Atomic windows automatically cease to exist when one of their constituents gets deleted. To dissolve an atomic window manually, reset the `window-atom` parameter of its constituents—the root of the atomic window and all its descendants.

The following code snippet, when applied to a single-window frame, first splits the selected window and makes the selected and the new window constituents of an atomic window with their parent as root. It then displays the buffer `*Messages*` in a new window at the frame's bottom and makes that new window part of the atomic window just created.

```
(let ((window (split-window-right)))
  (window-make-atom (window-parent window))
  (display-buffer-in-atom-window
    (get-buffer-create "*Messages*")
    `((window . ,(window-parent window)) (window-height . 5))))
```

At this moment typing `C-x 2` in any window of that frame produces a new window at the bottom of the frame. Typing `C-x 3` instead will put the new window at the frame's right. In either case, typing now `C-x 1` in any window of the atomic window will remove the new window only. Typing `C-x 0` in any window of the atomic window will make that new window fill the frame.

29.19 Windows and Point

Each window has its own value of point (see Section 31.1 [Point], page 853), independent of the value of point in other windows displaying the same buffer. This makes it useful to have multiple windows showing one buffer.

- The window point is established when a window is first created; it is initialized from the buffer's point, or from the window point of another window opened on the buffer if such a window exists.
- Selecting a window sets the value of point in its buffer from the window's value of point. Conversely, deselecting a window sets the window's value of point from that of the buffer. Thus, when you switch between windows that display a given buffer, the point value for the selected window is in effect in the buffer, while the point values for the other windows are stored in those windows.
- As long as the selected window displays the current buffer, the window's point and the buffer's point always move together; they remain equal.

Emacs displays the cursor, by default as a rectangular block, in each window at the position of that window's point. When the user switches to another buffer in a window, Emacs moves that window's cursor to where point is in that buffer. If the exact position of point is hidden behind some display element, such as a display string or an image, Emacs displays the cursor immediately before or after that display element.

window-point &optional window

[Function]

This function returns the current position of point in *window*. For a nonselected window, this is the value point would have (in that window's buffer) if that window were selected. The default for *window* is the selected window.

When *window* is the selected window, the value returned is the value of point in that window's buffer. Strictly speaking, it would be more correct to return the top-level value of point, outside of any `save-excursion` forms. But that value is hard to find.

set-window-point *window position*

[Function]

This function positions point in *window* at position *position* in *window*'s buffer. It returns *position*.

If *window* is selected, this simply does `goto-char` in *window*'s buffer.

window-point-insertion-type

[Variable]

This variable specifies the marker insertion type (see Section 32.5 [Marker Insertion Types], page 872) of `window-point`. The default is `nil`, so `window-point` will stay behind text inserted there.

29.20 The Window Start and End Positions

Each window maintains a marker used to keep track of a buffer position that specifies where in the buffer display should start. This position is called the *display-start* position of the window (or just the *start*). The character after this position is the one that appears at the upper left corner of the window. It is usually, but not inevitably, at the beginning of a text line.

After switching windows or buffers, and in some other cases, if the window start is in the middle of a line, Emacs adjusts the window start to the start of a line. This prevents certain operations from leaving the window start at a meaningless point within a line. This feature may interfere with testing some Lisp code by executing it using the commands of Lisp mode, because they trigger this readjustment. To test such code, put it into a command and bind the command to a key.

window-start &optional window

[Function]

This function returns the display-start position of window *window*. If *window* is `nil`, the selected window is used.

When you create a window, or display a different buffer in it, the display-start position is set to a display-start position recently used for the same buffer, or to `point-min` if the buffer doesn't have any.

Redisplay updates the window-start position (if you have not specified it explicitly since the previous redisplay)—to make sure point appears on the screen. Nothing except redisplay automatically changes the window-start position; if you move point, do not expect the window-start position to change in response until after the next redisplay.

window-group-start &optional window

[Function]

This function is like `window-start`, except that when *window* is a part of a group of windows (see [Window Group], page 698), `window-group-start` returns the start

position of the entire group. This condition holds when the buffer local variable `window-group-start-function` is set to a function. In this case, `window-group-start` calls the function with the single argument `window`, then returns its result.

window-end &optional window update

[Function]

This function returns the position where display of its buffer ends in `window`. The default for `window` is the selected window.

Simply changing the buffer text or moving point does not update the value that `window-end` returns. The value is updated only when Emacs redisplay and redisplay completes without being preempted.

If the last redisplay of `window` was preempted, and did not finish, Emacs does not know the position of the end of display in that window. In that case, this function returns `nil`.

If `update` is non-`nil`, `window-end` always returns an up-to-date value for where display ends, based on the current `window-start` value. If a previously saved value of that position is still valid, `window-end` returns that value; otherwise it computes the correct value by scanning the buffer text.

Even if `update` is non-`nil`, `window-end` does not attempt to scroll the display if point has moved off the screen, the way real redisplay would do. It does not alter the `window-start` value. In effect, it reports where the displayed text will end if scrolling is not required. Note that the position it returns might be only partially visible.

window-group-end &optional window update

[Function]

This function is like `window-end`, except that when `window` is a part of a group of windows (see [Window Group], page 698), `window-group-end` returns the end position of the entire group. This condition holds when the buffer local variable `window-group-end-function` is set to a function. In this case, `window-group-end` calls the function with the two arguments `window` and `update`, then returns its result. The argument `update` has the same meaning as in `window-end`.

set-window-start window position &optional noforce

[Function]

This function sets the display-start position of `window` to `position` in `window`'s buffer. It returns `position`.

The display routines insist that the position of point be visible when a buffer is displayed. Normally, they select the display-start position according to their internal logic (and scroll the window if necessary) to make point visible. However, if you specify the start position with this function using `nil` for `noforce`, it means you want display to start at `position` even if that would put the location of point off the screen. If this does place point off screen, the display routines attempt to move point to the left margin on the middle line in the window.

For example, if point is 1 and you set the start of the window to 37, the start of the next line, point will be above the top of the window. The display routines will automatically move point if it is still 1 when redisplay occurs. Here is an example:

```
;; Here is what 'foo' looks like before executing
;; the set-window-start expression.
```

```

----- Buffer: foo -----
★This is the contents of buffer foo.
2
3
4
5
6
----- Buffer: foo -----  

(set-window-start
 (selected-window)
 (save-excursion
   (goto-char 1)
   (forward-line 1)
   (point)))
⇒ 37
  

;; Here is what ‘foo’ looks like after executing
;; the set-window-start expression.
----- Buffer: foo -----
2
3
★4
5
6
----- Buffer: foo -----
```

If the attempt to make point visible (i.e., in a fully-visible screen line) fails, the display routines will disregard the requested window-start position and compute a new one anyway. Thus, for reliable results Lisp programs that call this function should always move point to be inside the window whose display starts at *position*.

If *noforce* is non-*nil*, and *position* would place point off screen at the next redisplay, then redisplay computes a new window-start position that works well with point, and thus *position* is not used.

set-window-group-start *window position &optional noforce* [Function]
 This function is like **set-window-start**, except that when *window* is a part of a group of windows (see [Window Group], page 698), **set-window-group-start** sets the start position of the entire group. This condition holds when the buffer local variable **set-window-group-start-function** is set to a function. In this case, **set-window-group-start** calls the function with the three arguments *window*, *position*, and *noforce*, then returns its result. The arguments *position* and *noforce* in this function have the same meaning as in **set-window-start**.

pos-visible-in-window-p *&optional position window partially* [Function]
 This function returns non-*nil* if *position* is within the range of text currently visible on the screen in *window*. It returns *nil* if *position* is scrolled vertically out of view. Locations that are partially obscured are not considered visible unless *partially* is

`non-nil`. The argument *position* defaults to the current position of point in *window*; *window* defaults to the selected window. If *position* is `t`, that means to check either the first visible position of the last screen line in *window*, or the end-of-buffer position, whichever comes first.

This function considers only vertical scrolling. If *position* is out of view only because *window* has been scrolled horizontally, `pos-visible-in-window-p` returns `non-nil` anyway. See Section 29.23 [Horizontal Scrolling], page 767.

If *position* is visible, `pos-visible-in-window-p` returns `t` if *partially* is `nil`; if *partially* is `non-nil`, and the character following *position* is fully visible, it returns a list of the form `(x y)`, where *x* and *y* are the pixel coordinates relative to the top left corner of the window; otherwise it returns an extended list of the form `(x y rtop rbot rowh ypos)`, where *rtop* and *rbot* specify the number of off-window pixels at the top and bottom of the row at *position*, *rowh* specifies the visible height of that row, and *ypos* specifies the vertical position (zero-based row number) of that row.

Here is an example:

```
;; If point is off the screen now, recenter it now.
(or (pos-visible-in-window-p
    (point) (selected-window))
    (recenter 0))
```

pos-visible-in-window-group-p &optional *position window partially* [Function]

This function is like `pos-visible-in-window-p`, except that when *window* is a part of a group of windows (see [Window Group], page 698), `pos-visible-in-window-group-p` tests the visibility of *pos* in the entire group, not just in the single *window*. This condition holds when the buffer local variable `pos-visible-in-window-group-p-function` is set to a function. In this case `pos-visible-in-window-group-p` calls the function with the three arguments *position*, *window*, and *partially*, then returns its result. The arguments *position* and *partially* have the same meaning as in `pos-visible-in-window-p`.

window-line-height &optional *line window* [Function]

This function returns the height of text line *line* in *window*. If *line* is one of `header-line` or `mode-line`, `window-line-height` returns information about the corresponding line of the window. Otherwise, *line* is a text line number starting from 0. A negative number counts from the end of the window. The default for *line* is the current line in *window*; the default for *window* is the selected window.

If the display is not up to date, `window-line-height` returns `nil`. In that case, `pos-visible-in-window-p` may be used to obtain related information.

If there is no line corresponding to the specified *line*, `window-line-height` returns `nil`. Otherwise, it returns a list `(height ypos ypos offbot)`, where *height* is the height in pixels of the visible part of the line, *ypos* and *ypos* are the vertical position in lines and pixels of the line relative to the top of the first text line, and *offbot* is the number of off-window pixels at the bottom of the text line. If there are off-window pixels at the top of the (first) text line, *ypos* is negative.

29.21 Textual Scrolling

Textual scrolling means moving the text up or down through a window. It works by changing the window's display-start location. It may also change the value of `window-point` to keep point on the screen (see Section 29.19 [Window Point], page 758).

The basic textual scrolling functions are `scroll-up` (which scrolls forward) and `scroll-down` (which scrolls backward). In these function names, “up” and “down” refer to the direction of motion of the buffer text relative to the window. Imagine that the text is written on a long roll of paper and that the scrolling commands move the paper up and down. Thus, if you are looking at the middle of a buffer and repeatedly call `scroll-down`, you will eventually see the beginning of the buffer.

Unfortunately, this sometimes causes confusion, because some people tend to think in terms of the opposite convention: they imagine the window moving over text that remains in place, so that “down” commands take you to the end of the buffer. This convention is consistent with fact that such a command is bound to a key named `PageDown` on modern keyboards.

Textual scrolling functions (aside from `scroll-other-window`) have unpredictable results if the current buffer is not the one displayed in the selected window. See Section 28.2 [Current Buffer], page 671.

If the window contains a row taller than the height of the window (for example in the presence of a large image), the scroll functions will adjust the window's vertical scroll position to scroll the partially visible row. Lisp callers can disable this feature by binding the variable `auto-window-vscroll` to `nil` (see Section 29.22 [Vertical Scrolling], page 766).

`scroll-up` &optional count

[Command]

This function scrolls forward by `count` lines in the selected window.

If `count` is negative, it scrolls backward instead. If `count` is `nil` (or omitted), the distance scrolled is `next-screen-context-lines` lines less than the height of the window's body.

If the selected window cannot be scrolled any further, this function signals an error. Otherwise, it returns `nil`.

`scroll-down` &optional count

[Command]

This function scrolls backward by `count` lines in the selected window.

If `count` is negative, it scrolls forward instead. In other respects, it behaves the same way as `scroll-up` does.

`scroll-up-command` &optional count

[Command]

This behaves like `scroll-up`, except that if the selected window cannot be scrolled any further and the value of the variable `scroll-error-top-bottom` is `t`, it tries to move to the end of the buffer instead. If point is already there, it signals an error.

