balances all windows on that frame. If **window-or-frame** specifies a window, it balances only that window and its siblings (see Section 29.2 [Windows and Frames], page 692).

balance-windows-area

[Command]

This function attempts to give all windows on the selected frame approximately the same share of the screen area. Full-width or full-height windows are not given more space than other windows.

maximize-window &optional window

[Command]

This function attempts to make **window** as large as possible, in both dimensions, without resizing its frame or deleting other windows. If **window** is omitted or **nil**, it defaults to the selected window.

minimize-window &optional window

[Command]

This function attempts to make **window** as small as possible, in both dimensions, without deleting it or resizing its frame. If **window** is omitted or **nil**, it defaults to the selected window.

29.6 Preserving Window Sizes

A window can get resized explicitly by using one of the functions from the preceding section or implicitly, for example, when resizing an adjacent window, when splitting or deleting a window (see Section 29.7 [Splitting Windows], page 708, see Section 29.8 [Deleting Windows], page 711) or when resizing the window’s frame (see Section 30.3.4 [Frame Size], page 799).

It is possible to avoid implicit resizing of a specific window when there are one or more other resizable windows on the same frame. For this purpose, Emacs must be advised to preserve the size of that window. There are two basic ways to do that.

window-size-fixed

[Variable]

If this buffer-local variable is non-*nil*, the size of any window displaying the buffer cannot normally be changed. Deleting a window or changing the frame’s size may still change the window’s size, if there is no choice.

If the value is *height*, then only the window’s height is fixed; if the value is *width*, then only the window’s width is fixed. Any other non-*nil* value fixes both the width and the height.

If this variable is *nil*, this does not necessarily mean that any window showing the buffer can be resized in the desired direction. To determine that, use the function `window-resizable`. See Section 29.5 [Resizing Windows], page 703.

Often `window-size-fixed` is overly aggressive because it inhibits any attempt to explicitly resize or split an affected window as well. This may even happen after the window has been resized implicitly, for example, when deleting an adjacent window or resizing the window’s frame. The following function tries hard to never disallow resizing such a window explicitly:

window-preserve-size &optional window horizontal preserve

[Function]

This function (un-)marks the height of window *window* as preserved for future resize operations. *window* must be a live window and defaults to the selected one. If the optional argument *horizontal* is non-*nil*, it (un-)marks the width of *window* as preserved.

If the optional argument *preserve* is *t*, this means to preserve the current height/width of *window*’s body. The height/width of *window* will change only if Emacs has no better choice. Resizing a window whose height/width is preserved by this function never throws an error.

If *preserve* is *nil*, this means to stop preserving the height/width of *window*, lifting any respective restraint induced by a previous call of this function for *window*. Calling `enlarge-window`, `shrink-window` or `fit-window-to-buffer` with *window* as argument may also remove the respective restraint.

`window-preserve-size` is currently invoked by the following functions:

fit-window-to-buffer

If the optional argument *preserve-size* of that function (see Section 29.5 [Resizing Windows], page 703) is non-*nil*, the size established by that function is preserved.

display-buffer

If the *alist* argument of that function (see Section 29.13.1 [Choosing Window], page 724) contains a `preserve-size` entry, the size of the window produced by that function is preserved.

`window-preserve-size` installs a window parameter (see Section 29.27 [Window Parameters], page 776) called `window-preserved-size` which is consulted by the window resizing functions. This parameter will not prevent resizing the window when the window shows another buffer than the one when `window-preserve-size` was invoked or if its size has changed since then.

The following function can be used to check whether the height of a particular window is preserved:

window-preserved-size &optional window horizontal [Function]

This function returns the preserved height of window `window` in pixels. `window` must be a live window and defaults to the selected one. If the optional argument `horizontal` is non-`nil`, it returns the preserved width of `window`. It returns `nil` if the size of `window` is not preserved.

29.7 Splitting Windows

This section describes functions for creating a new window by *splitting* an existing one. Note that some windows are special in the sense that these functions may fail to split them as described here. Examples of such windows are side windows (see Section 29.17 [Side Windows], page 752) and atomic windows (see Section 29.18 [Atomic Windows], page 756).

split-window &optional window size side pixelwise [Function]

This function creates a new live window next to the window `window`. If `window` is omitted or `nil`, it defaults to the selected window. That window is split, and reduced in size. The space is taken up by the new window, which is returned.

The optional second argument `size` determines the sizes of `window` and/or the new window. If it is omitted or `nil`, both windows are given equal sizes; if there is an odd line, it is allocated to the new window. If `size` is a positive number, `window` is given `size` lines (or columns, depending on the value of `side`). If `size` is a negative number, the new window is given `-size` lines (or columns).

If `size` is `nil`, this function obeys the variables `window-min-height` and `window-min-width` (see Section 29.4 [Window Sizes], page 699). Thus, it signals an error if splitting would result in making a window smaller than those variables specify. However, a non-`nil` value for `size` causes those variables to be ignored; in that case, the smallest allowable window is considered to be one that has space for a text that is one line tall and/or two columns wide.

Hence, if `size` is specified, it's the caller's responsibility to check whether the emanating windows are large enough to encompass all of their decorations like a mode line or a scroll bar. The function `window-min-size` (see Section 29.4 [Window Sizes], page 699) can be used to determine the minimum requirements of `window` in this regard. Since the new window usually inherits areas like the mode line or the scroll bar from `window`, that function is also a good guess for the minimum size of the new window. The caller should specify a smaller size only if it correspondingly removes an inherited area before the next redisplay.

The optional third argument `side` determines the position of the new window relative to `window`. If it is `nil` or `below`, the new window is placed below `window`. If it is

`above`, the new window is placed above `window`. In both these cases, `size` specifies a total window height, in lines.

If `side` is `t` or `right`, the new window is placed on the right of `window`. If `side` is `left`, the new window is placed on the left of `window`. In both these cases, `size` specifies a total window width, in columns.

The optional fourth argument `pixelwise`, if non-`nil`, means to interpret `size` in units of pixels, instead of lines and columns.

If `window` is a live window, the new window inherits various properties from it, including margins and scroll bars. If `window` is an internal window, the new window inherits the properties of the window selected within `window`'s frame.

The behavior of this function may be altered by the window parameters of `window`, so long as the variable `ignore-window-parameters` is `nil`. If the value of the `split-window` window parameter is `t`, this function ignores all other window parameters. Otherwise, if the value of the `split-window` window parameter is a function, that function is called with the arguments `window`, `size`, and `side`, in lieu of the usual action of `split-window`. Otherwise, this function obeys the `window-atom` or `window-side` window parameter, if any. See Section 29.27 [Window Parameters], page 776.

As an example, here is a sequence of `split-window` calls that yields the window configuration discussed in Section 29.2 [Windows and Frames], page 692. This example demonstrates splitting a live window as well as splitting an internal window. We begin with a frame containing a single window (a live root window), which we denote by `W4`. Calling (`split-window W4`) yields this window configuration:

The `split-window` call has created a new live window, denoted by `W5`. It has also created a new internal window, denoted by `W3`, which becomes the root window and the parent of both `W4` and `W5`.

Next, we call (`split-window W3 nil 'left`), passing the internal window `W3` as the argument. The result:

A new live window *W2* is created, to the left of the internal window *W3*. A new internal window *W1* is created, becoming the new root window.

For interactive use, Emacs provides two commands which always split the selected window. These call `split-window` internally.

`split-window-right` &optional size window-to-split [Command]

This function splits the window *window-to-split* into two side-by-side windows, putting *window-to-split* on the left. *window-to-split* defaults to the selected window. If *size* is positive, the left window gets *size* columns; if *size* is negative, the right window gets $-size$ columns.

split-window-below &optional size window-to-split [Command]

This function splits the window *window-to-split* into two windows, one above the other, leaving the upper window selected. *window-to-split* defaults to the selected window. If *size* is positive, the upper window gets *size* lines; if *size* is negative, the lower window gets $-size$ lines.

split-root-window-below &optional size [Command]

This function splits the whole frame in two. The current window configuration is retained on the top, and a new window is created below, taking up the whole width of the frame. *size* is treated as by `split-window-below`.

split-root-window-right &optional size [Command]

This function splits the whole frame in two. The current window configuration is retained on the left, and a new window is created on the right, taking up the whole height of the frame. `size` is treated as by `split-window-right`.

`split-window-keep-point` [User Option]

If the value of this variable is non-*nil* (the default), `split-window-below` behaves as described above.

If it is `nil`, `split-window-below` adjusts point in each of the two windows to minimize redisplay. (This is useful on slow terminals.) It selects whichever window contains the screen line that point was previously on. Note that this only affects `split-window-below`, not the lower-level `split-window` function.

29.8 Deleting Windows

Deleting a window removes it from the frame’s window tree. If the window is a live window, it disappears from the screen. If the window is an internal window, its child windows are deleted too.

Even after a window is deleted, it continues to exist as a Lisp object, until there are no more references to it. Window deletion can be reversed, by restoring a saved window configuration (see Section 29.26 [Window Configurations], page 774).

`delete-window &optional window`

[Command]

This function removes *window* from display and returns `nil`. If *window* is omitted or `nil`, it defaults to the selected window.

If deleting the window would leave no more windows in the window tree (e.g., if it is the only live window in the frame) or all remaining windows on *window*’s frame are side windows (see Section 29.17 [Side Windows], page 752), an error is signaled. If *window* is part of an atomic window (see Section 29.18 [Atomic Windows], page 756), this function tries to delete the root of that atomic window instead.

By default, the space taken up by *window* is given to one of its adjacent sibling windows, if any. However, if the variable `window-combination-resize` is non-`nil`, the space is proportionally distributed among any remaining windows in the same window combination. See Section 29.9 [Recombining Windows], page 712.

The behavior of this function may be altered by the window parameters of *window*, so long as the variable `ignore-window-parameters` is `nil`. If the value of the `delete-window` window parameter is `t`, this function ignores all other window parameters. Otherwise, if the value of the `delete-window` window parameter is a function, that function is called with the argument *window*, in lieu of the usual action of `delete-window`. See Section 29.27 [Window Parameters], page 776.

When `delete-window` deletes the selected window of its frame, it has to make another window the new selected window of that frame. The following option allows configuring which window is chosen.

`delete-window-choose-selected`

[User Option]

This option allows specifying which window should become a frame’s selected window after `delete-window` has deleted the previously selected one. Possible choices are

- `mru` (the default) choose the most recently used window on that frame.
- `pos` choose the window comprising the frame coordinates of point of the previously selected window on that frame.
- `nil` choose the first window (the window returned by `frame-first-window`) on that frame.

A window with a non-`nil` `no-other-window` parameter is chosen only if all other windows on that frame have that parameter set to a non-`nil` value too.

`delete-other-windows &optional window`

[Command]

This function makes *window* fill its frame, deleting other windows as necessary. If *window* is omitted or `nil`, it defaults to the selected window. An error is signaled if *window* is a side window (see Section 29.17 [Side Windows], page 752). If *window*

is part of an atomic window (see Section 29.18 [Atomic Windows], page 756), this function tries to make the root of that atomic window fill its frame. The return value is `nil`.

The behavior of this function may be altered by the window parameters of `window`, so long as the variable `ignore-window-parameters` is `nil`. If the value of the `delete-other-windows` window parameter is `t`, this function ignores all other window parameters. Otherwise, if the value of the `delete-other-windows` window parameter is a function, that function is called with the argument `window`, in lieu of the usual action of `delete-other-windows`. See Section 29.27 [Window Parameters], page 776.

Also, if `ignore-window-parameters` is `nil`, this function does not delete any window whose `no-delete-other-windows` parameter is non-`nil`.

delete-windows-on &optional *buffer-or-name frame* [Command]

This function deletes all windows showing *buffer-or-name*, by calling `delete-window` on those windows. *buffer-or-name* should be a buffer, or the name of a buffer; if omitted or `nil`, it defaults to the current buffer. If there are no windows showing the specified buffer, this function does nothing. If the specified buffer is a minibuffer, an error is signaled.

If there is a dedicated window showing the buffer, and that window is the only one on its frame, this function also deletes that frame if it is not the only frame on the terminal.

The optional argument *frame* specifies which frames to operate on:

- `nil` means operate on all frames.
- `t` means operate on the selected frame.
- `visible` means operate on all visible frames.
- `0` means operate on all visible or iconified frames.
- A frame means operate on that frame.

Note that this argument does not have the same meaning as in other functions which scan all live windows (see Section 29.10 [Cyclic Window Ordering], page 717). Specifically, the meanings of `t` and `nil` here are the opposite of what they are in those other functions.

29.9 Recombining Windows

When deleting the last sibling of a window *W*, its parent window is deleted too, with *W* replacing it in the window tree. This means that *W* must be recombined with its parent's siblings to form a new window combination (see Section 29.2 [Windows and Frames], page 692). In some occasions, deleting a live window may even entail the deletion of two internal windows.

Deleting W_5 in this configuration normally causes the deletion of W_3 and W_4 . The remaining live windows W_2 , W_6 and W_7 are recombined to form a new horizontal combination with parent W_1 .

Sometimes, however, it makes sense to not delete a parent window like W4. In particular, a parent window should not be removed when it was used to preserve a combination embedded in a combination of the same type. Such embeddings make sense to assure that when you split a window and subsequently delete the new window, Emacs reestablishes the layout of the associated frame as it existed before the splitting.

Consider a scenario starting with two live windows W_2 and W_3 and their parent W_1 .

Split W_2 to make a new window W_4 as follows.

Now, when enlarging a window vertically, Emacs tries to obtain the corresponding space from its lower sibling, provided such a window exists. In our scenario, enlarging W_4 will steal space from W_3 .

Deleting W_4 will now give its entire space to W_2 , including the space earlier stolen from W_3 .

This can be counterintuitive, in particular if `W4` were used for displaying a buffer only temporarily (see Section 41.8 [Temporary Displays], page 1146), and you want to continue working with the initial layout.

The behavior can be fixed by making a new parent window when splitting W2. The variable described next allows that to be done.

window-combination-limit

[User Option]

This variable controls whether splitting a window shall make a new parent window. The following values are recognized:

`nil` This means that the new live window is allowed to share the existing parent window, if one exists, provided the split occurs in the same direction as the existing window combination (otherwise, a new internal window is created anyway).

window-size

This means that `display-buffer` makes a new parent window when it splits a window and is passed a `window-height` or `window-width` entry in

the `alist` argument (see Section 29.13.2 [Buffer Display Action Functions], page 726). Otherwise, window splitting behaves as for a value of `nil`.

`temp-buffer-resize`

In this case `with-temp-buffer-window` makes a new parent window when it splits a window and `temp-buffer-resize-mode` is enabled (see Section 41.8 [Temporary Displays], page 1146). Otherwise, window splitting behaves as for `nil`.

`temp-buffer`

In this case `with-temp-buffer-window` always makes a new parent window when it splits an existing window (see Section 41.8 [Temporary Displays], page 1146). Otherwise, window splitting behaves as for `nil`.

`display-buffer`

This means that when `display-buffer` (see Section 29.13.1 [Choosing Window], page 724) splits a window it always makes a new parent window. Otherwise, window splitting behaves as for `nil`.

`t`

This means that splitting a window always creates a new parent window. Thus, if the value of this variable is at all times `t`, then at all times every window tree is a binary tree (a tree where each window except the root window has exactly one sibling).

The default is `window-size`. Other values are reserved for future use.

If, as a consequence of this variable's setting, `split-window` makes a new parent window, it also calls `set-window-combination-limit` (see below) on the newly-created internal window. This affects how the window tree is rearranged when the child windows are deleted (see below).

If `window-combination-limit` is `t`, splitting `W2` in the initial configuration of our scenario would have produced this:

A new internal window `W5` has been created; its children are `W2` and the new live window `W4`. Now, `W2` is the only sibling of `W4`, so enlarging `W4` will try to shrink `W2`, leaving `W3` unaffected. Observe that `W5` represents a vertical combination of two windows embedded in the vertical combination `W1`.

`set-window-combination-limit window limit` [Function]

This function sets the *combination limit* of the window *window* to *limit*. This value can be retrieved via the function `window-combination-limit`. See below for its effects; note that it is only meaningful for internal windows. The `split-window` function automatically calls this function, passing it *t* as *limit*, provided the value of the variable `window-combination-limit` is *t* when it is called.

window-combination-limit *window* [Function]

This function returns the combination limit for window.

The combination limit is meaningful only for an internal window. If it is `nil`, then Emacs is allowed to automatically delete `window`, in response to a window deletion, in order to group the child windows of `window` with its sibling windows to form a new window combination. If the combination limit is `t`, the child windows of `window` are never automatically recombined with its siblings.

If, in the configuration shown at the beginning of this section, the combination limit of W_4 (the parent window of W_6 and W_7) is t , deleting W_5 will not implicitly delete W_4 too.

Alternatively, the problems sketched above can be avoided by always resizing all windows in the same combination whenever one of its windows is split or deleted. This also permits splitting windows that would be otherwise too small for such an operation.

window-combination-resize [User Option]

If this variable is `nil`, `split-window` can only split a window (denoted by `window`) if `window`'s screen area is large enough to accommodate both itself and the new window.

If this variable is `t`, `split-window` tries to resize all windows that are part of the same combination as `window`, in order to accommodate the new window. In particular, this may allow `split-window` to succeed even if `window` is a fixed-size window or too small to ordinarily split. Furthermore, subsequently resizing or deleting `window` may resize all other windows in its combination.

The default is `nil`. Other values are reserved for future use. A specific split operation may ignore the value of this variable if it is affected by a non-`nil` value of `window-combination-limit`.

To illustrate the effect of `window-combination-resize`, consider the following frame layout.

If `window-combination-resize` is `nil`, splitting window `W3` leaves the size of `W2` unchanged:

If `window-combination-resize` is `t`, splitting `W3` instead leaves all three live windows with approximately the same height:

Deleting any of the live windows `W2`, `W3` or `W4` will distribute its space proportionally among the two remaining live windows.

29.10 Cyclic Ordering of Windows

When you use the command `C-x o (other-window)` to select some other window, it moves through live windows in a specific order. For any given configuration of windows, this order never varies. It is called the *cyclic ordering of windows*.

The ordering is determined by a depth-first traversal of each frame's window tree, retrieving the live windows which are the leaf nodes of the tree (see Section 29.2 [Windows and Frames], page 692). If the minibuffer is active, the minibuffer window is included too. The ordering is cyclic, so the last window in the sequence is followed by the first one.

next-window &optional window minibuf all-frames [Function]

This function returns a live window, the one following `window` in the cyclic ordering of windows. `window` should be a live window; if omitted or `nil`, it defaults to the selected window.

The optional argument `minibuf` specifies whether minibuffer windows should be included in the cyclic ordering. Normally, when `minibuf` is `nil`, a minibuffer window

is included only if it is currently active; this matches the behavior of `C-x o`. (Note that a minibuffer window is active as long as its minibuffer is in use; see Chapter 21 [Minibuffers], page 385).

If `minibuf` is `t`, the cyclic ordering includes all minibuffer windows. If `minibuf` is neither `t` nor `nil`, minibuffer windows are not included even if they are active.

The optional argument `all-frames` specifies which frames to consider:

- `nil` means to consider windows on `window`'s frame. If the minibuffer window is considered (as specified by the `minibuf` argument), then frames that share the minibuffer window are considered too.
- `t` means to consider windows on all existing frames.
- `visible` means to consider windows on all visible frames.
- `0` means to consider windows on all visible or iconified frames.
- A frame means to consider windows on that specific frame.
- Anything else means to consider windows on `window`'s frame, and no others.

If more than one frame is considered, the cyclic ordering is obtained by appending the orderings for those frames, in the same order as the list of all live frames (see Section 30.8 [Finding All Frames], page 823).

previous-window &optional window minibuf all-frames [Function]

This function returns a live window, the one preceding `window` in the cyclic ordering of windows. The other arguments are handled like in `next-window`.

other-window count &optional all-frames [Command]

This function selects a live window, one `count` places from the selected window in the cyclic ordering of windows. If `count` is a positive number, it skips `count` windows forwards; if `count` is negative, it skips $-count$ windows backwards; if `count` is zero, that simply re-selects the selected window. When called interactively, `count` is the numeric prefix argument.

The optional argument `all-frames` has the same meaning as in `next-window`, like a `nil minibuf` argument to `next-window`.

This function does not select a window that has a non-`nil` `no-other-window` window parameter (see Section 29.27 [Window Parameters], page 776), provided that `ignore-window-parameters` is `nil`.

If the `other-window` parameter of the selected window is a function, and `ignore-window-parameters` is `nil`, that function will be called with the arguments `count` and `all-frames` instead of the normal operation of this function.

walk-windows fun &optional minibuf all-frames [Function]

This function calls the function `fun` once for each live window, with the window as the argument.

It follows the cyclic ordering of windows. The optional arguments `minibuf` and `all-frames` specify the set of windows included; these have the same arguments as in `next-window`. If `all-frames` specifies a frame, the first window walked is the first window on that frame (the one returned by `frame-first-window`), not necessarily the selected window.

If *fun* changes the window configuration by splitting or deleting windows, that does not alter the set of windows walked, which is determined prior to calling *fun* for the first time.

one-window-p &optional no-mini all-frames [Function]

This function returns `t` if the selected window is the only live window, and `nil` otherwise.

If the minibuffer window is active, it is normally considered (so that this function returns `nil`). However, if the optional argument *no-mini* is non-`nil`, the minibuffer window is ignored even if active. The optional argument *all-frames* has the same meaning as for `next-window`.

The following functions return a window which satisfies some criterion, without selecting it:

get-lru-window &optional all-frames dedicated not-selected no-other [Function]

This function returns a live window which is heuristically the least recently used one. The *least recently used window* is the least recently selected one—the window whose use time is less than the use time of all other live windows (see Section 29.3 [Selecting Windows], page 696). The optional argument *all-frames* has the same meaning as in `next-window`.

If any full-width windows are present, only those windows are considered. A minibuffer window is never a candidate. A dedicated window (see Section 29.15 [Dedicated Windows], page 749) is never a candidate unless the optional argument *dedicated* is non-`nil`. The selected window is never returned, unless it is the only candidate. However, if the optional argument *not-selected* is non-`nil`, this function returns `nil` in that case. The optional argument *no-other*, if non-`nil`, means to never return a window whose *no-other-window* parameter is non-`nil`.

get-mru-window &optional all-frames dedicated not-selected no-other [Function]

This function is like `get-lru-window`, but it returns the most recently used window instead. The *most recently used window* is the most recently selected one—the window whose use time exceeds the use time of all other live windows (see Section 29.3 [Selecting Windows], page 696). The meaning of the arguments is the same as for `get-lru-window`.

Since in practice the most recently used window is always the selected one, it usually makes sense to call this function with a non-`nil` *not-selected* argument only.

**get-largest-window &optional all-frames dedicated not-selected
no-other** [Function]

This function returns the window with the largest area (height times width). If there are two candidate windows of the same size, it prefers the one that comes first in the cyclic ordering of windows, starting from the selected window. The meaning of the arguments is the same as for `get-lru-window`.

**get-window-with-predicate predicate &optional minibuf all-frames
default** [Function]

This function calls the function *predicate* for each of the windows in the cyclic order of windows in turn, passing it the window as an argument. If the predicate returns

`non-nil` for any window, this function stops and returns that window. If no such window is found, the return value is `default` (which defaults to `nil`).

The optional arguments `minibuf` and `all-frames` specify the windows to search, and have the same meanings as in `next-window`.

29.11 Buffers and Windows

This section describes low-level functions for examining and setting the contents of windows. See Section 29.12 [Switching Buffers], page 721, for higher-level functions for displaying a specific buffer in a window.

`window-buffer &optional window`

[Function]

This function returns the buffer that `window` is displaying. If `window` is omitted or `nil` it defaults to the selected window. If `window` is an internal window, this function returns `nil`.

`set-window-buffer window buffer-or-name &optional keep-margins`

[Function]

This function makes `window` display `buffer-or-name`. `window` should be a live window; if `nil`, it defaults to the selected window. `buffer-or-name` should be a buffer, or the name of an existing buffer. This function does not change which window is selected, nor does it directly change which buffer is current (see Section 28.2 [Current Buffer], page 671). Its return value is `nil`.

If `window` is *strongly dedicated* to a buffer and `buffer-or-name` does not specify that buffer, this function signals an error. See Section 29.15 [Dedicated Windows], page 749. By default, this function resets `window`'s position, display margins, fringe widths, and scroll bar settings, based on the local variables in the specified buffer. However, if the optional argument `keep-margins` is `non-nil`, it leaves `window`'s display margins, fringes and scroll bar settings alone.

When writing an application, you should normally use `display-buffer` (see Section 29.13.1 [Choosing Window], page 724) or the higher-level functions described in Section 29.12 [Switching Buffers], page 721, instead of calling `set-window-buffer` directly.

This runs `window-scroll-functions`, followed by `window-configuration-change-hook`. See Section 29.28 [Window Hooks], page 779.

`buffer-display-count`

[Variable]

This buffer-local variable records the number of times a buffer has been displayed in a window. It is incremented each time `set-window-buffer` is called for the buffer.

`buffer-display-time`

[Variable]

This buffer-local variable records the time at which a buffer was last displayed in a window. The value is `nil` if the buffer has never been displayed. It is updated each time `set-window-buffer` is called for the buffer, with the value returned by `current-time` (see Section 42.5 [Time of Day], page 1270).

`get-buffer-window &optional buffer-or-name all-frames`

[Function]

This function returns the first window displaying `buffer-or-name` in the cyclic ordering of windows, starting from the selected window (see Section 29.10 [Cyclic Window Ordering], page 717). If no such window exists, the return value is `nil`.

buffer-or-name should be a buffer or the name of a buffer; if omitted or `nil`, it defaults to the current buffer. The optional argument *all-frames* specifies which windows to consider:

- `t` means consider windows on all existing frames.
- `visible` means consider windows on all visible frames.
- `0` means consider windows on all visible or iconified frames.
- A frame means consider windows on that frame only.
- Any other value means consider windows on the selected frame.

Note that these meanings differ slightly from those of the *all-frames* argument to `next-window` (see Section 29.10 [Cyclic Window Ordering], page 717). This function may be changed in a future version of Emacs to eliminate this discrepancy.

get-buffer-window-list &optional *buffer-or-name minibuf all-frames* [Function]

This function returns a list of all windows currently displaying *buffer-or-name*. *buffer-or-name* should be a buffer or the name of an existing buffer. If omitted or `nil`, it defaults to the current buffer. If the currently selected window displays *buffer-or-name*, it will be the first in the list returned by this function.

The arguments *minibuf* and *all-frames* have the same meanings as in the function `next-window` (see Section 29.10 [Cyclic Window Ordering], page 717). Note that the *all-frames* argument does *not* behave exactly like in `get-buffer-window`.

replace-buffer-in-windows &optional *buffer-or-name* [Command]

This command replaces *buffer-or-name* with some other buffer, in all windows displaying it. *buffer-or-name* should be a buffer, or the name of an existing buffer; if omitted or `nil`, it defaults to the current buffer.

The replacement buffer in each window is chosen via `switch-to-prev-buffer` (see Section 29.14 [Window History], page 746). With the exception of side windows (see Section 29.17 [Side Windows], page 752), any dedicated window displaying *buffer-or-name* is deleted if possible (see Section 29.15 [Dedicated Windows], page 749). If such a window is the only window on its frame and there are other frames on the same terminal, the frame is deleted as well. If the dedicated window is the only window on the only frame on its terminal, the buffer is replaced anyway.