`scroll-down-command` &optional count

[Command]

This behaves like `scroll-down`, except that if the selected window cannot be scrolled any further and the value of the variable `scroll-error-top-bottom` is `t`, it tries to move to the beginning of the buffer instead. If point is already there, it signals an error.

scroll-other-window &optional count [Command]

This function scrolls the text in another window upward *count* lines. Negative values of *count*, or `nil`, are handled as in `scroll-up`.

You can specify which buffer to scroll by setting the variable `other-window-scroll-buffer` to a buffer. If that buffer isn't already displayed, `scroll-other-window` displays it in some window.

When the selected window is the minibuffer, the next window is normally the leftmost one immediately above it. You can specify a different window to scroll, when the minibuffer is selected, by setting the variable `minibuffer-scroll-window`. This variable has no effect when any other window is selected. When it is non-`nil` and the minibuffer is selected, it takes precedence over `other-window-scroll-buffer`. See [Definition of `minibuffer-scroll-window`], page 421.

scroll-other-window-down &optional count [Command]

This function scrolls the text in another window downward *count* lines. Negative values of *count*, or `nil`, are handled as in `scroll-down`. In other respects, it behaves the same way as `scroll-other-window` does.

other-window-scroll-buffer [Variable]

If this variable is non-`nil`, it tells `scroll-other-window` which buffer's window to scroll.

scroll-margin [User Option]

This option specifies the size of the scroll margin—a minimum number of lines between point and the top or bottom of a window. Whenever point gets within this many lines of the top or bottom of the window, redisplay scrolls the text automatically (if possible) to move point out of the margin, closer to the center of the window.

maximum-scroll-margin [User Option]

This variable limits the effective value of `scroll-margin` to a fraction of the current window line height. For example, if the current window has 20 lines and `maximum-scroll-margin` is 0.1, then the scroll margins will never be larger than 2 lines, no matter how big `scroll-margin` is.

`maximum-scroll-margin` itself has a maximum value of 0.5, which allows setting margins large to keep the cursor at the middle line of the window (or two middle lines if the window has an even number of lines). If it's set to a larger value (or any value other than a float between 0.0 and 0.5) then the default value of 0.25 will be used instead.

scroll-conservatively [User Option]

This variable controls how scrolling is done automatically when point moves off the screen (or into the scroll margin). If the value is a positive integer *n*, then redisplay scrolls the text up to *n* lines in either direction, if that will bring point back into proper view. This behavior is called *conservative scrolling*. Otherwise, scrolling happens in the usual way, under the control of other variables such as `scroll-up-aggressively` and `scroll-down-aggressively`.

The default value is zero, which means that conservative scrolling never happens.

scroll-down-aggressively [User Option]

The value of this variable should be either `nil` or a fraction f between 0 and 1. If it is a fraction, that specifies where on the screen to put point when scrolling down. More precisely, when a window scrolls down because point is above the window start, the new start position is chosen to put point f part of the window height from the top. The larger f , the more aggressive the scrolling.

A value of `nil` is equivalent to .5, since its effect is to center point. This variable automatically becomes buffer-local when set in any fashion.

scroll-up-aggressively [User Option]

Likewise, for scrolling up. The value, f , specifies how far point should be placed from the bottom of the window; thus, as with `scroll-down-aggressively`, a larger value scrolls more aggressively.

scroll-step [User Option]

This variable is an older variant of `scroll-conservatively`. The difference is that if its value is n , that permits scrolling only by precisely n lines, not a smaller number. This feature does not work with `scroll-margin`. The default value is zero.

scroll-preserve-screen-position [User Option]

If this option is `t`, whenever a scrolling command moves point off-window, Emacs tries to adjust point to keep the cursor at its old vertical position in the window, rather than the window edge.

If the value is `non-nil` and not `t`, Emacs adjusts point to keep the cursor at the same vertical position, even if the scrolling command didn't move point off-window.

This option affects all scroll commands that have a `non-nil scroll-command` symbol property.

next-screen-context-lines [User Option]

The value of this variable is the number of lines of continuity to retain when scrolling by full screens. For example, `scroll-up` with an argument of `nil` scrolls so that this many lines at the bottom of the window appear instead at the top. The default value is 2.

scroll-error-top-bottom [User Option]

If this option is `nil` (the default), `scroll-up-command` and `scroll-down-command` simply signal an error when no more scrolling is possible.

If the value is `t`, these commands instead move point to the beginning or end of the buffer (depending on scrolling direction); only if point is already on that position do they signal an error.

recenter &optional count redisplay [Command]

This function scrolls the text in the selected window so that point is displayed at a specified vertical position within the window. It does not move point with respect to the text.

If `count` is a non-negative number, that puts the line containing point `count` lines down from the top of the window. If `count` is a negative number, then it counts upward from the bottom of the window, so that `-1` stands for the last usable line in the window.

If *count* is `nil` (or a non-`nil` list), `recenter` puts the line containing point in the middle of the window. If *count* is `nil` and `redisplay` is non-`nil`, this function may redraw the frame, according to the value of `recenter-redisplay`. Thus, omitting the second argument can be used to countermand the effect of `recenter-redisplay` being non-`nil`. Interactive calls pass non-`nil` for `redisplay`.

When `recenter` is called interactively, *count* is the raw prefix argument. Thus, typing `C-u` as the prefix sets the *count* to a non-`nil` list, while typing `C-u 4` sets *count* to 4, which positions the current line four lines from the top.

With an argument of zero, `recenter` positions the current line at the top of the window. The command `recenter-top-bottom` offers a more convenient way to achieve this.

`recenter-window-group` &optional *count*

[Function]

This function is like `recenter`, except that when the selected window is part of a group of windows (see [Window Group], page 698), `recenter-window-group` scrolls the entire group. This condition holds when the buffer local variable `recenter-window-group-function` is set to a function. In this case, `recenter-window-group` calls the function with the argument *count*, then returns its result. The argument *count* has the same meaning as in `recenter`, but with respect to the entire window group.

`recenter-redisplay`

[User Option]

If this variable is non-`nil`, calling `recenter` with a `nil` *count* argument and non-`nil` `redisplay` argument redraws the frame. The default value is `tty`, which means only redraw the frame if it is a tty frame.

`recenter-top-bottom` &optional *count*

[Command]

This command, which is the default binding for `C-l`, acts like `recenter`, except if called with no argument. In that case, successive calls place point according to the cycling order defined by the variable `recenter-positions`.

`recenter-positions`

[User Option]

This variable controls how `recenter-top-bottom` behaves when called with no argument. The default value is `(middle top bottom)`, which means that successive calls of `recenter-top-bottom` with no argument cycle between placing point at the middle, top, and bottom of the window.

29.22 Vertical Fractional Scrolling

Vertical fractional scrolling means shifting text in a window up or down by a specified multiple or fraction of a line. Emacs uses it, for example, on images and screen lines which are taller than the window. Each window has a *vertical scroll position*, which is a number, never less than zero. It specifies how far to raise the contents of the window when displaying them. Raising the window contents generally makes all or part of some lines disappear off the top, and all or part of some other lines appear at the bottom. The usual value is zero.

The vertical scroll position is measured in units of the normal line height, which is the height of the default font. Thus, if the value is `.5`, that means the window contents will be scrolled up half the normal line height. If it is `3.3`, that means the window contents are scrolled up somewhat over three times the normal line height.

What fraction of a line the vertical scrolling covers, or how many lines, depends on what the lines contain. A value of .5 could scroll a line whose height is very short off the screen, while a value of 3.3 could scroll just part of the way through a tall line or an image.

window-vscroll &optional window pixels-p

[Function]

This function returns the current vertical scroll position of *window*. The default for *window* is the selected window. If *pixels-p* is non-*nil*, the return value is measured in pixels, rather than in units of the normal line height.

```
(window-vscroll)
⇒ 0
```

set-window-vscroll window lines &optional pixels-p

[Function]

preserve-vscroll-p

This function sets *window*'s vertical scroll position to *lines*. If *window* is *nil*, the selected window is used. The argument *lines* should be zero or positive; if not, it is taken as zero.

The actual vertical scroll position must always correspond to an integral number of pixels, so the value you specify is rounded accordingly.

The return value is the result of this rounding.

```
(set-window-vscroll (selected-window) 1.2)
⇒ 1.13
```

If *pixels-p* is non-*nil*, *lines* specifies a number of pixels. In this case, the return value is *lines*.

Normally, the vscroll does not take effect on windows that aren't the **minibuffer-scroll-window** or the selected window when the mini-window is resized (see Section 21.11 [Minibuffer Windows], page 418). This "frozen" behavior is disabled when the *preserve-vscroll-p* parameter is non-*nil*, which means to set the vscroll as usual.

auto-window-vscroll

[Variable]

If this variable is non-*nil*, the **line-move**, **scroll-up**, and **scroll-down** functions will automatically modify the vertical scroll position to scroll through display rows that are taller than the height of the window, for example in the presence of large images.

29.23 Horizontal Scrolling

Horizontal scrolling means shifting the image in the window left or right by a specified multiple of the normal character width. Each window has a *horizontal scroll position*, which is a number, never less than zero. It specifies how far to shift the contents left. Shifting the window contents left generally makes all or part of some characters disappear off the left, and all or part of some other characters appear at the right. The usual value is zero.

The horizontal scroll position is measured in units of the normal character width, which is the width of space in the default font. Thus, if the value is 5, that means the window contents are scrolled left by 5 times the normal character width. How many characters actually disappear off to the left depends on their width, and could vary from line to line.

Because we read from side to side in the inner loop, and from top to bottom in the outer loop, the effect of horizontal scrolling is not like that of textual or vertical scrolling. Textual scrolling involves selection of a portion of text to display, and vertical scrolling moves the window contents contiguously; but horizontal scrolling causes part of *each line* to go off screen.

Usually, no horizontal scrolling is in effect; then the leftmost column is at the left edge of the window. In this state, scrolling to the right is meaningless, since there is no data to the left of the edge to be revealed by it; so this is not allowed. Scrolling to the left is allowed; it scrolls the first columns of text off the edge of the window and can reveal additional columns on the right that were truncated before. Once a window has a nonzero amount of leftward horizontal scrolling, you can scroll it back to the right, but only so far as to reduce the net horizontal scroll to zero. There is no limit to how far left you can scroll, but eventually all the text will disappear off the left edge.

If `auto-hscroll-mode` is set, redisplay automatically alters the horizontal scrolling of a window as necessary to ensure that point is always visible. However, you can still set the horizontal scrolling value explicitly. The value you specify serves as a lower bound for automatic scrolling, i.e., automatic scrolling will not scroll a window to a column less than the specified one.

The default value of `auto-hscroll-mode` is `t`; setting it to `current-line` activates a variant of automatic horizontal scrolling whereby only the line showing the cursor is horizontally scrolled to make point visible, the rest of the window is left either unscrolled, or at the minimum scroll amount set by `scroll-left` and `scroll-right`, see below.

`scroll-left` &*optional count set-minimum*

[Command]

This function scrolls the selected window *count* columns to the left (or to the right if *count* is negative). The default for *count* is the window width, minus 2.

The return value is the total amount of leftward horizontal scrolling in effect after the change—just like the value returned by `window-hscroll` (below).

Note that text in paragraphs whose base direction is right-to-left (see Section 41.27 [Bidirectional Display], page 1250) moves in the opposite direction: e.g., it moves to the right when `scroll-left` is invoked with a positive value of *count*.

Once you scroll a window as far right as it can go, back to its normal position where the total leftward scrolling is zero, attempts to scroll any farther right have no effect.

If *set-minimum* is non-`nil`, the new scroll amount becomes the lower bound for automatic scrolling; that is, automatic scrolling will not scroll a window to a column less than the value returned by this function. Interactive calls pass `non-nil` for *set-minimum*.

`scroll-right` &*optional count set-minimum*

[Command]

This function scrolls the selected window *count* columns to the right (or to the left if *count* is negative). The default for *count* is the window width, minus 2. Aside from the direction of scrolling, this works just like `scroll-left`.

`window-hscroll` &*optional window*

[Function]

This function returns the total leftward horizontal scrolling of *window*—the number of columns by which the text in *window* is scrolled left past the left margin. (In right-

to-left paragraphs, the value is the total amount of the rightward scrolling instead.) The default for *window* is the selected window.