29.12 Switching to a Buffer in a Window

This section describes high-level functions for switching to a specified buffer in some window. In general, “switching to a buffer” means to (1) show the buffer in some window, (2) make that window the selected window (and its frame the selected frame), and (3) make the buffer the current buffer.

Do *not* use these functions to make a buffer temporarily current just so a Lisp program can access or modify it. They have side-effects, such as changing window histories (see Section 29.14 [Window History], page 746), which will surprise the user if used that way. If you want to make a buffer current to modify it in Lisp, use `with-current-buffer`, `save-current-buffer`, or `set-buffer`. See Section 28.2 [Current Buffer], page 671.

switch-to-buffer *buffer-or-name* &optional *norecord* [Command]
force-same-window

This command attempts to display *buffer-or-name* in the selected window and make it the current buffer. It is often used interactively (as the binding of *C-x b*), as well as in Lisp programs. The return value is the buffer switched to.

If *buffer-or-name* is *nil*, it defaults to the buffer returned by **other-buffer** (see Section 28.8 [Buffer List], page 681). If *buffer-or-name* is a string that is not the name of any existing buffer, this function creates a new buffer with that name; the new buffer's major mode is determined by the variable **major-mode** (see Section 24.2 [Major Modes], page 526).

Normally, the specified buffer is put at the front of the buffer list—both the global buffer list and the selected frame's buffer list (see Section 28.8 [Buffer List], page 681). However, this is not done if the optional argument *norecord* is non-*nil*.

Sometimes, the selected window may not be suitable for displaying the buffer. This happens if the selected window is a minibuffer window, or if the selected window is strongly dedicated to its buffer (see Section 29.15 [Dedicated Windows], page 749). In such cases, the command normally tries to display the buffer in some other window, by invoking **pop-to-buffer** (see below).

If the optional argument *force-same-window* is non-*nil* and the selected window is not suitable for displaying the buffer, this function always signals an error when called non-interactively. In interactive use, if the selected window is a minibuffer window, this function will try to use some other window instead. If the selected window is strongly dedicated to its buffer, the option **switch-to-buffer-in-dedicated-window** described next can be used to proceed.

switch-to-buffer-in-dedicated-window [User Option]

This option, if non-*nil*, allows **switch-to-buffer** to proceed when called interactively and the selected window is strongly dedicated to its buffer.

The following values are respected:

- nil* Disallows switching and signals an error as in non-interactive use.
- prompt* Prompts the user whether to allow switching.
- pop* Invokes **pop-to-buffer** to proceed.
- t* Marks the selected window as non-dedicated and proceeds.

This option does not affect non-interactive calls of **switch-to-buffer**.

By default, **switch-to-buffer** tries to preserve **window-point**. This behavior can be tuned using the following option.

switch-to-buffer-preserve-window-point [User Option]

If this variable is *nil*, **switch-to-buffer** displays the buffer specified by *buffer-or-name* at the position of that buffer's *point*. If this variable is *already-displayed*, it tries to display the buffer at its previous position in the selected window, provided the buffer is currently displayed in some other window on any visible or iconified frame. If this variable is *t*, **switch-to-buffer** unconditionally tries to display the buffer at its previous position in the selected window.

This variable is ignored if the buffer is already displayed in the selected window or never appeared in it before, or if `switch-to-buffer` calls `pop-to-buffer` to display the buffer.

switch-to-buffer-obey-display-actions [User Option]

If this variable is non-`nil`, `switch-to-buffer` respects display actions specified by `display-buffer-overriding-action`, `display-buffer-alist` and other display related variables.

The next two commands are similar to `switch-to-buffer`, except for the described features.

switch-to-buffer-other-window *buffer-or-name* &optional
 norecord [Command]

This function displays the buffer specified by *buffer-or-name* in some window other than the selected window. It uses the function `pop-to-buffer` internally (see below). If the selected window already displays the specified buffer, it continues to do so, but another window is nonetheless found to display it as well.

The *buffer-or-name* and *norecord* arguments have the same meanings as in `switch-to-buffer`.

switch-to-buffer-other-frame *buffer-or-name* &optional
 norecord [Command]

This function displays the buffer specified by *buffer-or-name* in a new frame. It uses the function `pop-to-buffer` internally (see below).

If the specified buffer is already displayed in another window, in any frame on the current terminal, this switches to that window instead of creating a new frame. However, the selected window is never used for this.

The *buffer-or-name* and *norecord* arguments have the same meanings as in `switch-to-buffer`.

The above commands use the function `pop-to-buffer`, which flexibly displays a buffer in some window and selects that window for editing. In turn, `pop-to-buffer` uses `display-buffer` for displaying the buffer. Hence, all the variables affecting `display-buffer` will affect it as well. See Section 29.13.1 [Choosing Window], page 724, for the documentation of `display-buffer`.

pop-to-buffer *buffer-or-name* &optional *action* *norecord* [Command]

This function makes *buffer-or-name* the current buffer and displays it in some window, preferably not the window currently selected. It then selects the displaying window. If that window is on a different graphical frame, that frame is given input focus if possible (see Section 30.10 [Input Focus], page 824).

If *buffer-or-name* is `nil`, it defaults to the buffer returned by `other-buffer` (see Section 28.8 [Buffer List], page 681). If *buffer-or-name* is a string that is not the name of any existing buffer, this function creates a new buffer with that name; the new buffer's major mode is determined by the variable `major-mode` (see Section 24.2 [Major Modes], page 526). In any case, that buffer is made current and returned, even when no suitable window was found to display it.

If *action* is non-`nil`, it should be a display action to pass to `display-buffer` (see Section 29.13.1 [Choosing Window], page 724). Alternatively, a non-`nil`, non-list value means to pop to a window other than the selected one—even if the buffer is already displayed in the selected window.

Like `switch-to-buffer`, this function updates the buffer list unless *norecord* is non-`nil`.

29.13 Displaying a Buffer in a Suitable Window

This section describes lower-level functions Emacs uses to find or create a window for displaying a specified buffer. The common workhorse of these functions is `display-buffer` which eventually handles all incoming requests for buffer display (see Section 29.13.1 [Choosing Window], page 724).

`display-buffer` delegates the task of finding a suitable window to so-called action functions (see Section 29.13.2 [Buffer Display Action Functions], page 726). First, `display-buffer` compiles a so-called action alist—a special association list that action functions can use to fine-tune their behavior. Then it passes that alist on to each action function it calls (see Section 29.13.3 [Buffer Display Action Alists], page 730).

The behavior of `display-buffer` is highly customizable. To understand how customizations are used in practice, you may wish to study examples illustrating the order of precedence which `display-buffer` uses to call action functions (see Section 29.13.5 [Precedence of Action Functions], page 738). To avoid conflicts between Lisp programs calling `display-buffer` and user customizations of its behavior, it may make sense to follow a number of guidelines which are sketched in the final part of this section (see Section 29.13.6 [The Zen of Buffer Display], page 743).

29.13.1 Choosing a Window for Displaying a Buffer

The command `display-buffer` flexibly chooses a window for display, and displays a specified buffer in that window. It can be called interactively, via the key binding `C-x 4 C-o`. It is also used as a subroutine by many functions and commands, including `switch-to-buffer` and `pop-to-buffer` (see Section 29.12 [Switching Buffers], page 721).

This command performs several complex steps to find a window to display in. These steps are described by means of *display actions*, which have the form `(functions . alist)`. Here, *functions* is either a single function or a list of functions, referred to as “action functions” (see Section 29.13.2 [Buffer Display Action Functions], page 726); and *alist* is an association list, referred to as “action alist” (see Section 29.13.3 [Buffer Display Action Alists], page 730). See Section 29.13.6 [The Zen of Buffer Display], page 743, for samples of display actions.

An action function accepts two arguments: the buffer to display and an action alist. It attempts to display the buffer in some window, picking or creating a window according to its own criteria. If successful, it returns the window; otherwise, it returns `nil`.

`display-buffer` works by combining display actions from several sources, and calling the action functions in turn, until one of them manages to display the buffer and returns a non-`nil` value.

`display-buffer` *buffer-or-name* &*optional action frame* [Command]

This command makes *buffer-or-name* appear in some window, without selecting the window or making the buffer current. The argument *buffer-or-name* must be a buffer

or the name of an existing buffer. The return value is the window chosen to display the buffer, or `nil` if no suitable window was found.

The optional argument *action*, if non-`nil`, should normally be a display action (described above). `display-buffer` builds a list of action functions and an action alist, by consolidating display actions from the following sources (in order of their precedence, from highest to lowest):

- The variable `display-buffer-overriding-action`.
- The user option `display-buffer-alist`.
- The *action* argument.
- The user option `display-buffer-base-action`.
- The constant `display-buffer-fallback-action`.

In practice this means that `display-buffer` builds a list of all action functions specified by these display actions. The first element of this list is the first action function specified by `display-buffer-overriding-action`, if any. Its last element is `display-buffer-pop-up-frame`—the last action function specified by `display-buffer-fallback-action`. Duplicates are not removed from this list—hence one and the same action function may be called multiple times during one call of `display-buffer`.

`display-buffer` calls the action functions specified by this list in turn, passing the buffer as the first argument and the combined action alist as the second argument, until one of the functions returns non-`nil`. See Section 29.13.5 [Precedence of Action Functions], page 738, for examples how display actions specified by different sources are processed by `display-buffer`.

Note that the second argument is always the list of *all* action alist entries specified by the sources named above. Hence, the first element of that list is the first action alist entry specified by `display-buffer-overriding-action`, if any. Its last element is the last alist entry of `display-buffer-base-action`, if any (the action alist of `display-buffer-fallback-action` is empty).

Note also, that the combined action alist may contain duplicate entries and entries for the same key with different values. As a rule, action functions always use the first association of a key they find. Hence, the association an action function uses is not necessarily the association provided by the display action that specified that action function,

The argument *action* can also have a non-`nil`, non-list value. This has the special meaning that the buffer should be displayed in a window other than the selected one, even if the selected window is already displaying it. If called interactively with a prefix argument, *action* is `t`. Lisp programs should always supply a list value.

The optional argument *frame*, if non-`nil`, specifies which frames to check when deciding whether the buffer is already displayed. It is equivalent to adding an element (`reusable-frames . frame`) to the action alist of *action* (see Section 29.13.3 [Buffer Display Action Alists], page 730). The *frame* argument is provided for compatibility reasons, Lisp programs should not use it.

display-buffer-overriding-action [Variable]

The value of this variable should be a display action, which is treated with the highest priority by `display-buffer`. The default value is an empty display action, i.e., `(nil . nil)`.

display-buffer-alist [User Option]

The value of this option is an alist mapping conditions to display actions. Each condition is passed to `buffer-match-p` (see Section 28.8 [Buffer List], page 681), along with the buffer name and the *action* argument passed to `display-buffer`. If it returns a non-nil value, then `display-buffer` uses the corresponding display action to display the buffer. Caveat: if you use `derived-mode` or `major-mode` as condition, `buffer-match-p` could fail to report a match if `display-buffer` is called before the major mode of the buffer is set.

display-buffer-base-action [User Option]

The value of this option should be a display action. This option can be used to define a standard display action for calls to `display-buffer`.

display-buffer-fallback-action [Constant]

This display action specifies the fallback behavior for `display-buffer` if no other display actions are given.

29.13.2 Action Functions for Buffer Display

An *action function* is a function `display-buffer` calls for choosing a window to display a buffer. Action functions take two arguments: *buffer*, the buffer to display, and *alist*, an action alist (see Section 29.13.3 [Buffer Display Action Alists], page 730). They are supposed to return a window displaying *buffer* if they succeed and `nil` if they fail.

The following basic action functions are defined in Emacs.

display-buffer-same-window *buffer alist* [Function]

This function tries to display *buffer* in the selected window. It fails if the selected window is a minibuffer window or is dedicated to another buffer (see Section 29.15 [Dedicated Windows], page 749). It also fails if *alist* has a non-nil `inhibit-same-window` entry.

display-buffer-reuse-window *buffer alist* [Function]

This function tries to display *buffer* by finding a window that is already displaying it. Windows on the selected frame are preferred to windows on other frames.

If *alist* has a non-nil `inhibit-same-window` entry, the selected window is not eligible for reuse. The set of frames to search for a window already displaying *buffer* can be specified with the help of the `reusable-frames` action alist entry. If *alist* contains no `reusable-frames` entry, this function searches just the selected frame.

If this function chooses a window on another frame, it makes that frame visible and, unless *alist* contains an `inhibit-switch-frame` entry, raises that frame if necessary.

display-buffer-reuse-mode-window *buffer alist* [Function]

This function tries to display *buffer* by finding a window that is displaying a buffer in a given mode.

If *alist* contains a `mode` entry, its value specifies a major mode (a symbol) or a list of major modes. If *alist* contains no `mode` entry, the current major mode of *buffer* is used instead. A window is a candidate if it displays a buffer whose mode derives from one of the modes specified thusly.

The behavior is also controlled by *alist* entries for `inhibit-same-window`, `reusable-frames` and `inhibit-switch-frame`, like `display-buffer-reuse-window` does.

display-buffer-pop-up-window *buffer alist* [Function]

This function tries to display *buffer* by splitting the largest or least recently-used window (usually located on the selected frame). It actually performs the split by calling the function specified by `split-window-preferred-function` (see Section 29.13.4 [Choosing Window Options], page 736).

The size of the new window can be adjusted by supplying `window-height` and `window-width` entries in *alist*. If *alist* contains a `preserve-size` entry, Emacs will also try to preserve the size of the new window during future resize operations (see Section 29.6 [Preserving Window Sizes], page 707).

This function fails if no window can be split. More often than not, this happens because no window is large enough to allow splitting. Setting `split-height-threshold` or `split-width-threshold` to lower values may help in this regard. Splitting also fails when the selected frame has an `unsplittable` frame parameter; see Section 30.4.3.5 [Buffer Parameters], page 812.

display-buffer-in-previous-window *buffer alist* [Function]

This function tries to display *buffer* in a window where it was displayed previously.

If *alist* contains a non-`nil` `inhibit-same-window` entry, the selected window is not eligible for use. A dedicated window is usable only if it already shows *buffer*. If *alist* contains a `previous-window` entry, the window specified by that entry is usable even if it never showed *buffer* before.

If *alist* contains a `reusable-frames` entry (see Section 29.13.3 [Buffer Display Action Alists], page 730), its value determines which frames to search for a suitable window. If *alist* contains no `reusable-frames` entry, this function searches just the selected frame if `display-buffer-reuse-frames` and `pop-up-frames` are both `nil`; it searches all frames on the current terminal if either of those variables is non-`nil`.

If more than one window qualifies as usable according to these rules, this function makes a choice in the following order of preference:

- The window specified by any `previous-window` *alist* entry, provided it is not the selected window.
- A window that showed *buffer* before, provided it is not the selected window.
- The selected window if it is either specified by a `previous-window` *alist* entry or showed *buffer* before.

display-buffer-use-some-window *buffer alist* [Function]

This function tries to display *buffer* by choosing an existing window and displaying the buffer in that window. It first tries to find a window that has not been used recently (see Section 29.10 [Cyclic Window Ordering], page 717) on any frame specified by a

`lru-frames` *alist* entry, falling back to the selected frame if no such entry exists. It also prefers windows that satisfy the constraints specified by `window-min-width` and `window-min-height` *alist* entries; preferring full-width windows if no `window-min-width` entry is found. Finally, it will not return a window whose use time is higher than that specified by any `lru-time` entry provided by *alist*.

If no less recently used window is found, this function will try to use some other window, preferably a large window on some visible frame. It can fail if all windows are dedicated to other buffers (see Section 29.15 [Dedicated Windows], page 749).

display-buffer-use-least-recent-window *buffer alist* [Function]

This function is similar to `display-buffer-use-some-window`, but will try harder to not use the a recently used window. In particular, it does not use the selected window. In addition, it will first try to reuse a window that shows *buffer* already, base the decision whether it should use a window showing another buffer on that window's use time alone and pop up a new window if no usable window is found.

Finally, this function will bump the use time (see Section 29.3 [Selecting Windows], page 696) of any window it returns in order to avoid that further invocations will use that window for showing another buffer. An application that wants to display several buffers in a row can help this function by providing a `lru-time` *alist* entry it has initially set to the value of the selected window's use time. Each invocation of this function will then bump the use time of the window returned to a value higher than that and a subsequent invocation will inhibit this function to use a window it returned earlier.

display-buffer-in-direction *buffer alist* [Function]

This function tries to display *buffer* at a location specified by *alist*. For this purpose, *alist* should contain a `direction` entry whose value is one of `left`, `above` (or `up`), `right` and `below` (or `down`). Other values are usually interpreted as `below`.

If *alist* also contains a `window` entry, its value specifies a reference window. That value can be a special symbol like `main` which stands for the selected frame's main window (see Section 29.17.2 [Side Window Options and Functions], page 753) or `root` standing for the selected frame's root window (see Section 29.2 [Windows and Frames], page 692). It can also specify an arbitrary valid window. Any other value (or omitting the `window` entry entirely) means to use the selected window as reference window.

This function first tries to reuse a window in the specified direction that already shows *buffer*. If no such window exists, it tries to split the reference window in order to produce a new window in the specified direction. If this fails as well, it will try to display *buffer* in an existing window in the specified direction. In either case, the window chosen will appear on the side of the reference window specified by the `direction` entry, sharing at least one edge with the reference window.

If the reference window is live, the edge the chosen window will share with it is always the opposite of the one specified by the `direction` entry. For example, if the value of the `direction` entry is `left`, the chosen window's right edge coordinate (see Section 29.24 [Coordinates and Windows], page 769) will equal the reference window's left edge coordinate.

If the reference window is internal, a reused window must share with it the edge specified by the `direction` entry. Hence if, for example, the reference window is the

frame's root window and the value of the `direction` entry is `left`, a reused window must be on the left of the frame. This means that the left edge coordinate of the chosen window and that of the reference window are the same.

A new window, however, will be created by splitting the reference window such that the chosen window will share the opposite edge with the reference window. In our example, a new root window would be created with a new live window and the reference window as its children. The chosen window's right edge coordinate would then equal the left edge coordinate of the reference window. Its left edge coordinate would equal the left edge coordinate of the frame's new root window.

Four special values for `direction` entries allow to implicitly specify the selected frame's main window as the reference window: `leftmost`, `top`, `rightmost` and `bottom`. This means that instead of, for example, (`direction . left`) (`window . main`) one can just specify (`direction . leftmost`). An existing `window alist` entry is ignored in such cases.

`display-buffer-below-selected buffer alist` [Function]

This function tries to display `buffer` in a window below the selected window. If there is a window below the selected one and that window already displays `buffer`, it reuses that window.

If there is no such window, this function tries to create a new window by splitting the selected one, and displays `buffer` there. It will also try to adjust that window's size provided `alist` contains a suitable `window-height` or `window-width` entry, see above.

If splitting the selected window fails and there is a non-dedicated window below the selected one showing some other buffer, this function tries to use that window for showing `buffer`.

If `alist` contains a `window-min-height` entry, this function ensures that the window used is or can become at least as high as specified by that entry's value. Note that this is only a guarantee. In order to actually resize the window used, `alist` must also provide an appropriate `window-height` entry.

`display-buffer-at-bottom buffer alist` [Function]

This function tries to display `buffer` in a window at the bottom of the selected frame.

This either tries to split the window at the bottom of the frame or the frame's root window, or to reuse an existing window at the bottom of the selected frame.

`display-buffer-pop-up-frame buffer alist` [Function]

This function creates a new frame, and displays the buffer in that frame's window. It actually performs the frame creation by calling the function specified in `pop-up-frame-function` (see Section 29.13.4 [Choosing Window Options], page 736). If `alist` contains a `pop-up-frame-parameters` entry, the associated value is added to the newly created frame's parameters.

`display-buffer-full-frame buffer alist` [Function]

This function displays the buffer on the current frame, deleting all other windows so that it takes up the full frame.

display-buffer-in-child-frame *buffer alist* [Function]

This function tries to display *buffer* in a child frame (see Section 30.14 [Child Frames], page 831) of the selected frame, either reusing an existing child frame or by making a new one. If *alist* has a non-nil **child-frame-parameters** entry, the corresponding value is an alist of frame parameters to give the new frame. A **parent-frame** parameter specifying the selected frame is provided by default. If the child frame should become the child of another frame, a corresponding entry must be added to *alist*.

The appearance of child frames is largely dependent on the parameters provided via *alist*. It is advisable to use at least ratios to specify the size (see Section 30.4.3.3 [Size Parameters], page 808) and the position (see Section 30.4.3.2 [Position Parameters], page 805) of the child frame, and to add a **keep-ratio** parameter (see Section 30.4.3.6 [Frame Interaction Parameters], page 812), in order to make sure that the child frame remains visible. For other parameters that should be considered see Section 30.14 [Child Frames], page 831.

display-buffer-use-some-frame *buffer alist* [Function]

This function tries to display *buffer* by finding a frame that meets a predicate (by default any frame other than the selected frame).

If this function chooses a window on another frame, it makes that frame visible and, unless *alist* contains an **inhibit-switch-frame** entry, raises that frame if necessary.

If *alist* has a non-nil **frame-predicate** entry, its value is a function taking one argument (a frame), returning non-nil if the frame is a candidate; this function replaces the default predicate.

If *alist* has a non-nil **inhibit-same-window** entry, the selected window is not used; thus if the selected frame has a single window, it is not used.

display-buffer-no-window *buffer alist* [Function]

If *alist* has a non-nil **allow-no-window** entry, then this function does not display *buffer* and returns the symbol **fail**. This constitutes the only exception to the convention that an action function returns either **nil** or a window showing *buffer*. If *alist* has no such **allow-no-window** entry, this function returns **nil**.

If this function returns **fail**, **display-buffer** will skip the execution of any further display actions and return **nil** immediately. If this function returns **nil**, **display-buffer** will continue with the next display action, if any.

It is assumed that when a caller of **display-buffer** specifies a non-nil **allow-no-window** entry, it is also able to handle a **nil** return value.

Two other action functions are described in their proper sections—**display-buffer-in-side-window** (see Section 29.17.1 [Displaying Buffers in Side Windows], page 752) and **display-buffer-in-atom-window** (see Section 29.18 [Atomic Windows], page 756).

29.13.3 Action Alists for Buffer Display

An *action alist* is an association list mapping predefined symbols recognized by action functions to values these functions are supposed to interpret accordingly. In each call, **display-buffer** constructs a new, possibly empty action alist and passes that entire list on to any action function it calls.

By design, action functions are free in their interpretation of action alist entries. In fact, some entries like `allow-no-window` or `previous-window` have a meaning only for one or a few action functions, and are ignored by the rest. Other entries, like `inhibit-same-window` or `window-parameters`, are supposed to be respected by most action functions, including those provided by application programs and external packages.

In the previous subsection we have described in detail how individual action functions interpret the action alist entries they care about. Here we give a reference list of all known action alist entries according to their symbols, together with their values and action functions (see Section 29.13.2 [Buffer Display Action Functions], page 726) that recognize them. Throughout this list, the terms “buffer” will refer to the buffer `display-buffer` is supposed to display, and “value” refers to the entry’s value.

`inhibit-same-window`

If the value is non-`nil`, this signals that the selected window must not be used for displaying the buffer. All action functions that (re-)use an existing window should respect this entry.

`previous-window`

The value must specify a window that may have displayed the buffer previously. `display-buffer-in-previous-window` will give preference to such a window provided it is still live and not dedicated to another buffer.

`mode`

The value is either a major mode or a list of major modes. `display-buffer-reuse-mode-window` may reuse a window whenever the value specified by this entry matches the major mode of that window’s buffer. Other action functions ignore such entries.

`frame-predicate`

The value must be a function taking one argument (a frame), supposed to return `non-nil` if that frame is a candidate for displaying the buffer. This entry is used by `display-buffer-use-some-frame`.

`reusable-frames`

The value specifies the set of frames to search for a window that can be reused because it already displays the buffer. It can be set as follows:

- `nil` means consider only windows on the selected frame. (Actually, the last frame used that is not a minibuffer-only frame.)
- `visible` means consider windows on all visible frames.
- `0` means consider windows on all visible or iconified frames.
- A frame means consider windows on that frame only.
- `t` means consider windows on all frames. (Note that this value is rarely the right thing to use—it might also return a tooltip frame.)

Note that the meaning of `nil` differs slightly from that of the `all-frames` argument to `next-window` (see Section 29.10 [Cyclic Window Ordering], page 717).

A major client of this is `display-buffer-reuse-window`, but all other action functions that try to reuse a window are affected as well. `display-buffer-in-previous-window` consults it when searching for a window that previously displayed the buffer on another frame.

inhibit-switch-frame

A non-nil value prevents another frame from being raised or selected, if the window chosen by `display-buffer` is displayed there. Primarily affected by this are `display-buffer-use-some-frame` and `display-buffer-reuse-window`. Ideally, `display-buffer-pop-up-frame` should be affected as well, but there is no guarantee that the window manager will comply.

window-parameters

The value specifies an alist of window parameters to give the chosen window. All action functions that choose a window should process this entry.

window-min-width

The value specifies a minimum width of the window used, in canonical frame columns. The special value `full-width` means the chosen window should be one that has no other windows on the left or right of it in its frame.

This entry is currently honored by `display-buffer-use-some-window` and `display-buffer-use-least-recent-window`, which try hard to avoid returning a less recently used window that does not satisfy the entry.

Note that providing such an entry alone does not necessarily make the window as wide as specified by its value. To actually resize an existing window or make a new window as wide as specified by this entry's value, a `window-width` entry specifying that value should be provided as well. Such a `window-width` entry can, however, specify a completely different value, or ask the window width to fit that of its buffer, in which case the `window-min-width` entry provides the guaranteed minimum width of the window.

window-min-height

The value specifies a minimum height of the window used, in canonical frame lines. The special value `full-height` means the chosen window should be a full-height window, one that has no other windows above or below it in its frame.

This entry is currently honored by `display-buffer-below-selected` which does not use a window that is not as high as specified by this entry. It's also honored by `display-buffer-use-some-window` and `display-buffer-use-least-recent-window` which try hard to avoid returning a less recently used window if it does not satisfy this constraint.

Note that providing such an entry alone does not necessarily make the window as tall as specified by its value. To actually resize an existing window or make a new window as tall as specified by that value, a `window-height` entry specifying that value should be provided as well. Such a `window-height` entry can, however, specify a completely different value or ask the window height to be fit to that of its buffer in which case the `window-min-height` entry provides the guaranteed minimum height of the window used.

window-height

The value specifies whether and how to adjust the height of the chosen window and can be one of the following:

- `nil` means to leave the height of the chosen window alone.

- An integer number specifies the desired total height of the chosen window in lines.
- A floating-point number specifies the fraction of the chosen window's desired total height with respect to the total height of its frame's root window.
- A cons cell whose CAR is **body-lines** and whose CDR is an integer that specifies the height of the chosen window's body in frame lines.
- If the value specifies a function, that function is called with one argument—the chosen window. The function is supposed to adjust the height of the window; its return value is ignored. Suitable functions are **fit-window-to-buffer** and **shrink-window-if-larger-than-buffer**, see Section 29.5 [Resizing Windows], page 703.