The return value is never negative. It is zero when no horizontal scrolling has been done in *window* (which is usually the case).

```
(window-hscroll)
⇒ 0
(scroll-left 5)
⇒ 5
(window-hscroll)
⇒ 5
```

set-window-hscroll *window columns*

[Function]

This function sets horizontal scrolling of *window*. The value of *columns* specifies the amount of scrolling, in terms of columns from the left margin (right margin in right-to-left paragraphs). The argument *columns* should be zero or positive; if not, it is taken as zero. Fractional values of *columns* are not supported at present.

Note that **set-window-hscroll** may appear not to work if you test it by evaluating a call with *M-:* in a simple way. What happens is that the function sets the horizontal scroll value and returns, but then redisplay adjusts the horizontal scrolling to make point visible, and this overrides what the function did. You can observe the function's effect if you call it while point is sufficiently far from the left margin that it will remain visible.

The value returned is *columns*.

```
(set-window-hscroll (selected-window) 10)
⇒ 10
```

Here is how you can determine whether a given position *position* is off the screen due to horizontal scrolling:

```
(defun hscroll-on-screen (window position)
  (save-excursion
    (goto-char position)
    (and
      (≥ (- (current-column) (window-hscroll window)) 0)
      (< (- (current-column) (window-hscroll window))
          (window-width window))))
```

29.24 Coordinates and Windows

This section describes functions that report positions of and within a window. Most of these functions report positions relative to an origin at the native position of the window's frame (see Section 30.3 [Frame Geometry], page 791). Some functions report positions relative to the origin of the display of the window's frame. In any case, the origin has the coordinates (0, 0) and X and Y coordinates increase rightward and downward respectively.

For the following functions, X and Y coordinates are reported in integer character units, i.e., numbers of lines and columns respectively. On a graphical display, each “line” and “column” corresponds to the height and width of the default character specified by the frame's default font (see Section 30.3.2 [Frame Font], page 797).

window-edges &optional window body absolute pixelwise [Function]

This function returns a list of the edge coordinates of *window*. If *window* is omitted or **nil**, it defaults to the selected window.

The return value has the form (*left top right bottom*). These list elements are, respectively, the X coordinate of the leftmost column occupied by the window, the Y coordinate of the topmost row, the X coordinate one column to the right of the rightmost column, and the Y coordinate one row down from the bottommost row.

Note that these are the actual outer edges of the window, including any of its decorations. On a text terminal, if the window has a neighbor on its right, its right edge includes the separator line between the window and its neighbor.

If the optional argument *body* is **nil**, this means to return the edges corresponding to the total size of *window*. *body non-nil* means to return the edges of *window*'s body. If *body* is non-**nil**, *window* must specify a live window.

If the optional argument *absolute* is **nil**, this means to return edges relative to the native position of *window*'s frame. *absolute non-nil* means to return coordinates relative to the origin (0, 0) of *window*'s display. On non-graphical systems this argument has no effect.

If the optional argument *pixelwise* is **nil**, this means to return the coordinates in terms of the default character width and height of *window*'s frame (see Section 30.3.2 [Frame Font], page 797), rounded if necessary. *pixelwise non-nil* means to return the coordinates in pixels. Note that the pixel specified by *right* and *bottom* is immediately outside of these edges. If *absolute* is non-**nil**, *pixelwise* is implicitly non-**nil** too.

window-body-edges &optional window [Function]

This function returns the edges of *window*'s body (see Section 29.4 [Window Sizes], page 699). Calling (*window-body-edges window*) is equivalent to calling (*window-edges window t*), see above.

The following functions can be used to relate a set of frame-relative coordinates to a window:

window-at x y &optional frame [Function]

This function returns the live window at the coordinates *x* and *y* given in default character sizes (see Section 30.3.2 [Frame Font], page 797) relative to the native position of *frame* (see Section 30.3 [Frame Geometry], page 791).

If there is no window at that position, the return value is **nil**. If *frame* is omitted or **nil**, it defaults to the selected frame.

coordinates-in-window-p coordinates window [Function]

This function checks whether a window *window* occupies the frame relative coordinates *coordinates*, and if so, which part of the window that is. *window* should be a live window.

coordinates should be a cons cell of the form (*x . y*), where *x* and *y* are given in default character sizes (see Section 30.3.2 [Frame Font], page 797) relative to the native position of *window*'s frame (see Section 30.3 [Frame Geometry], page 791).

If there is no window at the specified position, the return value is `nil`. Otherwise, the return value is one of the following:

(*relx . rely*)

The coordinates are inside *window*. The numbers *relx* and *rely* are the equivalent window-relative coordinates for the specified position, counting from 0 at the top left corner of the window.

mode-line

The coordinates are in the mode line of *window*.

header-line

The coordinates are in the header line of *window*.

tab-line The coordinates are in the tab line of *window*.

right-divider

The coordinates are in the divider separating *window* from a window on the right.

bottom-divider

The coordinates are in the divider separating *window* from a window beneath.

vertical-line

The coordinates are in the vertical line between *window* and its neighbor to the right. This value occurs only if the window doesn't have a scroll bar; positions in a scroll bar are considered outside the window for these purposes.

left-fringe

right-fringe

The coordinates are in the left or right fringe of the window.

left-margin

right-margin

The coordinates are in the left or right margin of the window.

nil The coordinates are not in any part of *window*.

The function `coordinates-in-window-p` does not require a frame as argument because it always uses the frame that *window* is on.

The following functions return window positions in pixels, rather than character units. Though mostly useful on graphical displays, they can also be called on text terminals, where the screen area of each text character is taken to be one pixel.

window-pixel-edges &optional *window*

[Function]

This function returns a list of pixel coordinates for the edges of *window*. Calling `(window-pixel-edges window)` is equivalent to calling `(window-edges window nil nil t)`, see above.

window-body-pixel-edges &optional *window*

[Function]

This function returns the pixel edges of *window*'s body. Calling `(window-body-pixel-edges window)` is equivalent to calling `(window-edges window t nil t)`, see above.

The following functions return window positions in pixels, relative to the origin of the display screen rather than that of the frame:

window-absolute-pixel-edges &optional window [Function]

This function returns the pixel coordinates of *window* relative to an origin at (0, 0) of the display of *window*'s frame. Calling (`window-absolute-pixel-edges`) is equivalent to calling (`window-edges window nil t t`), see above.

window-absolute-body-pixel-edges &optional window [Function]

This function returns the pixel coordinates of *window*'s body relative to an origin at (0, 0) of the display of *window*'s frame. Calling (`window-absolute-body-pixel-edges window`) is equivalent to calling (`window-edges window t t t`), see above.

Combined with `set-mouse-absolute-pixel-position`, this function can be used to move the mouse pointer to an arbitrary buffer position visible in some window:

```
(let ((edges (window-absolute-body-pixel-edges))
      (position (pos-visible-in-window-p nil nil t)))
  (set-mouse-absolute-pixel-position
    (+ (nth 0 edges) (nth 0 position))
    (+ (nth 1 edges) (nth 1 position))))
```

On a graphical terminal this form “warps” the mouse cursor to the upper left corner of the glyph at the selected window's point. A position calculated this way can be also used to show a tooltip window there.

The following function returns the screen coordinates of a buffer position visible in a window:

window-absolute-pixel-position &optional position window [Function]

If the buffer position *position* is visible in window *window*, this function returns the display coordinates of the upper/left corner of the glyph at *position*. The return value is a cons of the X- and Y-coordinates of that corner, relative to an origin at (0, 0) of *window*'s display. It returns `nil` if *position* is not visible in *window*.

window must be a live window and defaults to the selected window. *position* defaults to the value of `window-point` of *window*.

This means that in order to move the mouse pointer to the position of point in the selected window, it's sufficient to write:

```
(let ((position (window-absolute-pixel-position)))
  (set-mouse-absolute-pixel-position
    (car position) (cdr position)))
```

The following function returns the largest rectangle that can be inscribed in a window without covering text displayed in that window.

window-largest-empty-rectangle &optional window count [Function]
min-width min-height positions left

This function calculates the dimensions of the largest empty rectangle that can be inscribed in the specified *window*'s text area. *window* must be a live window and defaults to the selected one.

The return value is a triple of the width and the start and end y-coordinates of the largest rectangle that can be inscribed into the empty space (space not displaying any text) of the text area of *window*. No x-coordinates are returned by this function—any such rectangle is assumed to end at the right edge of *window*'s text area. If no empty space can be found, the return value is `nil`.

The optional argument *count*, if non-`nil`, specifies a maximum number of rectangles to return. This means that the return value is a list of triples specifying rectangles with the largest rectangle first. *count* can be also a cons cell whose car specifies the number of rectangles to return and whose CDR, if non-`nil`, states that all rectangles returned must be disjoint.

The optional arguments *min-width* and *min-height*, if non-`nil`, specify the minimum width and height of any rectangle returned.

The optional argument *positions*, if non-`nil`, is a cons cell whose CAR specifies the uppermost and whose CDR specifies the lowermost pixel position that must be covered by any rectangle returned. These positions measure from the start of the text area of *window*.

The optional argument *left*, if non-`nil`, means to return values suitable for buffers displaying right to left text. In that case, any rectangle returned is assumed to start at the left edge of *window*'s text area.

Note that this function has to retrieve the dimensions of each line of *window*'s glyph matrix via `window-lines-pixel-dimensions` (see Section 41.10 [Size of Displayed Text], page 1157). Hence, this function may also return `nil` when the current glyph matrix of *window* is not up-to-date.

29.25 Mouse Window Auto-selection

The following option allows to automatically select the window under the mouse pointer. This accomplishes a policy similar to that of window managers that give focus to a frame (and thus trigger its subsequent selection) whenever the mouse pointer enters its window-system window (see Section 30.10 [Input Focus], page 824).

`mouse-autoselect-window`

[User Option]

If this variable is non-`nil`, Emacs will try to automatically select the window under the mouse pointer. The following values are meaningful:

A positive number

This specifies a delay in seconds after which auto-selection triggers. The window under the mouse pointer is selected after the mouse has remained in it for the entire duration of the delay.

A negative number

A negative number has a similar effect as a positive number, but selects the window under the mouse pointer only after the mouse pointer has remained in it for the entire duration of the absolute value of that number and in addition has stopped moving.

Other value

Any other non-`nil` value means to select a window instantaneously as soon as the mouse pointer enters it.

In either case, the mouse pointer must enter the text area of a window in order to trigger its selection. Dragging the scroll bar slider or the mode line of a window conceptually should not cause its auto-selection.

Mouse auto-selection selects the minibuffer window only if it is active, and never deselects the active minibuffer window.

Mouse auto-selection can be used to emulate a focus follows mouse policy for child frames (see Section 30.14 [Child Frames], page 831) which usually are not tracked by the window manager. This requires to set the value of `focus-follows-mouse` (see Section 30.10 [Input Focus], page 824) to a non-`nil` value. If the value of `focus-follows-mouse` is `auto-raise`, entering a child frame with the mouse will raise it automatically above all other child frames of that frame's parent frame.

29.26 Window Configurations

A *window configuration* records the entire layout of one frame—all windows, their sizes, their decorations, which buffers they contain, how those buffers are scrolled, and their value of point. It also includes the value of `minibuffer-scroll-window`. As a special exception, the window configuration does not record the value of point in the selected window for the current buffer.

You can bring back an entire frame layout by restoring a previously saved window configuration. If you want to record the layout of all frames instead of just one, use a frame configuration instead of a window configuration. See Section 30.13 [Frame Configurations], page 831.

current-window-configuration &optional *frame* [Function]

This function returns a new object representing *frame*'s current window configuration. The default for *frame* is the selected frame. The variable `window-persistent-parameters` specifies which window parameters (if any) are saved by this function. See Section 29.27 [Window Parameters], page 776.

set-window-configuration *configuration* &optional *dont-set-frame* [Function]
dont-set-miniwindow

This function restores the configuration of windows and buffers as specified by *configuration*, for the frame that *configuration* was created for, regardless of whether that frame is selected or not. The argument *configuration* must be a value that was previously returned by `current-window-configuration` for that frame. Normally the function also selects the frame which is recorded in the configuration, but if *dont-set-frame* is non-`nil`, it leaves selected the frame which was already selected at the start of the function.

Normally the function restores the saved minibuffer (if any), but if *dont-set-miniwindow* is non-`nil`, the minibuffer current at the start of the function (if any) remains in the mini-window.

If the frame from which *configuration* was saved is dead, all this function does is to restore the value of the variable `minibuffer-scroll-window` and to adjust the value returned by `minibuffer-selected-window`. In this case, the function returns `nil`. Otherwise, it returns `t`.

If the buffer of a window of *configuration* has been killed since *configuration* was made, that window is, as a rule, removed from the restored configuration. However, if that window is the last window remaining in the restored configuration, another live buffer is shown in it.

Here is a way of using this function to get the same effect as `save-window-excursion`:

```
(let ((config (current-window-configuration)))
  (unwind-protect
    (progn (split-window-below nil)
           ...)
    (set-window-configuration config)))
```

`save-window-excursion forms...` [Macro]

This macro records the window configuration of the selected frame, executes *forms* in sequence, then restores the earlier window configuration. The return value is the value of the final form in *forms*.

Most Lisp code should not use this macro; `save-selected-window` is typically sufficient. In particular, this macro cannot reliably prevent the code in *forms* from opening new windows, because new windows might be opened in other frames (see Section 29.13.1 [Choosing Window], page 724), and `save-window-excursion` only saves and restores the window configuration on the current frame.

`window-configuration-p object` [Function]

This function returns `t` if *object* is a window configuration.

`window-configuration-equal-p config1 config2` [Function]

This function says whether two window configurations have the same window layout, but ignores the values of point and the saved scrolling positions—it can return `t` even if those aspects differ.

`window-configuration-frame config` [Function]

This function returns the frame for which the window configuration *config* was made.

Other primitives to look inside of window configurations would make sense, but are not implemented because we did not need them. See the file `winner.el` for some more operations on windows configurations.

The objects returned by `current-window-configuration` die together with the Emacs process. In order to store a window configuration on disk and read it back in another Emacs session, you can use the functions described next. These functions are also useful to clone the state of a frame into an arbitrary live window (`set-window-configuration` effectively clones the windows of a frame into the root window of that very frame only).

`window-state-get &optional window writable` [Function]

This function returns the state of *window* as a Lisp object. The argument *window* must be a valid window and defaults to the root window of the selected frame.

If the optional argument *writable* is non-`nil`, this means to not use markers for sampling positions like `window-point` or `window-start`. This argument should be `non-nil` when the state will be written to disk and read back in another session.

Together, the argument `writable` and the variable `window-persistent-parameters` specify which window parameters are saved by this function. See Section 29.27 [Window Parameters], page 776.

The value returned by `window-state-get` can be used in the same session to make a clone of a window in another window. It can be also written to disk and read back in another session. In either case, use the following function to restore the state of the window.

window-state-put state &optional window ignore [Function]

This function puts the window state `state` into `window`. The argument `state` should be the state of a window returned by an earlier invocation of `window-state-get`, see above. The optional argument `window` can be either a live window or an internal window (see Section 29.2 [Windows and Frames], page 692). If `window` is not a live window, it is replaced by a new live window created on the same frame before putting `state` into it. If `window` is `nil`, it puts the window state into a new window.

If the optional argument `ignore` is `non-nil`, it means to ignore minimum window sizes and fixed-size restrictions. If `ignore` is `safe`, this means windows can get as small as one line and/or two columns.

The functions `window-state-get` and `window-state-put` also allow to exchange the contents of two live windows. The following function does precisely that:

window-swap-states &optional window-1 window-2 size [Command]

This command swaps the states of the two live windows `window-1` and `window-2`. `window-1` must specify a live window and defaults to the selected one. `window-2` must specify a live window and defaults to the window following `window-1` in the cyclic ordering of windows, excluding minibuffer windows and including live windows on all visible frames.

Optional argument `size non-nil` means to try swapping the sizes of `window-1` and `window-2` as well. A value of `height` means to swap heights only, a value of `width` means to swap widths only, while `t` means to swap both widths and heights, if possible. Frames are not resized by this function.

29.27 Window Parameters

This section describes the window parameters that can be used to associate additional information with windows.

window-parameter window parameter [Function]

This function returns `window`'s value for `parameter`. The default for `window` is the selected window. If `window` has no setting for `parameter`, this function returns `nil`.

window-parameters &optional window [Function]

This function returns all parameters of `window` and their values. The default for `window` is the selected window. The return value is either `nil`, or an association list whose elements have the form `(parameter . value)`.

set-window-parameter window parameter value [Function]

This function sets `window`'s value of `parameter` to `value` and returns `value`. The default for `window` is the selected window.

By default, the functions that save and restore window configurations or the states of windows (see Section 29.26 [Window Configurations], page 774) do not care about window parameters. This means that when you change the value of a parameter within the body of a `save-window-excursion`, the previous value is not restored when that macro exits. It also means that when you restore via `window-state-put` a window state saved earlier by `window-state-get`, all cloned windows have their parameters reset to `nil`. The following variable allows you to override the standard behavior:

window-persistent-parameters

[Variable]

This variable is an alist specifying which parameters get saved by `current-window-configuration` and `window-state-get`, and subsequently restored by `set-window-configuration` and `window-state-put`. See Section 29.26 [Window Configurations], page 774.

The CAR of each entry of this alist is a symbol specifying the parameter. The CDR should be one of the following:

nil

This value means the parameter is saved neither by `window-state-get` nor by `current-window-configuration`.

t

This value specifies that the parameter is saved by `current-window-configuration` and (provided its `writable` argument is `nil`) by `window-state-get`.

writable

This means that the parameter is saved unconditionally by both `current-window-configuration` and `window-state-get`. This value should not be used for parameters whose values do not have a read syntax. Otherwise, invoking `window-state-put` in another session may fail with an `invalid-read-syntax` error.

Some functions (notably `delete-window`, `delete-other-windows` and `split-window`), may behave specially when the window specified by their `window` argument has a parameter whose name is equal to the function's name. You can override such special behavior by binding the following variable to a non-`nil` value:

ignore-window-parameters

[Variable]

If this variable is non-`nil`, some standard functions do not process window parameters. The functions currently affected by this are `split-window`, `delete-window`, `delete-other-windows`, and `other-window`.

An application can bind this variable to a non-`nil` value around calls to these functions. If it does so, the application is fully responsible for correctly assigning the parameters of all involved windows when exiting that function.

The following parameters are currently used by the window management code:

delete-window

This parameter affects the execution of `delete-window` (see Section 29.8 [Deleting Windows], page 711).

delete-other-windows

This parameter affects the execution of `delete-other-windows` (see Section 29.8 [Deleting Windows], page 711).

no-delete-other-windows

This parameter marks the window as not deletable by `delete-other-windows` (see Section 29.8 [Deleting Windows], page 711).

split-window

This parameter affects the execution of `split-window` (see Section 29.7 [Splitting Windows], page 708).

other-window

This parameter affects the execution of `other-window` (see Section 29.10 [Cyclic Window Ordering], page 717).

no-other-window

This parameter marks the window as not selectable by `other-window` (see Section 29.10 [Cyclic Window Ordering], page 717).

clone-of This parameter specifies the window that this one has been cloned from. It is installed by `window-state-get` (see Section 29.26 [Window Configurations], page 774).

window-preserved-size

This parameter specifies a buffer, a direction where `nil` means vertical and `t` horizontal, and a size in pixels. If this window displays the specified buffer and its size in the indicated direction equals the size specified by this parameter, then Emacs will try to preserve the size of this window in the indicated direction. This parameter is installed and updated by the function `window-preserve-size` (see Section 29.6 [Preserving Window Sizes], page 707).

quit-restore

This parameter is installed by the buffer display functions (see Section 29.13.1 [Choosing Window], page 724) and consulted by `quit-restore-window` (see Section 29.16 [Quitting Windows], page 749). It is a list of four elements, see the description of `quit-restore-window` in Section 29.16 [Quitting Windows], page 749, for details.

window-side**window-slot**

These parameters are used internally for implementing side windows (see Section 29.17 [Side Windows], page 752).

window-atom

This parameter is used internally for implementing atomic windows, see Section 29.18 [Atomic Windows], page 756.

mode-line-format

This parameter replaces the value of the buffer-local variable `mode-line-format` (see Section 24.4.1 [Mode Line Basics], page 550) of this window's buffer whenever this window is displayed. The symbol `none` means to suppress display of a mode line for this window. Display and contents of the mode line on other windows showing this buffer are not affected.

header-line-format

This parameter replaces the value of the buffer-local variable `header-line-format` (see Section 24.4.1 [Mode Line Basics], page 550) of this window's buffer whenever this window is displayed. The symbol `none` means to suppress display of a header line for this window. Display and contents of the header line on other windows showing this buffer are not affected.

tab-line-format

This parameter replaces the value of the buffer-local variable `tab-line-format` (see Section 24.4.1 [Mode Line Basics], page 550) of this window's buffer whenever this window is displayed. The symbol `none` means to suppress display of a tab line for this window. Display and contents of the tab line on other windows showing this buffer are not affected.

min-margins

The value of this parameter is a cons cell whose CAR and CDR, if non-`nil`, specify the minimum values (in columns) for the left and right margin of this window (see Section 41.16.5 [Display Margins], page 1205). When present, Emacs will use these values instead of the actual margin widths for determining whether a window can be split or shrunk horizontally.

Emacs never auto-adjusts the margins of any window after splitting or resizing it. It is the sole responsibility of any application setting this parameter to adjust the margins of this window as well as those of any new window that inherits this window's margins due to a split. Both `window-configuration-change-hook` and `window-size-change-functions` (see Section 29.28 [Window Hooks], page 779) should be employed for this purpose.

This parameter was introduced in Emacs version 25.1 to support applications that use large margins to center buffer text within a window and should be used, with due care, exclusively by those applications. It might be replaced by an improved solution in future versions of Emacs.

29.28 Hooks for Window Scrolling and Changes

This section describes how Lisp programs can take action after a window has been scrolled or other window modifications occurred. We first consider the case where a window shows a different part of its buffer.

window-scroll-functions

[Variable]

This variable holds a list of functions that Emacs should call before redisplaying a window with scrolling. Displaying a different buffer in a window and making a new window also call these functions.

This variable is not a normal hook, because each function is called with two arguments: the window, and its new display-start position. At the time of the call, the display-start position of the argument window is already set to its new value, and the buffer to be displayed in the window is set as the current buffer.

These functions must take care when using `window-end` (see Section 29.20 [Window Start and End], page 759); if you need an up-to-date value, you must use the `update` argument to ensure you get it.

Warning: don't use this feature to alter the way the window is scrolled. It's not designed for that, and such use probably won't work.

In addition, you can use `jit-lock-register` to register a Font Lock fontification function, which will be called whenever parts of a buffer are (re)fontified because a window was scrolled or its size changed. See Section 24.6.4 [Other Font Lock Variables], page 571.

The remainder of this section covers six hooks that are called during redisplay provided a significant, non-scrolling change of a window has been detected. For simplicity, these hooks and the functions they call will be collectively referred to as *window change functions*. As any hook, these hooks can be set either globally or buffer-locally via the *local* argument of `add-hook` (see Section 24.1.2 [Setting Hooks], page 525) when the hook is installed.

The first of these hooks is run after a *window buffer change* is detected, which means that a window was created, deleted or assigned another buffer.

`window-buffer-change-functions`

[Variable]

This variable specifies functions called during redisplay when window buffers have changed. The value should be a list of functions that take one argument.

Functions specified buffer-locally are called for any window showing the corresponding buffer if that window has been created or assigned that buffer since the last time window change functions were run. In this case the window is passed as argument.

Functions specified by the default value are called for a frame if at least one window on that frame has been added, deleted or assigned another buffer since the last time window change functions were run. In this case the frame is passed as argument.

The second of these hooks is run when a *window size change* has been detected which means that a window was created, assigned another buffer, or changed its total size or that of its text area.

`window-size-change-functions`

[Variable]

This variable specifies functions called during redisplay when a window size change occurred. The value should be a list of functions that take one argument.

Functions specified buffer-locally are called for any window showing the corresponding buffer if that window has been added or assigned another buffer or changed its total or body size since the last time window change functions were run. In this case the window is passed as argument.

Functions specified by the default value are called for a frame if at least one window on that frame has been added or assigned another buffer or changed its total or body size since the last time window change functions were run. In this case the frame is passed as argument.

The third of these hooks is run when a *window selection change* has selected another window since the last redisplay.