By convention, the height of the chosen window is adjusted only if the window is part of a vertical combination (see Section 29.2 [Windows and Frames], page 692) to avoid changing the height of other, unrelated windows. Also, this entry should be processed only under certain conditions which are specified right below this list.

window-width

This entry is similar to the **window-height** entry described before, but used to adjust the chosen window's width instead. The value can be one of the following:

- **nil** means to leave the width of the chosen window alone.
- An integer specifies the desired total width of the chosen window in columns.
- A floating-point number specifies the fraction of the chosen window's desired total width with respect to the total width of the frame's root window.
- A cons cell whose CAR is **body-columns** and whose CDR is an integer that specifies the width of the chosen window's body in frame columns.
- If the value specifies a function, that function is called with one argument—the chosen window. The function is supposed to adjust the width of the window; its return value is ignored.

window-size

This entry is a combination of the two preceding ones and can be used to adjust the chosen window's height *and* width. Since windows can be resized in one direction only without affecting other windows, **window-size** is effective only to set up the size of a window appearing alone on a frame. The value can be one of the following:

- **nil** means to leave the size of the chosen window alone.
- A cons cell of two integers specifies the desired total width and height of the chosen window in lines and columns. Its effect is to adjust the size of the frame accordingly.
- A cons cell whose CAR equals **body-chars** and whose CDR is a cons cell of two integers—the desired body width and height of the chosen window in frame columns and lines. Its effect is to adjust the size of the frame accordingly.

- If the value specifies a function, that function is called with one argument—the chosen window. The function is supposed to adjust the size of the window's frame; its return value is ignored.

This entry should be processed under only certain conditions which are specified right below this list.

dedicated

If non-`nil`, such an entry tells `display-buffer` to mark any window it creates as dedicated to its buffer (see Section 29.15 [Dedicated Windows], page 749). It does that by calling `set-window-dedicated-p` with the chosen window as first argument and the entry's value as second. Side windows are by default dedicated with the value `side` (see Section 29.17.2 [Side Window Options and Functions], page 753).

preserve-size

If non-`nil` such an entry tells Emacs to preserve the size of the window chosen (see Section 29.6 [Preserving Window Sizes], page 707). The value should be either `(t . nil)` to preserve the width of the window, `(nil . t)` to preserve its height or `(t . t)` to preserve both, its width and its height. This entry should be processed only under certain conditions which are specified right after this list.

lru-frames

The value specifies the set of frames to search for a window that can be used to display the buffer. It is honored by `display-buffer-use-some-window` and `display-buffer-use-least-recent-window` when trying to find a less recently used window showing some other buffer. Its values are the same as for the `reusable-frames` entry described above.

lru-time

The value is supposed to specify a use time (see Section 29.3 [Selecting Windows], page 696). This entry is honored by `display-buffer-use-some-window` and `display-buffer-use-least-recent-window` when trying to find a less recently used window showing some other buffer. If a window's use time is higher than the value specified by this option, these action functions will not consider such a window for displaying the buffer.

bump-use-time

If non-`nil`, such an entry will cause `display-buffer` to bump the use time (see Section 29.3 [Selecting Windows], page 696) of the window it uses. This should avoid later use of this window by action functions like `display-buffer-use-some-window` and `display-buffer-use-least-recent-window` for showing another buffer.

There is a fine difference between using this entry and using the action function `display-buffer-use-least-recent-window`. Calling the latter means to only bump the use times of windows that function uses for displaying the buffer. The entry described here will cause `display-buffer` to bump the use time of *any* window used for displaying a buffer.

pop-up-frame-parameters

The value specifies an alist of frame parameters to give a new frame, if one is created. **display-buffer-pop-up-frame** is its one and only addressee.

parent-frame

The value specifies the parent frame to be used when the buffer is displayed on a child frame. This entry is used only by **display-buffer-in-child-frame**.

child-frame-parameters

The value specifies an alist of frame parameters to use when the buffer is displayed on a child frame. This entry is used only by **display-buffer-in-child-frame**.

side

The value denotes the side of the frame or window where a new window displaying the buffer shall be created. This entry is used by **display-buffer-in-side-window** to indicate the side of the frame where a new side window shall be placed (see Section 29.17.1 [Displaying Buffers in Side Windows], page 752). It is also used by **display-buffer-in-atom-window** to indicate the side of an existing window where the new window shall be located (see Section 29.18 [Atomic Windows], page 756).

slot

If non-*nil*, the value specifies the slot of the side window supposed to display the buffer. This entry is used only by **display-buffer-in-side-window**.

direction

The value specifies a direction which, together with a **window** entry, allows **display-buffer-in-direction** to determine the location of the window to display the buffer.

window

The value specifies a window that is in some way related to the window chosen by **display-buffer**. This entry is currently used by **display-buffer-in-atom-window** to indicate the window on whose side the new window shall be created. It is also used by **display-buffer-in-direction** to specify the reference window on whose side the resulting window shall appear.

allow-no-window

If the value is non-*nil*, **display-buffer** does not necessarily have to display the buffer and the caller is prepared to accept that. This entry is not intended for user customizations, since there is no guarantee that an arbitrary caller of **display-buffer** will be able to handle the case that no window will display the buffer. **display-buffer-no-window** is the only action function that cares about this entry.

body-function

The value must be a function taking one argument (a displayed window). This function can be used to fill the displayed window's body with some contents that might depend on dimensions of the displayed window. It is called *after* the buffer is displayed, and *before* the entries **window-height**, **window-width** and **preserve-size** are applied that could resize the window to fit it to the inserted contents.

By convention, the entries **window-height**, **window-width** and **preserve-size** are applied after the chosen window's buffer has been set up and if and only if that window never

showed another buffer before. More precisely, the latter means that the window must have been either created by the current `display-buffer` call or the window was created earlier by `display-buffer` to show the buffer and never was used to show another buffer until it was reused by the current invocation of `display-buffer`.

If no `window-height`, `window-width` or `window-size` entry was specified, the window may still be resized automatically when the buffer is temporary and `temp-buffer-resize-mode` has been enabled, Section 41.8 [Temporary Displays], page 1146. In that case, the CDR of a `window-height`, `window-width` or `window-size` entry can be used to inhibit or override the default behavior of `temp-buffer-resize-mode` for specific buffers or invocations of `display-buffer`.

29.13.4 Additional Options for Displaying Buffers

The behavior of buffer display actions (see Section 29.13.1 [Choosing Window], page 724) can be further modified by the following user options.

`pop-up-windows`

[User Option]

If the value of this variable is non-`nil`, `display-buffer` is allowed to split an existing window to make a new window for displaying in. This is the default.

This variable is provided for backward compatibility only. It is obeyed by `display-buffer` via a special mechanism in `display-buffer-fallback-action`, which calls the action function `display-buffer-pop-up-window` (see Section 29.13.2 [Buffer Display Action Functions], page 726) when the value of this option is non-`nil`. It is not consulted by `display-buffer-pop-up-window` itself, which the user may specify directly in `display-buffer-alist` etc.

`split-window-preferred-function`

[User Option]

This variable specifies a function for splitting a window, in order to make a new window for displaying a buffer. It is used by the `display-buffer-pop-up-window` action function to actually split the window.

The value must be a function that takes one argument, a window, and returns either a new window (which will be used to display the desired buffer) or `nil` (which means the splitting failed). The default value is `split-window-sensibly`, which is documented next.

`split-window-sensibly` &`optional window`

[Function]

This function tries to split `window` and return the newly created window. If `window` cannot be split, it returns `nil`. If `window` is omitted or `nil`, it defaults to the selected window.

This function obeys the usual rules that determine when a window may be split (see Section 29.7 [Splitting Windows], page 708). It first tries to split by placing the new window below, subject to the restriction imposed by `split-height-threshold` (see below), in addition to any other restrictions. If that fails, it tries to split by placing the new window to the right, subject to `split-width-threshold` (see below). If that also fails, and the window is the only window on its frame, this function again tries to split and place the new window below, disregarding `split-height-threshold`. If this fails as well, this function gives up and returns `nil`.

split-height-threshold

[User Option]

This variable specifies whether `split-window-sensibly` is allowed to split the window placing the new window below. If it is an integer, that means to split only if the original window has at least that many lines. If it is `nil`, that means not to split this way.

split-width-threshold

[User Option]

This variable specifies whether `split-window-sensibly` is allowed to split the window placing the new window to the right. If the value is an integer, that means to split only if the original window has at least that many columns. If the value is `nil`, that means not to split this way.

even-window-sizes

[User Option]

This variable, if non-`nil`, causes `display-buffer` to even window sizes whenever it reuses an existing window, and that window is adjacent to the selected one.

If its value is `width-only`, sizes are evened only if the reused window is on the left or right of the selected one and the selected window is wider than the reused one. If its value is `height-only` sizes are evened only if the reused window is above or beneath the selected window and the selected window is higher than the reused one. Any other non-`nil` value means to even sizes in any of these cases provided the selected window is larger than the reused one in the sense of their combination.

pop-up-frames

[User Option]

If the value of this variable is non-`nil`, that means `display-buffer` may display buffers by making new frames. The default is `nil`.

A non-`nil` value also means that when `display-buffer` is looking for a window already displaying `buffer-or-name`, it can search any visible or iconified frame, not just the selected frame.

This variable is provided mainly for backward compatibility. It is obeyed by `display-buffer` via a special mechanism in `display-buffer-fallback-action`, which calls the action function `display-buffer-pop-up-frame` (see Section 29.13.2 [Buffer Display Action Functions], page 726) if the value is non-`nil`. (This is done before attempting to split a window.) This variable is not consulted by `display-buffer-pop-up-frame` itself, which the user may specify directly in `display-buffer-alist` etc.

pop-up-frame-function

[User Option]

This variable specifies a function for creating a new frame, in order to make a new window for displaying a buffer. It is used by the `display-buffer-pop-up-frame` action function.

The value should be a function that takes no arguments and returns a frame, or `nil` if no frame could be created. The default value is a function that creates a frame using the parameters specified by `pop-up-frame-alist` (see below).

pop-up-frame-alist

[User Option]

This variable holds an alist of frame parameters (see Section 30.4 [Frame Parameters], page 802), which is used by the function specified by `pop-up-frame-function` to make a new frame. The default is `nil`.

This option is provided for backward compatibility only. Note, that when `display-buffer-pop-up-frame` calls the function specified by `pop-up-frame-function`, it prepends the value of all `pop-up-frame-parameters` action alist entries to `pop-up-frame-alist` so that the values specified by the action alist entry effectively override any corresponding values of `pop-up-frame-alist`.

Hence, users should set up a `pop-up-frame-parameters` action alist entry in `display-buffer-alist` instead of customizing `pop-up-frame-alist`. Only this will guarantee that the value of a parameter specified by the user overrides the value of that parameter specified by the caller of `display-buffer`.

Many efforts in the design of `display-buffer` have been given to maintain compatibility with code that uses older options like `pop-up-windows`, `pop-up-frames`, `pop-up-frame-alist`, `same-window-buffer-names` and `same-window-regexp`s. Lisp Programs and users should refrain from using these options. Above we already warned against customizing `pop-up-frame-alist`. Here we describe how to convert the remaining options to use display actions instead.

`pop-up-windows`

This variable is `t` by default. Instead of customizing it to `nil` and thus telling `display-buffer` what not to do, it's much better to list in `display-buffer-base-action` the action functions it should try instead as, for example:

```
(setopt
  display-buffer-base-action
  '((display-buffer-reuse-window display-buffer-same-window
    display-buffer-in-previous-window
    display-buffer-use-some-window)))
```

`pop-up-frames`

Instead of customizing this variable to `t`, customize `display-buffer-base-action`, for example, as follows:

```
(setopt
  display-buffer-base-action
  '((display-buffer-reuse-window display-buffer-pop-up-frame)
    (reusable-frames . 0)))
```

`same-window-buffer-names`

`same-window-regexp`s

Instead of adding a buffer name or a regular expression to one of these options use a `display-buffer-alist` entry for that buffer specifying the action function `display-buffer-same-window`.

```
(setopt
  display-buffer-alist
  (cons '("/*foo*/" (display-buffer-same-window))
    display-buffer-alist))
```

29.13.5 Precedence of Action Functions

From the past subsections we already know that `display-buffer` must be supplied with a number of display actions (see Section 29.13.1 [Choosing Window], page 724) in order

to display a buffer. In a completely uncustomized Emacs, these actions are specified by `display-buffer-fallback-action` in the following order of precedence: Reuse a window, pop up a new window on the same frame, use a window previously showing the buffer, use some window and pop up a new frame. (Note that the remaining actions named by `display-buffer-fallback-action` are void in an uncustomized Emacs).

Consider the following form:

```
(display-buffer (get-buffer-create "*foo*"))
```

Evaluating this form in the buffer `*scratch*` of an uncustomized Emacs session will usually fail to reuse a window that shows `*foo*` already, but succeed in popping up a new window. Evaluating the same form again will now not cause any visible changes—`display-buffer` reused the window already showing `*foo*` because that action was applicable and had the highest precedence among all applicable actions.

Popping up a new window will fail if there is not enough space on the selected frame. In an uncustomized Emacs it typically fails when there are already two windows on a frame. For example, if you now type `C-x 1` followed by `C-x 2` and evaluate the form once more, `*foo*` should show up in the lower window—`display-buffer` just used “some” window. If, before typing `C-x 2` you had typed `C-x o`, `*foo*` would have been shown in the upper window because “some” window stands for the “least recently used” window and the selected window has been least recently used if and only if it is alone on its frame.

Let’s assume you did not type `C-x o` and `*foo*` is shown in the lower window. Type `C-x o` to get there followed by `C-x left` and evaluate the form again. This should display `*foo*` in the same, lower window because that window had already shown `*foo*` previously and was therefore chosen instead of some other window.

So far we have only observed the default behavior in an uncustomized Emacs session. To see how this behavior can be customized, let’s consider the option `display-buffer-base-action`. It provides a very coarse customization which conceptually affects the display of *any* buffer. It can be used to supplement the actions supplied by `display-buffer-fallback-action` by reordering them or by adding actions that are not present there but fit more closely the user’s editing practice. However, it can also be used to change the default behavior in a more profound way.

Let’s consider a user who, as a rule, prefers to display buffers on another frame. Such a user might provide the following customization:

```
(setopt
  display-buffer-base-action
  '((display-buffer-reuse-window display-buffer-pop-up-frame)
    (reusable-frames . 0)))
```

This setting will cause `display-buffer` to first try to find a window showing the buffer on a visible or iconified frame and, if no such frame exists, pop up a new frame. You can observe this behavior on a graphical system by typing `C-x 1` in the window showing `*scratch*` and evaluating our canonical `display-buffer` form. This will usually create (and give focus to) a new frame whose root window shows `*foo*`. Iconify that frame and evaluate the canonical form again: `display-buffer` will reuse the window on the new frame (usually raising the frame and giving it focus too).

Only if creating a new frame fails, `display-buffer` will apply the actions supplied by `display-buffer-fallback-action` which means to again try reusing a window, popping

up a new window and so on. A trivial way to make frame creation fail is supplied by the following form:

```
(let ((pop-up-frame-function 'ignore))
  (display-buffer (get-buffer-create "*foo*")))
```

We will forget about that form immediately after observing that it fails to create a new frame and uses a fallback action instead.

Note that `display-buffer-reuse-window` appears redundant in the customization of `display-buffer-base-action` because it is already part of `display-buffer-fallback-action` and should be tried there anyway. However, that would fail because due to the precedence of `display-buffer-base-action` over `display-buffer-fallback-action`, at that time `display-buffer-pop-up-frame` would have already won the race. In fact, this:

```
(setopt
  display-buffer-base-action
  '(display-buffer-pop-up-frame (reusable-frames . 0)))
```

would cause `display-buffer` to *always* pop up a new frame which is probably not what our user wants.

So far, we have only shown how *users* can customize the default behavior of `display-buffer`. Let us now see how *applications* can change the course of `display-buffer`. The canonical way to do that is to use the `action` argument of `display-buffer` or a function that calls it, like, for example, `pop-to-buffer` (see Section 29.12 [Switching Buffers], page 721).

Suppose an application wants to display `*foo*` preferably below the selected window (to immediately attract the attention of the user to the new window) or, if that fails, in a window at the bottom of the frame. It could do that with a call like this:

```
(display-buffer
  (get-buffer-create "*foo*")
  '((display-buffer-below-selected display-buffer-at-bottom)))
```

In order to see how this new, modified form works, delete any frame showing `*foo*`, type `C-x 1` followed by `C-x 2` in the window showing `*scratch*`, and subsequently evaluate that form. `display-buffer` should split the upper window, and show `*foo*` in the new window. Alternatively, if after `C-x 2` you had typed `C-x o`, `display-buffer` would have split the window at the bottom instead.

Suppose now that, before evaluating the new form, you have made the selected window as small as possible, for example, by evaluating the form (`fit-window-to-buffer`) in that window. In that case, `display-buffer` would have failed to split the selected window and would have split the frame's root window instead, effectively displaying `*foo*` at the bottom of the frame.

In either case, evaluating the new form a second time should reuse the window already showing `*foo*` since both functions supplied by the `action` argument try to reuse such a window first.

By setting the `action` argument, an application effectively overrules any customization of `display-buffer-base-action`. Our user can now either accept the choice of the application, or redouble by customizing the option `display-buffer-alist` as follows:

```
(setopt
  display-buffer-alist
  '("(""\*foo\*"
      (display-buffer-reuse-window display-buffer-pop-up-frame))))
```

Trying this with the new, modified form above in a configuration that does not show ***foo*** anywhere, will display ***foo*** on a separate frame, completely ignoring the *action* argument of **display-buffer**.

Note that we didn't care to specify a **reusable-frames** action alist entry in our specification of **display-buffer-alist**. **display-buffer** always takes the first one it finds—in our case the one specified by **display-buffer-base-action**. If we wanted to use a different specification, for example, to exclude iconified frames showing ***foo*** from the list of reusable ones, we would have to specify that separately, however:

```
(setopt
  display-buffer-alist
  '("(""\*foo\*"
      (display-buffer-reuse-window display-buffer-pop-up-frame)
      (reusable-frames . visible))))
```

If you try this, you will notice that repeated attempts to display ***foo*** will succeed to reuse a frame only if that frame is visible.

The above example would allow the conclusion that users customize **display-buffer-alist** for the sole purpose to overrule the *action* argument chosen by applications. Such a conclusion would be incorrect. **display-buffer-alist** is the standard option for users to direct the course of display of specific buffers in a preferred way regardless of whether the display is also guided by an *action* argument.

We can, however, reasonably conclude that customizing **display-buffer-alist** differs from customizing **display-buffer-base-action** in two major aspects: it is stronger because it overrides the *action* argument of **display-buffer**, and it allows to explicitly specify the affected buffers. In fact, displaying other buffers is not affected in any way by a customization for ***foo***. For example,

```
(display-buffer (get-buffer-create "*bar*"))
continues being governed by the settings of display-buffer-base-action and
display-buffer-fallback-action only.
```

We could stop with our examples here but Lisp programs still have an ace up their sleeves which they can use to overrule any customization of **display-buffer-alist**. It's the variable **display-buffer-overriding-action** which they can bind around **display-buffer** calls as follows:

```
(let ((display-buffer-overriding-action
      '((display-buffer-same-window))))
  (display-buffer
    (get-buffer-create "*foo*")
    '((display-buffer-below-selected display-buffer-at-bottom))))
```

Evaluating this form will usually display ***foo*** in the selected window regardless of the *action* argument and any user customizations. (Usually, an application will not bother to also provide an *action* argument. Here it just serves to illustrate the fact that it gets overridden.)

It might be illustrative to look at the list of action functions `display-buffer` would have tried to display `*foo*` with the customizations we provided here. The list (including comments explaining who added this and the subsequent elements) is:

```
(display-buffer-same-window  ;; `display-buffer-overriding-action'
  display-buffer-reuse-window  ;; `display-buffer-alist'
  display-buffer-pop-up-frame
  display-buffer-below-selected  ;; ACTION argument
  display-buffer-at-bottom
  display-buffer-reuse-window  ;; `display-buffer-base-action'
  display-buffer-pop-up-frame
  display-buffer--maybe-same-window  ;; `display-buffer-fallback-action'
  display-buffer-reuse-window
  display-buffer--maybe-pop-up-frame-or-window
  display-buffer-in-previous-window
  display-buffer-use-some-window
  display-buffer-pop-up-frame)
```

Note that among the internal functions listed here, `display-buffer--maybe-same-window` is effectively ignored while `display-buffer--maybe-pop-up-frame-or-window` actually runs `display-buffer-pop-up-window`.

The action alist passed in each function call is:

```
((reusable-frames . visible)
 (reusable-frames . 0))
```

which shows that we have used the second specification of `display-buffer-alist` above, overriding the specification supplied by `display-buffer-base-action`. Suppose our user had written that as

```
(setopt
  display-buffer-alist
  '((("\\*foo\\*"
       (display-buffer-reuse-window display-buffer-pop-up-frame)
       (inhibit-same-window . t)
       (reusable-frames . visible))))
```

In this case the `inhibit-same-window` alist entry will successfully invalidate the `display-buffer-same-window` specification from `display-buffer-overriding-action` and `display-buffer` will show `*foo*` on another frame. To make `display-buffer-overriding-action` more robust in this regard, the application would have to specify an appropriate `inhibit-same-window` entry too, for example, as follows:

```
(let ((display-buffer-overriding-action
        '(display-buffer-same-window (inhibit-same-window . nil))))
  (display-buffer (get-buffer-create "*foo*")))
```

This last example shows that while the precedence order of action functions is fixed, as described in Section 29.13.1 [Choosing Window], page 724, an action alist entry specified by a display action ranked lower in that order can affect the execution of a higher ranked display action.

29.13.6 The Zen of Buffer Display

In its most simplistic form, a frame accommodates always one single window that can be used for displaying a buffer. As a consequence, it is always the latest call of `display-buffer` that will have succeeded in placing its buffer there.

Since working with such a frame is not very practical, Emacs by default allows for more complex frame layouts controlled by the default values of the frame size and the `split-height-threshold` and `split-width-threshold` options. Displaying a buffer not yet shown on a frame then either splits the single window on that frame or (re-)uses one of its two windows.

The default behavior is abandoned as soon as the user customizes one of these thresholds or manually changes the frame's layout. The default behavior is also abandoned when calling `display-buffer` with a non-`nil` `action` argument or the user customizes one of the options mentioned in the previous subsections. Mastering `display-buffer` soon may become a frustrating experience due to the plethora of applicable display actions and the resulting frame layouts.

However, refraining from using buffer display functions and falling back on a split & delete windows metaphor is not a good idea either. Buffer display functions give Lisp programs and users a framework to reconcile their different needs; no comparable framework exists for splitting and deleting windows. Buffer display functions also allow to at least partially restore the layout of a frame when removing a buffer from it later (see Section 29.16 [Quitting Windows], page 749).

Below we will give a number of guidelines to redeem the frustration mentioned above and thus to avoid literally losing buffers in-between the windows of a frame.

Write display actions without stress

Writing display actions can be a pain because one has to lump together action functions and action alists in one huge list. (Historical reasons prevented us from having `display-buffer` support separate arguments for these.) It might help to memorize some basic forms like the ones listed below:

```
'(nil (inhibit-same-window . t))
```

specifies an action alist entry only and no action function. Its sole purpose is to inhibit a `display-buffer-same-window` function specified elsewhere from showing the buffer in the same window, see also the last example of the preceding subsection.

```
'(display-buffer-below-selected)
```

on the other hand, specifies one action function and an empty action alist. To combine the effects of the above two specifications one would write the form

```
'(display-buffer-below-selected (inhibit-same-window . t))
```

to add another action function one would write

```
'((display-buffer-below-selected display-buffer-at-bottom)
  (inhibit-same-window . t))
```

and to add another alist entry one would write

```
'((display-buffer-below-selected display-buffer-at-bottom)
  (inhibit-same-window . t)
  (window-height . fit-window-to-buffer))
```

That last form can be used as *action* argument of `display-buffer` in the following way:

```
(display-buffer
  (get-buffer-create "*foo*")
  '((display-buffer-below-selected display-buffer-at-bottom)
    (inhibit-same-window . t)
    (window-height . fit-window-to-buffer)))
```

In a customization of `display-buffer-alist` it would be used as follows:

```
(setopt
  display-buffer-alist
  '(("＼＼*foo＼＼*"
      (display-buffer-below-selected display-buffer-at-bottom)
      (inhibit-same-window . t)
      (window-height . fit-window-to-buffer))))
```

To add a customization for a second buffer one would then write:

```
(setopt
  display-buffer-alist
  '(("＼＼*foo＼＼*"
      (display-buffer-below-selected display-buffer-at-bottom)
      (inhibit-same-window . t)
      (window-height . fit-window-to-buffer))
    ("＼＼*bar＼＼*"
      (display-buffer-reuse-window display-buffer-pop-up-frame)
      (reusable-frames . visible))))
```

Treat each other with respect

`display-buffer-alist` and `display-buffer-base-action` are user options—Lisp programs must never set or rebind them. `display-buffer-overriding-action`, on the other hand, is reserved for applications—who seldom use that option and if they use it, then with utmost care.

Older implementations of `display-buffer` frequently caused users and applications to fight over the settings of user options like `pop-up-frames` and `pop-up-windows` (see Section 29.13.4 [Choosing Window Options], page 736). This was one major reason for redesigning `display-buffer`—to provide a clear framework specifying what users and applications should be allowed to do.

Lisp programs must be prepared that user customizations may cause buffers to get displayed in an unexpected way. They should never assume in their subsequent behavior, that the buffer has been shown precisely the way they asked for in the *action* argument of `display-buffer`.

Users should not pose too many and too severe restrictions on how arbitrary buffers get displayed. Otherwise, they will risk to lose the characteristics of showing a buffer for a certain purpose. Suppose a Lisp program has been written to compare different versions of a buffer in two windows side-by-side. If the customization of `display-buffer-alist` prescribes that any such buffer should be always shown in or below the selected window, the program will have a hard time to set up the desired window configuration via `display-buffer`.

To specify a preference for showing an arbitrary buffer, users should customize `display-buffer-base-action`. An example of how users who prefer working with multiple frames would do that was given in the previous subsection. `display-buffer-alist` should be reserved for displaying specific buffers in a specific way.

Consider reusing a window that already shows the buffer

Generally, it's always a good idea for users and Lisp programmers to be prepared for the case that a window already shows the buffer in question and to reuse that window. In the preceding subsection we have shown that failing to do so properly may cause `display-buffer` to continuously pop up a new frame although a frame showing that buffer existed already. In a few cases only, it might be undesirable to reuse a window, for example, when a different portion of the buffer should be shown in that window.

Hence, `display-buffer-reuse-window` is one action function that should be used as often as possible, both in `action` arguments and customizations. An `inhibit-same-window` entry in the `action` argument usually takes care of the most common case where reusing a window showing the buffer should be avoided—that where the window in question is the selected one.

Attract focus to the window chosen

This is a no-brainer for people working with multiple frames—the frame showing the buffer will automatically raise and get focus unless an `inhibit-switch-frame` entry forbids it. For single frame users this task can be considerably more difficult. In particular, `display-buffer-pop-up-window` and `display-buffer-use-some-window` can become obtrusive in this regard. They split or use a seemingly arbitrary (often the largest or least recently used) window, distracting the user's attention.

Some Lisp programs therefore try to choose a window at the bottom of the frame, for example, in order to display the buffer in vicinity of the minibuffer window where the user is expected to answer a question related to the new window. For non-input related actions `display-buffer-below-selected` might be preferable because the selected window usually already has the user's attention.

Take care which window is selected

Many applications call `display-buffer` from within window excursions produced by `with-selected-window` or `select-window` calls with a `non-nil norecord` argument. This is almost always a bad idea because the window selected within such an excursion is usually not the window selected in the configuration presented to the user.