`window-selection-change-functions`

[Variable]

This variable specifies functions called during redisplay when the selected window or a frame's selected window has changed. The value should be a list of functions that take one argument.

Functions specified buffer-locally are called for any window showing the corresponding buffer if that window has been selected or deselected (among all windows or among all windows on its frame) since the last time window change functions were run. In this case the window is passed as argument.

Functions specified by the default value are called for a frame if that frame has been selected or deselected or the frame's selected window has changed since the last time window change functions were run. In this case the frame is passed as argument.

The fourth of these hooks is run when a *window state change* has been detected, which means that at least one of the three preceding window changes has occurred.

window-state-change-functions

[Variable]

This variable specifies functions called during redisplay when a window buffer or size change occurred or the selected window or a frame's selected window has changed. The value should be a list of functions that take one argument.

Functions specified buffer-locally are called for any window showing the corresponding buffer if that window has been added or assigned another buffer, changed its total or body size or has been selected or deselected (among all windows or among all windows on its frame) since the last time window change functions were run. In this case the window is passed as argument.

Functions specified by the default value are called for a frame if at least one window on that frame has been added, deleted or assigned another buffer, changed its total or body size or that frame has been selected or deselected or the frame's selected window has changed since the last time window change functions were run. In this case the frame is passed as argument.

Functions specified by the default value are also run for a frame when that frame's window state change flag (see below) has been set since last redisplay.

The fifth of these hooks is run when a *window configuration change* has been detected which means that either the buffer or the size of a window changed. It differs from the four preceding hooks in the way it is run.

window-configuration-change-hook

[Variable]

This variable specifies functions called during redisplay when either the buffer or the size of a window has changed. The value should be a list of functions that take no argument.

Functions specified buffer-locally are called for any window showing the corresponding buffer if at least one window on that frame has been added, deleted or assigned another buffer or changed its total or body size since the last time window change functions were run. Each call is performed with the window showing the buffer temporarily selected and its buffer current.

Functions specified by the default value are called for each frame if at least one window on that frame has been added, deleted or assigned another buffer or changed its total or body size since the last time window change functions were run. Each call is performed with the frame temporarily selected and the selected window's buffer current.

Finally, Emacs runs a normal hook that generalizes the behavior of `window-state-change-functions`.

window-state-change-hook

[Variable]

The default value of this variable specifies functions called during redisplay when a window state change has been detected or the window state change flag has been set on at least one frame. The value should be a list of functions that take no argument.

Applications should put a function on this hook only if they want to react to changes that happened on (or have been signaled for) two or more frames since last redisplay. In every other case, putting the function on `window-state-change-functions` should be preferred.

Window change functions are called during redisplay for each frame as follows: First, any buffer-local window buffer change function, window size change function, selected window change and window state change functions are called in this order. Next, the default values for these functions are called in the same order. Then any buffer-local window configuration change functions are called followed by functions specified by the default value of those functions. Finally, functions on `window-state-change-hook` are run.

Window change functions are run for a specific frame only if a corresponding change was registered for that frame earlier. Such changes include the creation or deletion of a window or the assignment of another buffer or size to a window. Note that even when such a change has been registered, this does not mean that any of the hooks described above is run. If, for example, a change was registered within the scope of a window excursion (see Section 29.26 [Window Configurations], page 774), this will trigger a call of window change functions only if that excursion still persists at the time change functions are run. If it is exited earlier, hooks will be run only if registered by a change outside the scope of that excursion.

The *window state change flag* of a frame, if set, will cause the default values of `window-state-change-functions` (for that frame) and `window-state-change-hook` to be run during next redisplay regardless of whether a window state change actually occurred for that frame or not. After running any functions on these hooks, the flag is reset for each frame. Applications can set that flag and inspect its value using the following functions.

set-frame-window-state-change &optional frame arg

[Function]

This function sets *frame*'s window state change flag if *arg* is non-*nil* and resets it otherwise. *frame* must be a live frame and defaults to the selected one.

frame-window-state-change &optional frame

[Function]

This function returns *t* if *frame*'s window state change flag is set and *nil* otherwise. *frame* must be a live frame and defaults to the selected one.

While window change functions are run, the functions described next can be called to get more insight into what has changed for a specific window or frame since the last redisplay. All these functions take a live window as single, optional argument, defaulting to the selected window.

window-old-buffer &optional window

[Function]

This function returns the buffer shown in *window* at the last time window change functions were run for *window*'s frame. If it returns *nil*, *window* has been created

after that. If it returns `t`, `window` was not shown at that time but has been restored from a previously saved window configuration afterwards. Otherwise, the return value is the buffer shown by `window` at that time.

window-old-pixel-width &optional window [Function]

This function returns the total pixel width of `window` the last time window change functions found `window` live on its frame. It is zero if `window` was created after that.

window-old-pixel-height &optional window [Function]

This function returns the total pixel height of `window` the last time window change functions found `window` live on its frame. It is zero if `window` was created after that.

window-old-body-pixel-width &optional window [Function]

This function returns the pixel width of `window`'s text area the last time window change functions found `window` live on its frame. It is zero if `window` was created after that.

window-old-body-pixel-height &optional window [Function]

This function returns the pixel height of `window`'s text area the last time window change functions found `window` live on its frame. It is zero if `window` was created after that.

In order to find out which window or frame was selected the last time window change functions were run, the following functions can be used:

frame-old-selected-window &optional frame [Function]

This function returns the selected window of `frame` at the last time window change functions were run. If omitted or `nil` `frame` defaults to the selected frame.

old-selected-window [Function]

This function returns the selected window at the last time window change functions were run.

old-selected-frame [Function]

This function returns the selected frame at the last time window change functions were run.

Note that window change functions provide no information about which windows have been deleted since the last time they were run. If necessary, applications should remember any window showing a specific buffer in a local variable of that buffer and update it in a function run by the default values of any of the hooks that are run when a window buffer change was detected.

The following caveats should be considered when adding a function to window change functions:

- Some operations will not trigger a call of window change functions. These include showing another buffer in a minibuffer window or any change of a tooltip window.
- Window change functions should not create or delete windows or change the buffer, size or selection status of any window because there is no guarantee that the information about such a change will be propagated to other window change functions. If at all, any

such change should be executed only by the last function listed by the default value of `window-state-change-hook`.

- Macros like `save-window-excursion`, `with-selected-window` or `with-current-buffer` can be used when running window change functions.
- Running window change functions does not save and restore match data. Unless running `window-configuration-change-hook` it does not save or restore the selected window or frame or the current buffer either.
- Any redisplay triggering the run of window change functions may be aborted. If the abort occurs before window change functions have run to their completion, they will be run again with the previous values, that is, as if redisplay had not been performed. If aborted later, they will be run with the new values, that is, as if redisplay had been actually performed.

30 Frames

A *frame* is a screen object that contains one or more Emacs windows (see Chapter 29 [Windows], page 690). It is the kind of object called a “window” in the terminology of graphical environments; but we can’t call it a “window” here, because Emacs uses that word in a different way. In Emacs Lisp, a *frame object* is a Lisp object that represents a frame on the screen. See Section 2.5.4 [Frame Type], page 27.

A frame initially contains a single main window and/or a minibuffer window; you can subdivide the main window vertically or horizontally into smaller windows. See Section 29.7 [Splitting Windows], page 708.

A *terminal* is a display device capable of displaying one or more Emacs frames. In Emacs Lisp, a *terminal object* is a Lisp object that represents a terminal. See Section 2.5.5 [Terminal Type], page 27.

There are two classes of terminals: *text terminals* and *graphical terminals*. Text terminals are non-graphics-capable displays, including `xterm` and other terminal emulators. On a text terminal, each Emacs frame occupies the terminal’s entire screen; although you can create additional frames and switch between them, the terminal only shows one frame at a time. Graphical terminals, on the other hand, are managed by graphical display systems such as the X Window System, which allow Emacs to show multiple frames simultaneously on the same display.

On GNU and Unix systems, you can create additional frames on any available terminal, within a single Emacs session, regardless of whether Emacs was started on a text or graphical terminal. Emacs can display on both graphical and text terminals simultaneously. This comes in handy, for instance, when you connect to the same session from several remote locations. See Section 30.2 [Multiple Terminals], page 787.

`framep object`

[Function]

This predicate returns a non-`nil` value if *object* is a frame, and `nil` otherwise. For a frame, the value indicates which kind of display the frame uses:

- `t` The frame is displayed on a text terminal.
- `x` The frame is displayed on an X graphical terminal.
- `w32` The frame is displayed on a MS-Windows graphical terminal.
- `ns` The frame is displayed on a GNUstep or Macintosh Cocoa graphical terminal.
- `pc` The frame is displayed on an MS-DOS terminal.
- `pgtk` The frame is displayed using pure GTK facilities.

`frame-terminal &optional frame`

[Function]

This function returns the terminal object that displays *frame*. If *frame* is `nil` or unspecified, it defaults to the selected frame.

`terminal-live-p object`

[Function]

This predicate returns a non-`nil` value if *object* is a terminal that is live (i.e., not deleted), and `nil` otherwise. For live terminals, the return value indicates what kind of frames are displayed on that terminal; the list of possible values is the same as for `framep` above.

On a graphical terminal we distinguish two types of frames: A normal *top-level frame* is a frame whose window-system window is a child of the window-system's root window for that terminal. A *child frame* is a frame whose window-system window is the child of the window-system window of another Emacs frame. See Section 30.14 [Child Frames], page 831.

30.1 Creating Frames

To create a new frame, call the function `make-frame`.

`make-frame &optional parameters`

[Command]

This function creates and returns a new frame, displaying the current buffer.

The *parameters* argument is an alist that specifies frame parameters for the new frame. See Section 30.4 [Frame Parameters], page 802. If you specify the `terminal` parameter in *parameters*, the new frame is created on that terminal. Otherwise, if you specify the `window-system` frame parameter in *parameters*, that determines whether the frame should be displayed on a text terminal or a graphical terminal. See Section 41.25 [Window Systems], page 1248. If neither is specified, the new frame is created in the same terminal as the selected frame.

Any parameters not mentioned in *parameters* default to the values in the alist `default-frame-alist` (see Section 30.4.2 [Initial Parameters], page 804); parameters not specified there default from the X resources or its equivalent on your operating system (see Section “X Resources” in *The GNU Emacs Manual*). After the frame is created, this function applies any parameters specified in `frame-inherited-parameters` (see below) it has no assigned yet, taking the values from the frame that was selected when `make-frame` was called.

Note that on multi-monitor displays (see Section 30.2 [Multiple Terminals], page 787), the window manager might position the frame differently than specified by the positional parameters in *parameters* (see Section 30.4.3.2 [Position Parameters], page 805). For example, some window managers have a policy of displaying the frame on the monitor that contains the largest part of the window (a.k.a. the *dominating monitor*). This function itself does not make the new frame the selected frame. See Section 30.10 [Input Focus], page 824. The previously selected frame remains selected. On graphical terminals, however, the window system may select the new frame for its own reasons.

`before-make-frame-hook`

[Variable]

A normal hook run by `make-frame` before it creates the frame.

`after-make-frame-functions`

[Variable]

An abnormal hook run by `make-frame` after it created the frame. Each function in `after-make-frame-functions` receives one argument, the frame just created.

Note that any functions added to these hooks by your initial file are usually not run for the initial frame, since Emacs reads the initial file only after creating that frame. However, if the initial frame is specified to use a separate minibuffer frame (see Section 30.9 [Minibuffers and Frames], page 824), the functions will be run for both, the minibuffer-less and the minibuffer frame. Alternatively, you can add functions to these hooks in your “early init file” (see Section 42.1.2 [Init File], page 1258), in which case they will be in effect for the initial frame as well.

frame-inherited-parameters

[Variable]

This variable specifies the list of frame parameters that a newly created frame inherits from the currently selected frame. For each parameter (a symbol) that is an element in this list and has not been assigned earlier when processing `make-frame`, the function sets the value of that parameter in the created frame to its value in the selected frame.

server-after-make-frame-hook

[User Option]

A normal hook run when the Emacs server starts using a client frame. When this hook is called, the client frame is the selected one. Note that, depending on how `emacsclient` was invoked (see Section “Invoking `emacsclient`” in *The GNU Emacs Manual*), this client frame could be a new frame created for the client, or it could be an existing frame that the server reused for handling the client commands. See Section “Emacs Server” in *The GNU Emacs Manual*.