If, for example, a user had added an `inhibit-same-window` alist entry, that entry would have avoided the window selected within the scope of the excursion and not the window selected in the resulting configuration. Even if no such entry has been added, the resulting behavior might be strange. While in a frame containing one live window, evaluating the following form

```
(progn
  (split-window)
  (display-buffer "*Messages*"))
```

will display a window showing the `*Messages*` buffer at the bottom and leave the other window selected. Evaluating the next form

```
(with-selected-window (split-window)
  (display-buffer "*Messages*"))
```

will display `*Messages*` in a window on the top and select it which is usually not what `display-buffer` is supposed to do.

On the other hand, while evaluating the following form

```
(progn
  (split-window)
  (pop-to-buffer "*Messages*"))
```

will correctly select the `*Messages*` buffer, the next form

```
(progn
  (split-window)
  (with-selected-window (selected-window)
    (pop-to-buffer "*Messages*")))
```

will not.

Also, invocations of action functions like `display-buffer-use-some-window` and `display-buffer-use-least-recent-window` that expect the selected window to have the highest use time among all windows, may fail to produce a window according to their specifications.

Hence, an application that relies on using a window excursion should try to postpone the `display-buffer` call until after the excursion has terminated.

29.14 Window History

Each window remembers in a list the buffers it has previously displayed, and the order in which these buffers were removed from it. This history is used, for example, by `replace-buffer-in-windows` (see Section 29.11 [Buffers and Windows], page 720), and when quitting windows (see Section 29.16 [Quitting Windows], page 749). The list is automatically maintained by Emacs, but you can use the following functions to explicitly inspect or alter it:

window-prev-buffers &optional *window* [Function]

This function returns a list specifying the previous contents of *window*. The optional argument *window* should be a live window and defaults to the selected one.

Each list element has the form `(buffer window-start window-pos)`, where *buffer* is a buffer previously shown in the window, *window-start* is the window start position (see Section 29.20 [Window Start and End], page 759) when that buffer was last shown, and *window-pos* is the point position (see Section 29.19 [Window Point], page 758) when that buffer was last shown in *window*.

The list is ordered so that earlier elements correspond to more recently-shown buffers, and the first element usually corresponds to the buffer most recently removed from the window.

set-window-prev-buffers *window prev-buffers* [Function]

This function sets *window*'s previous buffers to the value of *prev-buffers*. The argument *window* must be a live window and defaults to the selected one. The argument *prev-buffers* should be a list of the same form as that returned by `window-prev-buffers`.

In addition, each window maintains a list of *next buffers*, which is a list of buffers re-shown by `switch-to-prev-buffer` (see below). This list is mainly used by `switch-to-prev-buffer` and `switch-to-next-buffer` for choosing buffers to switch to.

window-next-buffers &optional *window* [Function]

This function returns the list of buffers recently re-shown in *window* via `switch-to-prev-buffer`. The *window* argument must denote a live window or `nil` (meaning the selected window).

set-window-next-buffers *window next-buffers* [Function]

This function sets the next buffer list of *window* to *next-buffers*. The *window* argument should be a live window or `nil` (meaning the selected window). The argument *next-buffers* should be a list of buffers.

The following commands can be used to cycle through the global buffer list, much like `bury-buffer` and `unbury-buffer`. However, they cycle according to the specified window's history list, rather than the global buffer list. In addition, they restore window-specific window start and point positions, and may show a buffer even if it is already shown in another window. The `switch-to-prev-buffer` command, in particular, is used by `replace-buffer-in-windows`, `bury-buffer` and `quit-window` to find a replacement buffer for a window.

switch-to-prev-buffer &optional *window bury-or-kill* [Command]

This command displays the previous buffer in *window*. The argument *window* should be a live window or `nil` (meaning the selected window). If the optional argument *bury-or-kill* is non-`nil`, this means that the buffer currently shown in *window* is about to be buried or killed and consequently should not be switched to in future invocations of this command.

The previous buffer is usually the buffer shown before the buffer currently shown in *window*. However, a buffer that has been buried or killed, or has been already shown by a recent invocation of `switch-to-prev-buffer`, does not qualify as previous buffer.

If repeated invocations of this command have already shown all buffers previously shown in *window*, further invocations will show buffers from the buffer list of the frame *window* appears on (see Section 28.8 [Buffer List], page 681).

The option `switch-to-prev-buffer-skip` described below can be used to inhibit switching to certain buffers, for example, to those already shown in another window. Also, if *window*'s frame has a `buffer-predicate` parameter (see Section 30.4.3.5 [Buffer Parameters], page 812), that predicate may inhibit switching to certain buffers.

switch-to-next-buffer &optional *window* [Command]

This command switches to the next buffer in *window*, thus undoing the effect of the last `switch-to-prev-buffer` command in *window*. The argument *window* must be a live window and defaults to the selected one.

If there is no recent invocation of `switch-to-prev-buffer` that can be undone, this function tries to show a buffer from the buffer list of the frame `window` appears on (see Section 28.8 [Buffer List], page 681).

The option `switch-to-prev-buffer-skip` and the `buffer-predicate` (see Section 30.4.3.5 [Buffer Parameters], page 812) of `window`'s frame affect this command as they do for `switch-to-prev-buffer`.

By default `switch-to-prev-buffer` and `switch-to-next-buffer` can switch to a buffer that is already shown in another window. The following option can be used to override this behavior.

switch-to-prev-buffer-skip [User Option]

If this variable is `nil`, `switch-to-prev-buffer` may switch to any buffer, including those already shown in other windows.

If this variable is `non-nil`, `switch-to-prev-buffer` will refrain from switching to certain buffers. The following values can be used:

- `this` means do not switch to a buffer shown on the frame that hosts the window `switch-to-prev-buffer` is acting upon.
- `visible` means do not switch to a buffer shown on any visible frame.
- `0` (the number zero) means do not switch to a buffer shown on any visible or iconified frame.
- `t` means do not switch to a buffer shown on any live frame.
- A function that takes three arguments—the `window` argument of `switch-to-prev-buffer`, a buffer `switch-to-prev-buffer` intends to switch to and the `bury-or-kill` argument of `switch-to-prev-buffer`. If that function returns `non-nil`, `switch-to-prev-buffer` will refrain from switching to the buffer specified by the second argument.

The command `switch-to-next-buffer` obeys this option in a similar way. If this option specifies a function, `switch-to-next-buffer` will call that function with the third argument always `nil`.

Note that since `switch-to-prev-buffer` is called by `bury-buffer`, `replace-buffer-in-windows` and `quit-restore-window` as well, customizing this option may also affect the behavior of Emacs when a window is quit or a buffer gets buried or killed.

Note also that under certain circumstances `switch-to-prev-buffer` and `switch-to-next-buffer` may ignore this option, for example, when there is only one buffer left these functions can switch to.

switch-to-prev-buffer-skip-regexp [User Option]

This user option should be either a regular expression or a list of regular expressions. Buffers whose names match one of those regular expressions will be ignored by `switch-to-prev-buffer` and `switch-to-next-buffer` (except when there's no other buffer to switch to).

29.15 Dedicated Windows

Functions for displaying a buffer can be told to not use specific windows by marking these windows as *dedicated* to their buffers. `display-buffer` (see Section 29.13.1 [Choosing Window], page 724) never uses a dedicated window for displaying another buffer in it. `get-lru-window` and `get-largest-window` (see Section 29.10 [Cyclic Window Ordering], page 717) do not consider dedicated windows as candidates when their *dedicated* argument is `non-nil`. The behavior of `set-window-buffer` (see Section 29.11 [Buffers and Windows], page 720) with respect to dedicated windows is slightly different, see below.

Functions supposed to remove a buffer from a window or a window from a frame can behave specially when a window they operate on is dedicated. We will distinguish four basic cases, namely where (1) the window is not the only window on its frame, (2) the window is the only window on its frame but there are other frames on the same terminal left, (3) the window is the only window on the only frame on the same terminal, and (4) the dedication's value is `side` (see Section 29.17.1 [Displaying Buffers in Side Windows], page 752).

In particular, `delete-windows-on` (see Section 29.8 [Deleting Windows], page 711) handles case (2) by deleting the associated frame and cases (3) and (4) by showing another buffer in that frame's only window. The function `replace-buffer-in-windows` (see Section 29.11 [Buffers and Windows], page 720) which is called when a buffer gets killed, deletes the window in case (1) and behaves like `delete-windows-on` otherwise.

When `bury-buffer` (see Section 28.8 [Buffer List], page 681) operates on the selected window (which shows the buffer that shall be buried), it handles case (2) by calling `frame-auto-hide-function` (see Section 29.16 [Quitting Windows], page 749) to deal with the selected frame. The other two cases are handled as with `replace-buffer-in-windows`.

window-dedicated-p &optional window [Function]

This function returns `non-nil` if `window` is dedicated to its buffer and `nil` otherwise. More precisely, the return value is the value assigned by the last call of `set-window-dedicated-p` for `window`, or `nil` if that function was never called with `window` as its argument. The default for `window` is the selected window.

set-window-dedicated-p window flag [Function]

This function marks `window` as dedicated to its buffer if `flag` is `non-nil`, and non-dedicated otherwise.

As a special case, if `flag` is `t`, `window` becomes *strongly* dedicated to its buffer. `set-window-buffer` signals an error when the window it acts upon is strongly dedicated to its buffer and does not already display the buffer it is asked to display. Other functions do not treat `t` differently from any `non-nil` value.

You can also tell `display-buffer` to mark a window it creates as dedicated to its buffer by providing a suitable `dedicated` action alist entry (see Section 29.13.3 [Buffer Display Action Alists], page 730).

29.16 Quitting Windows

After a command uses `display-buffer` to put a buffer on the screen, the user may decide to hide it and return to the previous configuration of the Emacs display. We call that

quitting the window. The way to do this is to call `quit-window` while the window used by `display-buffer` is the selected window.

The right way to restore the previous configuration of the display depends on what was done to the window where the buffer now appears. It might be right to delete that window, or delete its frame, or just display another buffer in that window. One complication is that the user may have changed the window configuration since the act of displaying that buffer, and it would be undesirable to undo the user's explicitly requested changes.

To enable `quit-window` to do the right thing, `display-buffer` saves information about what it did in the window's `quit-restore` parameter (see Section 29.27 [Window Parameters], page 776).

`quit-window &optional kill window`

[Command]

This command quits *window* and buries its buffer. The argument *window* must be a live window and defaults to the selected one. With prefix argument *kill non-nil*, it kills the buffer instead of burying it.

The function `quit-window` first runs `quit-window-hook`. Then it calls the function `quit-restore-window`, described next, which does the hard work.

You can get more control by calling `quit-restore-window` instead.

`quit-restore-window &optional window bury-or-kill`

[Function]

This function handles *window* and its buffer after quitting. The optional argument *window* must be a live window and defaults to the selected one. The function takes account of the *window*'s `quit-restore` parameter.

The optional argument *bury-or-kill* specifies how to deal with *window*'s buffer. The following values are meaningful:

nil This means to not deal with the buffer in any particular way. As a consequence, if *window* is not deleted, invoking `switch-to-prev-buffer` will usually show the buffer again.

append This means that if *window* is not deleted, its buffer is moved to the end of *window*'s list of previous buffers (see Section 29.14 [Window History], page 746), so it's less likely that future invocations of `switch-to-prev-buffer` will switch to it. Also, it moves the buffer to the end of the frame's buffer list (see Section 28.8 [Buffer List], page 681).

bury This means that if *window* is not deleted, its buffer is removed from *window*'s list of previous buffers. Also, it moves the buffer to the end of the frame's buffer list. This is the most reliable way to prevent `switch-to-prev-buffer` from switching to this buffer again, short of killing the buffer.

kill This means to kill *window*'s buffer.

The argument *bury-or-kill* also specifies what to do with *window*'s frame when *window* should be deleted, if it is the only window on its frame, and there are other frames on that frame's terminal. If *bury-or-kill* equals **kill**, it means to delete the frame. Otherwise, the fate of the frame is determined by calling `frame-auto-hide-function` (see below) with that frame as sole argument.

This function always sets *window*'s `quit-restore` parameter to **nil** unless it deletes the window.

The window *window*'s `quit-restore` parameter (see Section 29.27 [Window Parameters], page 776) should be `nil` or a list of four elements:

(method obuffer owindow this-buffer)

The first element, *method*, is one of the four symbols `window`, `frame`, `same` and `other`. `frame` and `window` control how to delete *window*, while `same` and `other` control displaying some other buffer in it.

Specifically, `window` means that the window has been specially created by `display-buffer`; `frame` means that a separate frame has been created; `same`, that the window has only ever displayed this buffer; `other`, that the window showed another buffer before.

The second element, *obuffer*, is either one of the symbols `window` or `frame`, or a list of the form

(prev-buffer prev-window-start prev-window-point height)

which says which buffer was shown in *window* before, that buffer's window start (see Section 29.20 [Window Start and End], page 759) and window point (see Section 29.19 [Window Point], page 758) positions at that time, and *window*'s height at that time. If *prev-buffer* is still live when quitting *window*, quitting the window may reuse *window* to display *prev-buffer*.

The third element, *owindow*, is the window that was selected just before the displaying was done. If quitting deletes *window*, it tries to select *owindow*.

The fourth element, *this-buffer*, is the buffer whose displaying set the `quit-restore` parameter. Quitting *window* may delete that window only if it still shows that buffer.

Quitting *window* tries to delete it if and only if (1) *method* is either `window` or `frame`, (2) the window has no history of previously-displayed buffers and (3) *this-buffer* equals the buffer currently displayed in *window*. If *window* is part of an atomic window (see Section 29.18 [Atomic Windows], page 756), quitting will try to delete the root of that atomic window instead. In either case, it tries to avoid signaling an error when *window* cannot be deleted.

If *obuffer* is a list, and *prev-buffer* is still live, quitting displays *prev-buffer* in *window* according to the rest of the elements of *obuffer*. This includes resizing the window to *height* if it was temporarily resized to display *this-buffer*.