30.2 Multiple Terminals

Emacs represents each terminal as a *terminal object* data type (see Section 2.5.5 [Terminal Type], page 27). On GNU and Unix systems, Emacs can use multiple terminals simultaneously in each session. On other systems, it can only use a single terminal. Each terminal object has the following attributes:

- The name of the device used by the terminal (e.g., ‘`:0.0`’ or `/dev/tty`).
- The terminal and keyboard coding systems used on the terminal. See Section 34.10.8 [Terminal I/O Encoding], page 990.
- The kind of display associated with the terminal. This is the symbol returned by the function `terminal-live-p` (i.e., `x`, `t`, `w32`, `ns`, `pc`, `haiku`, or `pgtk`). See Chapter 30 [Frames], page 785.
- A list of terminal parameters. See Section 30.5 [Terminal Parameters], page 820.

There is no primitive for creating terminal objects. Emacs creates them as needed, such as when you call `make-frame-on-display` (described below).

terminal-name &optional terminal

[Function]

This function returns the file name of the device used by *terminal*. If *terminal* is omitted or `nil`, it defaults to the selected frame’s terminal. *terminal* can also be a frame, meaning that frame’s terminal.

terminal-list

[Function]

This function returns a list of all live terminal objects.

get-device-terminal device

[Function]

This function returns a terminal whose device name is given by *device*. If *device* is a string, it can be either the file name of a terminal device, or the name of an X display of the form ‘`host:server.screen`’. If *device* is a frame, this function returns that frame’s terminal; `nil` means the selected frame. Finally, if *device* is a terminal object that represents a live terminal, that terminal is returned. The function signals an error if its argument is none of the above.

delete-terminal &optional *terminal force* [Function]

This function deletes all frames on *terminal* and frees the resources used by it. It runs the abnormal hook **delete-terminal-functions**, passing *terminal* as the argument to each function.

If *terminal* is omitted or `nil`, it defaults to the selected frame's terminal. *terminal* can also be a frame, meaning that frame's terminal.

Normally, this function signals an error if you attempt to delete the sole active terminal, but if *force* is non-`nil`, you are allowed to do so. Emacs automatically calls this function when the last frame on a terminal is deleted (see Section 30.7 [Deleting Frames], page 822).

delete-terminal-functions [Variable]

An abnormal hook run by **delete-terminal**. Each function receives one argument, the *terminal* argument passed to **delete-terminal**. Due to technical details, the functions may be called either just before the terminal is deleted, or just afterwards.

A few Lisp variables are *terminal-local*; that is, they have a separate binding for each terminal. The binding in effect at any time is the one for the terminal that the currently selected frame belongs to. These variables include **default-minibuffer-frame**, **defining-kbd-macro**, **last-kbd-macro**, and **system-key-alist**. They are always terminal-local, and can never be buffer-local (see Section 12.11 [Buffer-Local Variables], page 207).

On GNU and Unix systems, each X display is a separate graphical terminal. When Emacs is started from within the X window system, it uses the X display specified by the **DISPLAY** environment variable, or by the ‘`--display`’ option (see Section “Initial Options” in *The GNU Emacs Manual*). Emacs can connect to other X displays via the command **make-frame-on-display**. Each X display has its own selected frame and its own minibuffer windows; however, only one of those frames is *the* selected frame at any given moment (see Section 30.10 [Input Focus], page 824). Emacs can even connect to other text terminals, by interacting with the **emacsclient** program. See Section “Emacs Server” in *The GNU Emacs Manual*.

A single X server can handle more than one display. Each X display has a three-part name, ‘`hostname:displaynumber.screennumber`’. The first part, *hostname*, specifies the name of the machine to which the display is physically connected. The second part, *displaynumber*, is a zero-based number that identifies one or more monitors connected to that machine that share a common keyboard and pointing device (mouse, tablet, etc.). The third part, *screennumber*, identifies a zero-based screen number (a separate monitor) that is part of a single monitor collection on that X server. When you use two or more screens belonging to one server, Emacs knows by the similarity in their names that they share a single keyboard.

Systems that don't use the X window system, such as MS-Windows, don't support the notion of X displays, and have only one display on each host. The display name on these systems doesn't follow the above 3-part format; for example, the display name on MS-Windows systems is a constant string ‘`w32`’, and exists for compatibility, so that you could pass it to functions that expect a display name.

make-frame-on-display *display &optional parameters* [Command]

This function creates and returns a new frame on *display*, taking the other frame parameters from the alist *parameters*. *display* should be the name of an X display (a string).

Before creating the frame, this function ensures that Emacs is set up to display graphics. For instance, if Emacs has not processed X resources (e.g., if it was started on a text terminal), it does so at this time. In all other respects, this function behaves like **make-frame** (see Section 30.1 [Creating Frames], page 786).

x-display-list [Function]

This function returns a list that indicates which X displays Emacs has a connection to. The elements of the list are strings, and each one is a display name.

x-open-connection *display &optional xrm-string must-succeed* [Function]

This function opens a connection to the X display *display*, without creating a frame on that display. Normally, Emacs Lisp programs need not call this function, as **make-frame-on-display** calls it automatically. The only reason for calling it is to check whether communication can be established with a given X display.

The optional argument *xrm-string*, if not **nil**, is a string of resource names and values, in the same format used in the **.Xresources** file. See Section “X Resources” in *The GNU Emacs Manual*. These values apply to all Emacs frames created on this display, overriding the resource values recorded in the X server. Here’s an example of what this string might look like:

```
"*BorderWidth: 3\n*InternalBorder: 2\n"
```

If *must-succeed* is non-**nil**, failure to open the connection terminates Emacs. Otherwise, it is an ordinary Lisp error.

x-close-connection *display* [Function]

This function closes the connection to display *display*. Before you can do this, you must first delete all the frames that were open on that display (see Section 30.7 [Deleting Frames], page 822).

On some multi-monitor setups, a single X display outputs to more than one physical monitor. You can use the functions **display-monitor-attributes-list** and **frame-monitor-attributes** to obtain information about such setups.

display-monitor-attributes-list &optional display [Function]

This function returns a list of physical monitor attributes on *display*, which can be a display name (a string), a terminal, or a frame; if omitted or **nil**, it defaults to the selected frame’s display. Each element of the list is an association list, representing the attributes of a physical monitor. The first element corresponds to the primary monitor. The attribute keys and values are:

‘geometry’

Position of the top-left corner of the monitor’s screen and its size, in pixels, as ‘(*x y width height*)’. Note that, if the monitor is not the primary monitor, some of the coordinates might be negative.

'workarea'

Position of the top-left corner and size of the work area (usable space) in pixels as '(*x y width height*)'. This may be different from 'geometry' in that space occupied by various window manager features (docks, taskbars, etc.) may be excluded from the work area. Whether or not such features actually subtract from the work area depends on the platform and environment. Again, if the monitor is not the primary monitor, some of the coordinates might be negative.

- 'mm-size'** Width and height in millimeters as '(*width height*)'
- 'frames'** List of frames that this physical monitor dominates (see below).
- 'name'** Name of the physical monitor as *string*.
- 'source'** Source of the multi-monitor information as *string*; e.g., 'XRandR 1.5', 'XRandr' or 'Xinerama'.

x, *y*, *width*, and *height* are integers. '**'name'**' and '**'source'**' may be absent.

A frame is *dominated* by a physical monitor when either the largest area of the frame resides in that monitor, or (if the frame does not intersect any physical monitors) that monitor is the closest to the frame. Every (non-tooltip) frame (whether visible or not) in a graphical display is dominated by exactly one physical monitor at a time, though the frame can span multiple (or no) physical monitors.

Here's an example of the data produced by this function on a 2-monitor display:

```
(display-monitor-attributes-list)
⇒
(((geometry 0 0 1920 1080) ;; Left-hand, primary monitor
  (workarea 0 0 1920 1050) ;; A taskbar occupies some of the height
  (mm-size 677 381)
  (name . "DISPLAY1")
  (frames #<frame emacs@host *Messages* 0x11578c0>
           #<frame emacs@host *scratch* 0x114b838>))
  ((geometry 1920 0 1680 1050) ;; Right-hand monitor
   (workarea 1920 0 1680 1050) ;; Whole screen can be used
   (mm-size 593 370)
   (name . "DISPLAY2"))
  (frames)))
```

frame-monitor-attributes &optional frame

[Function]

This function returns the attributes of the physical monitor dominating (see above) *frame*, which defaults to the selected frame.

On multi-monitor displays it is possible to use the command **make-frame-on-monitor** to make frames on the specified monitor.

make-frame-on-monitor monitor &optional display parameters [Command]

This function creates and returns a new frame on *monitor* located on *display*, taking the other frame parameters from the alist *parameters*. *monitor* should be the name of

the physical monitor, the same string as returned by the function `display-monitor-attributes-list` in the attribute `name`. `display` should be the name of an X display (a string).

`display-monitors-changed-functions`

[Variable]

This variable is an abnormal hook run when the monitor configuration changes, which can happen if a monitor is rotated, moved, added or removed from a multiple-monitor setup, if the primary monitor changes, or if the resolution of a monitor changes. It is called with a single argument consisting of the terminal on which the monitor configuration changed. Programs should call `display-monitor-attributes-list` with the terminal as the argument to retrieve the new monitor configuration on that terminal.

30.3 Frame Geometry

The geometry of a frame depends on the toolkit that was used to build this instance of Emacs and the terminal that displays the frame. This chapter describes these dependencies and some of the functions to deal with them. Note that the `frame` argument of all of these functions has to specify a live frame (see Section 30.7 [Deleting Frames], page 822). If omitted or `nil`, it specifies the selected frame (see Section 30.10 [Input Focus], page 824).

30.3.1 Frame Layout

A visible frame occupies a rectangular area on its terminal’s display. This area may contain a number of nested rectangles, each serving a different purpose. The drawing below sketches the layout of a frame on a graphical terminal:

In practice not all of the areas shown in the drawing will or may be present. The meaning of these areas is described below.

Outer Frame

The *outer frame* is a rectangle comprising all areas shown in the drawing. The edges of that rectangle are called the *outer edges* of the frame. Together, the *outer width* and *outer height* of the frame specify the *outer size* of that rectangle.

Knowing the outer size of a frame is useful for fitting a frame into the working area of its display (see Section 30.2 [Multiple Terminals], page 787) or for placing two frames adjacent to each other on the screen. Usually, the outer size of a frame is available only after the frame has been mapped (made visible, see Section 30.11 [Visibility of Frames], page 828) at least once. For the initial frame or a frame that has not been created yet, the outer size can be only estimated or must be calculated from the window-system's or window manager's defaults. One workaround is to obtain the differences of the outer and native (see below) sizes of a mapped frame and use them for calculating the outer size of the new frame.

The position of the upper left corner of the outer frame (indicated by '(0)' in the drawing above) is the *outer position* of the frame. The outer position of a graphical frame is also referred to as "the position" of the frame because it usually remains unchanged on its display whenever the frame is resized or its layout is changed.

The outer position is specified by and can be set via the `left` and `top` frame parameters (see Section 30.4.3.2 [Position Parameters], page 805). For a normal, top-level frame these parameters usually represent its absolute position (see below) with respect to its display's origin. For a child frame (see Section 30.14 [Child Frames], page 831) these parameters represent its position relative to the native position (see below) of its parent frame. For frames on text terminals the values of these parameters are meaningless and always zero.

External Border

The *external border* is part of the decorations supplied by the window manager. It is typically used for resizing the frame with the mouse and is therefore not shown on "fullboth" and maximized frames (see Section 30.4.3.3 [Size Parameters], page 808). Its width is determined by the window manager and cannot be changed by Emacs' functions.

External borders don't exist on text terminal frames. For graphical frames, their display can be suppressed by setting the `override-redirect` or `undecorated` frame parameter (see Section 30.4.3.8 [Management Parameters], page 814).

Outer Border

The *outer border* is a separate border whose width can be specified with the `border-width` frame parameter (see Section 30.4.3.4 [Layout Parameters], page 810). In practice, either the external or the outer border of a frame are displayed but never both at the same time. Usually, the outer border is shown only for special frames that are not (fully) controlled by the window manager like tooltip frames (see Section 41.26 [Tooltips], page 1249), child frames (see Section 30.14 [Child Frames], page 831) and `undecorated` or `override-redirect` frames (see Section 30.4.3.8 [Management Parameters], page 814).

Outer borders are never shown on text terminal frames and on frames generated by GTK+ routines. On MS-Windows, the outer border is emulated with the help of a one pixel wide external border. Non-toolkit builds on X allow to change the color of the outer border by setting the `border-color` frame parameter (see Section 30.4.3.4 [Layout Parameters], page 810).

- | | |
|-----------|--|
| Title Bar | The <i>title bar</i> , a.k.a. <i>caption bar</i> , is also part of the window manager's decorations and typically displays the title of the frame (see Section 30.6 [Frame Titles], page 821) as well as buttons for minimizing, maximizing and deleting the frame. It can be also used for dragging the frame with the mouse. The title bar is usually not displayed for fullboth (see Section 30.4.3.3 [Size Parameters], page 808), tooltip (see Section 41.26 [Tooltips], page 1249) and child frames (see Section 30.14 [Child Frames], page 831) and doesn't exist for terminal frames. Display of the title bar can be suppressed by setting the <code>override-redirect</code> or the <code>undecorated</code> frame parameters (see Section 30.4.3.8 [Management Parameters], page 814). |
| Menu Bar | <p>The menu bar (see Section 23.18.5 [Menu Bar], page 516) can be either internal (drawn by Emacs itself) or external (drawn by the toolkit). Most builds (GTK+, Lucid, Motif and MS-Windows) rely on an external menu bar. NS also uses an external menu bar which, however, is not part of the outer frame. Non-toolkit builds can provide an internal menu bar. On text terminal frames, the menu bar is part of the frame's root window (see Section 29.2 [Windows and Frames], page 692). As a rule, menu bars are never shown on child frames (see Section 30.14 [Child Frames], page 831). Display of the menu bar can be suppressed by setting the <code>menu-bar-lines</code> parameter (see Section 30.4.3.4 [Layout Parameters], page 810) to zero.</p> <p>Whether the menu bar is wrapped or truncated whenever its width becomes too large to fit on its frame depends on the toolkit . Usually, only Motif and MS-Windows builds can wrap the menu bar. When they (un-)wrap the menu bar, they try to keep the outer height of the frame unchanged, so the native height of the frame (see below) will change instead.</p> |
| Tool Bar | <p>Like the menu bar, the tool bar (see Section 23.18.6 [Tool Bar], page 517) can be either internal (drawn by Emacs itself) or external (drawn by a toolkit). The GTK+ and NS builds have the tool bar drawn by the toolkit. The remaining builds use internal tool bars. With GTK+ the tool bar can be located on either side of the frame, immediately outside the internal border, see below. Tool bars are usually not shown for child frames (see Section 30.14 [Child Frames], page 831). Display of the tool bar can be suppressed by setting the <code>tool-bar-lines</code> parameter (see Section 30.4.3.4 [Layout Parameters], page 810) to zero.</p> <p>If the variable <code>auto-resize-tool-bars</code> is non-<code>nil</code>, Emacs wraps the internal tool bar when its width becomes too large for its frame. If and when Emacs (un-)wraps the internal tool bar, it by default keeps the outer height of the frame unchanged, so the native height of the frame (see below) will change instead. Emacs built with GTK+, on the other hand, never wraps the tool bar but may</p> |

automatically increase the outer width of a frame in order to accommodate an overlong tool bar.

Tab Bar The tab bar (see Section “Tab Bars” in *The GNU Emacs Manual*) is always drawn by Emacs itself. The tab bar appears above the tool bar in Emacs built with an internal tool bar, and below the tool bar in builds with an external tool bar. Display of the tab bar can be suppressed by setting the `tab-bar-lines` parameter (see Section 30.4.3.4 [Layout Parameters], page 810) to zero.

Native Frame

The *native frame* is a rectangle located entirely within the outer frame. It excludes the areas occupied by an external or outer border, the title bar and any external menu or tool bar. The edges of the native frame are called the *native edges* of the frame. Together, the *native width* and *native height* of a frame specify the *native size* of the frame.

The native size of a frame is the size Emacs passes to the window-system or window manager when creating or resizing the frame from within Emacs. It is also the size Emacs receives from the window-system or window manager whenever these resize the frame’s window-system window, for example, after maximizing the frame by clicking on the corresponding button in the title bar or when dragging its external border with the mouse.

The position of the top left corner of the native frame specifies the *native position* of the frame. (1)–(3) in the drawing above indicate that position for the various builds:

- (1) non-toolkit, Haiku, and terminal frames
- (2) Lucid, Motif, and MS-Windows frames
- (3) GTK+ and NS frames

Accordingly, the native height of a frame may include the height of the tool bar but not that of the menu bar (Lucid, Motif, MS-Windows) or those of the menu bar and the tool bar (non-toolkit and text terminal frames).

The native position of a frame is the reference position for functions that set or return the current position of the mouse (see Section 30.16 [Mouse Position], page 835) and for functions dealing with the position of windows like `window-edges`, `window-at` or `coordinates-in-window-p` (see Section 29.24 [Coordinates and Windows], page 769). It also specifies the (0, 0) origin for locating and positioning child frames within this frame (see Section 30.14 [Child Frames], page 831).

Note also that the native position of a frame usually remains unaltered on its display when removing or adding the window manager decorations by changing the frame’s `override-redirect` or `undecorated` parameter (see Section 30.4.3.8 [Management Parameters], page 814).

Internal Border

The internal border is a border drawn by Emacs around the inner frame (see below). The specification of its appearance depends on whether or not the given frame is a child frame (see Section 30.14 [Child Frames], page 831).

For normal frames its width is specified by the `internal-border-width` frame parameter (see Section 30.4.3.4 [Layout Parameters], page 810), and its color is specified by the background of the `internal-border` face.

For child frames its width is specified by the `child-frame-border-width` frame parameter (but will use the `internal-border-width` parameter as fallback), and its color is specified by the background of the `child-frame-border` face.

Inner Frame

The *inner frame* is the rectangle reserved for the frame’s windows. It’s enclosed by the internal border which, however, is not part of the inner frame. Its edges are called the *inner edges* of the frame. The *inner width* and *inner height* specify the *inner size* of the rectangle. The inner frame is sometimes also referred to as the *display area* of the frame.

As a rule, the inner frame is subdivided into the frame’s root window (see Section 29.2 [Windows and Frames], page 692) and the frame’s minibuffer window (see Section 21.11 [Minibuffer Windows], page 418). There are two notable exceptions to this rule: A *minibuffer-less frame* contains a root window only and does not contain a minibuffer window. A *minibuffer-only frame* contains only a minibuffer window which also serves as that frame’s root window. See Section 30.4.2 [Initial Parameters], page 804, for how to create such frame configurations.

Text Area The *text area* of a frame is a somewhat fictitious area that can be embedded in the native frame. Its position is unspecified. Its width can be obtained by removing from that of the native width the widths of the internal border, one vertical scroll bar, and one left and one right fringe if they are specified for this frame, see Section 30.4.3.4 [Layout Parameters], page 810. Its height can be obtained by removing from that of the native height the widths of the internal border and the heights of the frame’s internal menu and tool bars, the tab bar and one horizontal scroll bar if specified for this frame.

The *absolute position* of a frame is given as a pair (X, Y) of horizontal and vertical pixel offsets relative to an origin (0, 0) of the frame’s display. Correspondingly, the *absolute edges* of a frame are given as pixel offsets from that origin.

Note that with multiple monitors, the origin of the display does not necessarily coincide with the top-left corner of the entire usable display area of the terminal. Hence the absolute position of a frame can be negative in such an environment even when that frame is completely visible.

By convention, vertical offsets increase “downwards”. This means that the height of a frame is obtained by subtracting the offset of its top edge from that of its bottom edge. Horizontal offsets increase “rightwards”, as expected, so a frame’s width is calculated by subtracting the offset of its left edge from that of its right edge.

For a frame on a graphical terminal the following function returns the sizes of the areas described above:

`frame-geometry &optional frame`

[Function]

This function returns geometric attributes of *frame*. The return value is an association list of the attributes listed below. All coordinate, height and width values are integers

counting pixels. Note that if *frame* has not been mapped yet, (see Section 30.11 [Visibility of Frames], page 828) some of the return values may only represent approximations of the actual values—those that can be seen after the frame has been mapped.

outer-position

A cons representing the absolute position of the outer *frame*, relative to the origin at position (0, 0) of *frame*'s display.

outer-size

A cons of the outer width and height of *frame*.

external-border-size

A cons of the horizontal and vertical width of *frame*'s external borders as supplied by the window manager. If the window manager doesn't supply these values, Emacs will try to guess them from the coordinates of the outer and inner frame.

outer-border-width

The width of the outer border of *frame*. The value is meaningful for non-GTK+ X builds only.

title-bar-size

A cons of the width and height of the title bar of *frame* as supplied by the window manager or operating system. If both of them are zero, the frame has no title bar. If only the width is zero, Emacs was not able to retrieve the width information.

menu-bar-external

If non-nil, this means the menu bar is external (not part of the native frame of *frame*).

menu-bar-size

A cons of the width and height of the menu bar of *frame*.

tool-bar-external

If non-nil, this means the tool bar is external (not part of the native frame of *frame*).

tool-bar-position

This tells on which side the tool bar on *frame* is and can be one of `left`, `top`, `right` or `bottom`. The only toolkit that currently supports a value other than `top` is GTK+.

tool-bar-size

A cons of the width and height of the tool bar of *frame*.

internal-border-width

The width of the internal border of *frame*.

The following function can be used to retrieve the edges of the outer, native and inner frame.

frame-edges &optional frame type

[Function]

This function returns the absolute edges of the outer, native or inner frame of *frame*. *frame* must be a live frame and defaults to the selected one. The returned list has the form (*left top right bottom*) where all values are in pixels relative to the origin of *frame*'s display. For terminal frames the values returned for *left* and *top* are always zero.

Optional argument *type* specifies the type of the edges to return: **outer-edges** means to return the outer edges of *frame*, **native-edges** (or **nil**) means to return its native edges and **inner-edges** means to return its inner edges.

By convention, the pixels of the display at the values returned for *left* and *top* are considered to be inside (part of) *frame*. Hence, if *left* and *top* are both zero, the pixel at the display's origin is part of *frame*. The pixels at *bottom* and *right*, on the other hand, are considered to lie immediately outside *frame*. This means that if you have, for example, two side-by-side frames positioned such that the right outer edge of the frame on the left equals the left outer edge of the frame on the right, the pixels at that edge show a part of the frame on the right.

30.3.2 Frame Font

Each frame has a *default font* which specifies the default character size for that frame. This size is meant when retrieving or changing the size of a frame in terms of columns or lines (see Section 30.4.3.3 [Size Parameters], page 808). It is also used when resizing (see Section 29.4 [Window Sizes], page 699) or splitting (see Section 29.7 [Splitting Windows], page 708) windows.

The terms *line height* and *canonical character height* are sometimes used instead of “default character height”. Similarly, the terms *column width* and *canonical character width* are used instead of “default character width”.

frame-char-height &optional frame

[Function]

frame-char-width &optional frame

[Function]

These functions return the default height and width of a character in *frame*, measured in pixels. Together, these values establish the size of the default font on *frame*. The values depend on the choice of font for *frame*, see Section 30.4.3.10 [Font and Color Parameters], page 818.

The default font can be also set directly with the following function:

set-frame-font font &optional keep-size frames

[Command]

This sets the default font to *font*. When called interactively, it prompts for the name of a font, and uses that font on the selected frame. When called from Lisp, *font* should be a font name (a string), a font object, font entity, or a font spec.

If the optional argument *keep-size* is **nil**, this keeps the number of frame lines and columns fixed. (If non-**nil**, the option **frame-inhibit-implied-resize** described in the next section will override this.) If *keep-size* is non-**nil** (or with a prefix argument), it tries to keep the size of the display area of the current frame fixed by adjusting the number of lines and columns.

If the optional argument *frames* is `nil`, this applies the font to the selected frame only. If *frames* is non-`nil`, it should be a list of frames to act upon, or `t` meaning all existing and all future graphical frames.

30.3.3 Frame Position

On graphical systems, the position of a normal top-level frame is specified as the absolute position of its outer frame (see Section 30.3 [Frame Geometry], page 791). The position of a child frame (see Section 30.14 [Child Frames], page 831) is specified via pixel offsets of its outer edges relative to the native position of its parent frame.