Otherwise, if *window* was previously used for displaying other buffers (see Section 29.14 [Window History], page 746), the most recent buffer in that history will be displayed.

The following option specifies a function to do the right thing with a frame containing one window when quitting that window.

`frame-auto-hide-function`

[User Option]

The function specified by this option is called to automatically hide frames. This function is called with one argument—a frame.

The function specified here is called by `bury-buffer` (see Section 28.8 [Buffer List], page 681) when the selected window is dedicated and shows the buffer to bury. It is also called by `quit-restore-window` (see above) when the frame of the window to quit has been specially created for displaying that window's buffer and the buffer is not killed.

The default is to call `iconify-frame` (see Section 30.11 [Visibility of Frames], page 828). Alternatively, you may specify either `delete-frame` (see Section 30.7 [Deleting Frames], page 822) to remove the frame from its display, `make-frame-invisible` to make the frame invisible, `ignore` to leave the frame unchanged, or any other function that can take a frame as its sole argument.

Note that the function specified by this option is called only if the specified frame contains just one live window and there is at least one other frame on the same terminal.

For a particular frame, the value specified here may be overridden by that frame's `auto-hide-function` frame parameter (see Section 30.4.3.6 [Frame Interaction Parameters], page 812).

29.17 Side Windows

Side windows are special windows positioned at any of the four sides of a frame's root window (see Section 29.2 [Windows and Frames], page 692). In practice, this means that the area of the frame's root window is subdivided into a main window and a number of side windows surrounding that main window. The main window is either a "normal" live window or specifies the area containing all the normal windows.

In their most simple form of use, side windows allow to display specific buffers always in the same area of a frame. Hence they can be regarded as a generalization of the concept provided by `display-buffer-at-bottom` (see Section 29.13.2 [Buffer Display Action Functions], page 726) to the remaining sides of a frame. With suitable customizations, however, side windows can be also used to provide frame layouts similar to those found in so-called integrated development environments (IDEs).

29.17.1 Displaying Buffers in Side Windows

The following action function for `display-buffer` (see Section 29.13.2 [Buffer Display Action Functions], page 726) creates or reuses a side window for displaying the specified buffer.

`display-buffer-in-side-window buffer alist` [Function]

This function displays *buffer* in a side window of the selected frame. It returns the window used for displaying *buffer*, `nil` if no such window can be found or created.

alist is an association list of symbols and values as for `display-buffer`. The following symbols in *alist* are special for this function:

side Denotes the side of the frame where the window shall be located. Valid values are `left`, `top`, `right` and `bottom`. If unspecified, the window is located at the bottom of the frame.

slot Denotes a slot at the specified side where to locate the window. A value of zero means to preferably position the window in the middle of the specified side. A negative value means to use a slot preceding (that is, above or on the left of) the middle slot. A positive value means to use a slot following (that is, below or on the right of) the middle slot. Hence, all windows on a specific side are ordered by their **slot** value. If unspecified, the window is located in the middle of the specified side.

dedicated

The dedicated flag (see Section 29.15 [Dedicated Windows], page 749) has a slightly different meaning for side windows. When a side window is created, that flag is set to the value `side` to prevent `display-buffer` to use the window in other action functions. Its value persists across invocations of `quit-window`, `kill-buffer`, `previous-buffer` and `next-buffer`.

In particular, these commands will refrain from showing, in a side window, buffers that have not been displayed in that window before. They will also refrain from having a normal, non-side window show a buffer that has been already displayed in a side window. A notable exception to the latter rule occurs when an application, after displaying a buffer, resets that buffer's local variables. To override these rules and always delete a side window with `quit-window` or `kill-buffer`, and eventually prevent the use of `previous-buffer` and `next-buffer`, set this value to `t` or specify a value via `display-buffer-mark-dedicated`.

If you specify the same slot on the same side for two or more different buffers, the buffer displayed last is shown in the corresponding window. Hence, slots can be used for sharing the same side window between buffers.

This function installs the `window-side` and `window-slot` parameters (see Section 29.27 [Window Parameters], page 776) and makes them persistent. It does not install any other window parameters unless they have been explicitly provided via a `window-parameters` entry in `alist`.

By default, side windows cannot be split via `split-window` (see Section 29.7 [Splitting Windows], page 708). Also, a side window is not reused or split by any buffer display action (see Section 29.13.2 [Buffer Display Action Functions], page 726) unless it is explicitly specified as target of that action. Note also that `delete-other-windows` cannot make a side window the only window on its frame (see Section 29.8 [Deleting Windows], page 711).

29.17.2 Side Window Options and Functions

The following options provide additional control over the placement of side windows.

window-sides-vertical

[User Option]

If non-`nil`, the side windows on the left and right of a frame occupy the frame's full height. Otherwise, the side windows on the top and bottom of the frame occupy the frame's full width.

window-sides-slots

[User Option]

This option specifies the maximum number of side windows on each side of a frame. The value is a list of four elements specifying the number of side window slots on (in this order) the left, top, right and bottom of each frame. If an element is a number, it means to display at most that many windows on the corresponding side. If an element is `nil`, it means there's no bound on the number of slots on that side.

If any of the specified values is zero, no window can be created on the corresponding side. `display-buffer-in-side-window` will not signal an error in that case, but will return `nil`. If a specified value just forbids the creation of an additional side window,

the most suitable window on that side is reused and may have its `window-slot` parameter changed accordingly.

window-sides-reversed

[User Option]

This option specifies whether top/bottom side windows should appear in reverse order. When this is `nil`, side windows on the top and bottom of a frame are always drawn from left to right with increasing slot values. When this is `t`, the drawing order is reversed and side windows on the top and bottom of a frame are drawn from right to left with increasing slot values.

When this is `bidi`, the drawing order is reversed if and only if the value of `bidi-paragraph-direction` (see Section 41.27 [Bidirectional Display], page 1250) is `right-to-left` in the buffer displayed in the window most recently selected within the main window area of this frame. Sometimes that window may be hard to find, so heuristics are used to avoid that the drawing order changes inadvertently when another window gets selected.

The layout of side windows on the left or right of a frame is not affected by the value of this variable.

When a frame has side windows, the following function returns the main window of that frame.

window-main-window &optional frame

[Function]

This function returns the main window of the specified `frame`. The optional argument `frame` must be a live frame and defaults to the selected one.

If `frame` has no side windows, it returns `frame`'s root window. Otherwise, it returns either an internal non-side window such that all other non-side windows on `frame` descend from it, or the single live non-side window of `frame`. Note that the main window of a frame cannot be deleted via `delete-window`.

The following command is handy to toggle the appearance of all side windows on a specified frame.

window-toggle-side-windows &optional frame

[Command]

This command toggles side windows on the specified `frame`. The optional argument `frame` must be a live frame and defaults to the selected one.

If `frame` has at least one side window, this command saves the state of `frame`'s root window in the `frame`'s `window-state` frame parameter and deletes all side windows on `frame` afterwards.

If `frame` has no side windows, but does have a `window-state` parameter, this command uses that parameter's value to restore the side windows on `frame` leaving `frame`'s main window alone.

An error is signaled if `frame` has no side windows and no saved state is found for it.

29.17.3 Frame Layouts with Side Windows

Side windows can be used to create more complex frame layouts like those provided by integrated development environments (IDEs). In such layouts, the area of the main window is where the normal editing activities take place. Side windows are not conceived for editing

in the usual sense. Rather, they are supposed to display information complementary to the current editing activity, like lists of files, tags or buffers, help information, search or grep results or shell output.

The layout of such a frame might appear as follows:

The following example illustrates how window parameters (see Section 29.27 [Window Parameters], page 776) can be used with `display-buffer-in-side-window` (see Section 29.17.1 [Displaying Buffers in Side Windows], page 752) to set up code for producing the frame layout sketched above.

```
(defvar parameters
  '(window-parameters . ((no-other-window . t)
                         (no-delete-other-windows . t)))))

(setq fit-window-to-buffer-horizontally t)
(setq window-resize-pixelwise t)

(setq
  display-buffer-alist
  `(("\\*Buffer List\\*"
      display-buffer-in-side-window
      (side . top) (slot . 0) (window-height . fit-window-to-buffer)
      (preserve-size . (nil . t)) ,parameters)
    ("\\*Tags List\\*"
      display-buffer-in-side-window
      (side . right) (slot . 0) (window-width . fit-window-to-buffer)
      (preserve-size . (t . nil)) ,parameters)
    ("\\*\\(?:help\\|grep\\|Completions\\)\\*"
      display-buffer-in-side-window
      (side . bottom) (slot . -1) (preserve-size . (nil . t))
      ,parameters)
    ("\\*\\(?:shell\\|compilation\\)\\*"
      display-buffer-in-side-window
      (side . bottom) (slot . 1) (preserve-size . (nil . t))
      ,parameters)))
```

This specifies `display-buffer-alist` entries (see Section 29.13.1 [Choosing Window], page 724) for buffers with fixed names. In particular, it asks for showing `*Buffer List*` with adjustable height at the top of the frame and `*Tags List*` with adjustable width on the frame's right. It also asks for having the `*help*`, `*grep*` and `*Completions*` buffers share a window on the bottom left side of the frame and the `*shell*` and `*compilation*` buffers appear in a window on the bottom right side of the frame.

Note that the option `fit-window-to-buffer-horizontally` must have a non-`nil` value in order to allow horizontal adjustment of windows. Entries are also added that ask for preserving the height of side windows at the top and bottom of the frame and the width of side windows at the left or right of the frame. To assure that side windows retain their respective sizes when maximizing the frame, the variable `window-resize-pixelwise` is set to a non-`nil` value. See Section 29.5 [Resizing Windows], page 703.

The last form also makes sure that none of the created side windows are accessible via `C-x o` by installing the `no-other-window` parameter for each of these windows. In addition, it makes sure that side windows are not deleted via `C-x 1` by installing the `no-delete-other-windows` parameter for each of these windows.

Since `dired` buffers have no fixed names, we use a special function `dired-default-directory-on-left` in order to display a lean directory buffer on the left side of the frame.

```
(defun dired-default-directory-on-left ()
  "Display `default-directory' in side window on left, hiding details."
  (interactive)
  (let ((buffer (dired-noselect default-directory)))
    (with-current-buffer buffer (dired-hide-details-mode t))
    (display-buffer-in-side-window
     buffer `((side . left) (slot . 0)
              (window-width . fit-window-to-buffer)
              (preserve-size . (t . nil)) ,parameters))))
```

Evaluating the preceding forms and typing, in any order, `M-x list-buffers`, `C-h f`, `M-x shell`, `M-x list-tags`, and `M-x dired-default-directory-on-left` should now reproduce the frame layout sketched above.

29.18 Atomic Windows

Atomic windows are rectangular compositions of at least two live windows. They have the following distinctive characteristics:

- The function `split-window` (see Section 29.7 [Splitting Windows], page 708), when applied to a constituent of an atomic window, will try to create the new window outside of the atomic window.
- The function `delete-window` (see Section 29.8 [Deleting Windows], page 711), when applied to a constituent of an atomic window, will try to delete the entire atomic window instead.
- The function `delete-other-windows` (see Section 29.8 [Deleting Windows], page 711), when applied to a constituent of an atomic window, will try to make the atomic window fill its frame or main window (see Section 29.17 [Side Windows], page 752).

This means that the basic groups of functions that alter the window structure treat an atomic window like a live one, thus preserving the internal structure of the atomic window.

Atomic windows are useful to construct and preserve window layouts that are meaningful only when all involved buffers are shown simultaneously in a specific manner, such as when showing differences between file revisions, or the same text in different languages or markups. They can also be used to permanently display information pertinent to a specific window in bars on that window's sides.

Atomic windows are implemented with the help of the reserved `window-atom` window parameter (see Section 29.27 [Window Parameters], page 776) and an internal window (see Section 29.1 [Basic Windows], page 690) called the root window of the atomic window. All windows that are part of the same atomic window have this root window as their common ancestor and are assigned a non-`nil` `window-atom` parameter.

The following function returns the root of the atomic window a specified window is part of:

window-atom-root &optional window

[Function]

This functions returns the root of the atomic window `window` is a part of. The specified `window` must be a valid window and defaults to the selected one. It returns `nil` if `window` is not part of an atomic window.

The most simple approach to make a new atomic window is to take an existing internal window and apply the following function:

window-make-atom window

[Function]

This function converts `window` into an atomic window. The specified `window` must be an internal window. All this function does is to set the `window-atom` parameter of each descendant of `window` to `t`.

To create a new atomic window from an existing live window or to add a new window to an existing atomic window, the following buffer display action function (see Section 29.13.2 [Buffer Display Action Functions], page 726) can be used:

display-buffer-in-atom-window buffer alist

[Function]

This function tries to display `buffer` in a new window that will be combined with an existing window to form an atomic window. If the existing window is already part of an atomic window, it adds the new window to that atomic window.

The specified `alist` is an association list of symbols and values. The following symbols have a special meaning:

window The value of such an element specifies an existing window the new window shall be combined with. If it specifies an internal window, all children of that window become part of the atomic window too. If no window is specified, the new window becomes a sibling of the selected window. The `window-atom` parameter of the existing window is set to `main` provided that window is live and its `window-atom` parameter was not already set.

side The value of such an element denotes the side of the existing window where the new window shall be located. Valid values are `below`, `right`, `above` and `left`. The default is `below`. The `window-atom` parameter of the new window is set to this value.

The return value is the new window, `nil` when creating that window failed.

Note that the value of the `window-atom` parameter does not really matter as long as it is non-`nil`. The values assigned by `display-buffer-in-atom-window` just allow for easy retrieval of the original and the new window after that function has been applied. Note also that the `window-atom` parameter is the only window parameter assigned by `display-buffer-in-atom-window`. Further parameters have to be set by the application explicitly via a `window-parameters` entry in `alist`.