You can access or change the position of a frame using the frame parameters `left` and `top` (see Section 30.4.3.2 [Position Parameters], page 805). Here are two additional functions for working with the positions of an existing, visible frame. For both functions, the argument *frame* must denote a live frame and defaults to the selected frame.

`frame-position` &optional *frame*

[Function]

For a normal, non-child frame this function returns a cons of the pixel coordinates of its outer position (see Section 30.3.1 [Frame Layout], page 791) with respect to the origin $(0, 0)$ of its display. For a child frame (see Section 30.14 [Child Frames], page 831) this function returns the pixel coordinates of its outer position with respect to an origin $(0, 0)$ at the native position of *frame*'s parent.

Negative values never indicate an offset from the right or bottom edge of *frame*'s display or parent frame. Rather, they mean that *frame*'s outer position is on the left and/or above the origin of its display or the native position of its parent frame. This usually means that *frame* is only partially visible (or completely invisible). However, on systems where the display's origin does not coincide with its top-left corner, the frame may be visible on a secondary monitor.

On a text terminal frame both values are zero.

`set-frame-position` *frame* *x* *y*

[Function]

This function sets the outer frame position of *frame* to (x, y) . The latter arguments specify pixels and normally count from the origin at the position $(0, 0)$ of *frame*'s display. For child frames, they count from the native position of *frame*'s parent frame.

Negative parameter values position the right edge of the outer frame by $-x$ pixels left from the right edge of the screen (or the parent frame's native rectangle) and the bottom edge by $-y$ pixels up from the bottom edge of the screen (or the parent frame's native rectangle).

Note that negative values do not permit to align the right or bottom edge of *frame* exactly at the right or bottom edge of its display or parent frame. Neither do they allow to specify a position that does not lie within the edges of the display or parent frame. The frame parameters `left` and `top` (see Section 30.4.3.2 [Position Parameters], page 805) allow to do that, but may still fail to provide good results for the initial or a new frame.

This function has no effect on text terminal frames.

`move-frame-functions`

[Variable]

This hook specifies the functions that are run when an Emacs frame is moved (assigned a new position) by the window-system or window manager. The functions are run

with one argument, the frame that moved. For a child frame (see Section 30.14 [Child Frames], page 831), the functions are run only when the position of the frame changes in relation to that of its parent frame.

30.3.4 Frame Size

The canonical way to specify the size of a frame from within Emacs is by specifying its *text size*—a tuple of the width and height of the frame’s text area (see Section 30.3.1 [Frame Layout], page 791). It can be measured either in pixels or in terms of the frame’s canonical character size (see Section 30.3.2 [Frame Font], page 797).

For frames with an internal menu or tool bar, the frame’s native height cannot be told exactly before the frame has been actually drawn. This means that in general you cannot use the native size to specify the initial size of a frame. As soon as you know the native size of a visible frame, you can calculate its outer size (see Section 30.3.1 [Frame Layout], page 791) by adding in the remaining components from the return value of `frame-geometry`. For invisible frames or for frames that have yet to be created, however, the outer size can only be estimated. This also means that calculating an exact initial position of a frame specified via offsets from the right or bottom edge of the screen (see Section 30.3.3 [Frame Position], page 798) is impossible.

The text size of any frame can be set and retrieved with the help of the `height` and `width` frame parameters (see Section 30.4.3.3 [Size Parameters], page 808). The text size of the initial frame can be also set with the help of an X-style geometry specification. See Section “Command Line Arguments for Emacs Invocation” in *The GNU Emacs Manual*. Below we list some functions to access and set the size of an existing, visible frame, by default the selected one.

`frame-height &optional frame`

[Function]

`frame-width &optional frame`

[Function]

These functions return the height and width of the text area of *frame*, measured in units of the default font height and width of *frame* (see Section 30.3.2 [Frame Font], page 797). These functions are plain shorthands for writing `(frame-parameter frame 'height)` and `(frame-parameter frame 'width)`.

If the text area of *frame* measured in pixels is not a multiple of its default font size, the values returned by these functions are rounded down to the number of characters of the default font that fully fit into the text area.

The functions following next return the pixel widths and heights of the native, outer and inner frame and the text area (see Section 30.3.1 [Frame Layout], page 791) of a given frame. For a text terminal, the results are in characters rather than pixels.

`frame-outer-width &optional frame`

[Function]

`frame-outer-height &optional frame`

[Function]

These functions return the outer width and height of *frame* in pixels.

`frame-native-height &optional frame`

[Function]

`frame-native-width &optional frame`

[Function]

These functions return the native width and height of *frame* in pixels.

frame-inner-width &optional frame [Function]
frame-inner-height &optional frame [Function]

These functions return the inner width and height of *frame* in pixels.

frame-text-width &optional frame [Function]
frame-text-height &optional frame [Function]

These functions return the width and height of the text area of *frame* in pixels.

On window systems that support it, Emacs tries by default to make the text size of a frame measured in pixels a multiple of the frame's character size. This, however, usually means that a frame can be resized only in character size increments when dragging its external borders. It also may break attempts to truly maximize the frame or making it "fullheight" or "fullwidth" (see Section 30.4.3.3 [Size Parameters], page 808) leaving some empty space below and/or on the right of the frame. The following option may help in that case.

frame-resize-pixelwise [User Option]

If this option is `nil` (the default), a frame's text pixel size is usually rounded to a multiple of the current values of that frame's `frame-char-height` and `frame-char-width` whenever the frame is resized. If this is non-`nil`, no rounding occurs, hence frame sizes can increase/decrease by one pixel.

Setting this variable usually causes the next resize operation to pass the corresponding size hints to the window manager. This means that this variable should be set only in a user's initial file; applications should never bind it temporarily.

The precise meaning of a value of `nil` for this option depends on the toolkit used. Dragging the external border with the mouse is done character-wise provided the window manager is willing to process the corresponding size hints. Calling `set-frame-size` (see below) with arguments that do not specify the frame size as an integer multiple of its character size, however, may: be ignored, cause a rounding (GTK+), or be accepted (Lucid, Motif, MS-Windows).

With some window managers you may have to set this to non-`nil` in order to make a frame appear truly maximized or full-screen.

set-frame-size frame width height &optional pixelwise [Function]

This function sets the size of the text area of *frame*, measured in terms of the canonical height and width of a character on *frame* (see Section 30.3.2 [Frame Font], page 797).

The optional argument *pixelwise* non-`nil` means to measure the new width and height in units of pixels instead. Note that if `frame-resize-pixelwise` is `nil`, some toolkits may refuse to truly honor the request if it does not increase/decrease the frame size to a multiple of its character size.

set-frame-height frame height &optional pretend pixelwise [Function]

This function resizes the text area of *frame* to a height of *height* lines. The sizes of existing windows in *frame* are altered proportionally to fit.

If *pretend* is non-`nil`, then Emacs displays *height* lines of output in *frame*, but does not change its value for the actual height of the frame. This is only useful on text terminals. Using a smaller height than the terminal actually implements may be useful

to reproduce behavior observed on a smaller screen, or if the terminal malfunctions when using its whole screen. Setting the frame height directly does not always work, because knowing the correct actual size may be necessary for correct cursor positioning on text terminals.

The optional fourth argument *pixelwise non-nil* means that *frame* should be *height* pixels high. Note that if `frame-resize-pixelwise` is `nil`, some window managers may refuse to truly honor the request if it does not increase/decrease the frame height to a multiple of its character height.

When used interactively, this command will ask the user for the number of lines to set the height of the currently selected frame. You can also provide this value with a numeric prefix.

set-frame-width *frame width &optional pretend pixelwise* [Function]

This function sets the width of the text area of *frame*, measured in characters. The argument *pretend* has the same meaning as in `set-frame-height`.

The optional fourth argument *pixelwise non-nil* means that *frame* should be *width* pixels wide. Note that if `frame-resize-pixelwise` is `nil`, some window managers may refuse to fully honor the request if it does not increase/decrease the frame width to a multiple of its character width.

When used interactively, this command will ask the user for the number of columns to set the width of the currently selected frame. You can also provide this value with a numeric prefix.

None of these three functions will make a frame smaller than needed to display all of its windows together with their scroll bars, fringes, margins, dividers, mode and header lines. This contrasts with requests by the window manager triggered, for example, by dragging the external border of a frame with the mouse. Such requests are always honored by clipping, if necessary, portions that cannot be displayed at the right, bottom corner of the frame. The parameters `min-width` and `min-height` (see Section 30.4.3.3 [Size Parameters], page 808) can be used to obtain a similar behavior when changing the frame size from within Emacs.

The abnormal hook `window-size-change-functions` (see Section 29.28 [Window Hooks], page 779) tracks all changes of the inner size of a frame including those induced by request of the window-system or window manager. To rule out false positives that might occur when changing only the sizes of a frame's windows without actually changing the size of the inner frame, use the following function.

frame-size-changed-p *&optional frame* [Function]

This function returns `non-nil` when the inner width or height of *frame* has changed since `window-size-change-functions` was run the last time for *frame*. It always returns `nil` immediately after running `window-size-change-functions` for *frame*.

30.3.5 Implied Frame Resizing

By default, Emacs tries to keep the number of lines and columns of a frame's text area unaltered when, for example, toggling its menu or tool bar, changing its default font or setting the width of any of its scroll bars. This means that in such case Emacs must ask the window manager to resize the frame's window in order to accommodate the size change.

Occasionally, such *implied frame resizing* may be unwanted, for example, when a frame has been maximized or made full-screen (where it's turned off by default). In general, users can disable implied resizing with the following option:

frame-inhibit-implied-resize

[User Option]

If this option is `nil`, changing a frame's font, menu bar, tool bar, internal borders, fringes or scroll bars may resize its outer frame in order to keep the number of columns or lines of its text area unaltered. If this option is `t`, no such resizing is done.

The value of this option can be also a list of frame parameters. In that case, implied resizing is inhibited for the change of a parameter that appears in this list. Parameters currently handled by this option are `font`, `font-backend`, `internal-border-width`, `menu-bar-lines` and `tool-bar-lines`.

Changing any of the `scroll-bar-width`, `scroll-bar-height`, `vertical-scroll-bars`, `horizontal-scroll-bars`, `left-fringe` and `right-fringe` frame parameters is handled as if the frame contained just one live window. This means, for example, that removing vertical scroll bars on a frame containing several side by side windows will shrink the outer frame width by the width of one scroll bar provided this option is `nil` and keep it unchanged if this option is `t` or a list containing `vertical-scroll-bars`.

The default value is `(tab-bar-lines tool-bar-lines)` for Lucid, Motif and MS-Windows (which means that adding/removing a tool or tab bar there does not change the outer frame height), `(tab-bar-lines)` on all other window systems including GTK+ (which means that changing any of the parameters listed above with the exception of `tab-bar-lines` may change the size of the outer frame), and `t` otherwise (which means the outer frame size never changes implicitly when there's no window system support).

Note that when a frame is not large enough to accommodate a change of any of the parameters listed above, Emacs may try to enlarge the frame even if this option is non-`nil`.

Note also that window managers usually do not ask for resizing a frame when they change the number of lines occupied by an external menu or tool bar. Typically, such "wrappings" occur when a user shrinks a frame horizontally, making it impossible to display all elements of its menu or tool bar. They may also result from a change of the major mode altering the number of items of a menu or tool bar. Any such wrappings may implicitly alter the number of lines of a frame's text area and are unaffected by the setting of this option.

30.4 Frame Parameters

A frame has many parameters that control its appearance and behavior. Just what parameters a frame has depends on what display mechanism it uses.

Frame parameters exist mostly for the sake of graphical displays. Most frame parameters have no effect when applied to a frame on a text terminal; only the `height`, `width`, `name`, `title`, `menu-bar-lines`, `buffer-list` and `buffer-predicate` parameters do something special. If the terminal supports colors, the parameters `foreground-color`, `background-color`, `background-mode` and `display-type` are also meaningful. If the terminal supports frame transparency, the parameter `alpha` is also meaningful.

By default, frame parameters are saved and restored by the desktop library functions (see Section 24.8 [Desktop Save Mode], page 594) when the variable `desktop-restore-frames` is non-`nil`. It's the responsibility of applications that their parameters are included in `frameset-persistent-filter-alist` to avoid that they get meaningless or even harmful values in restored sessions.

30.4.1 Access to Frame Parameters

These functions let you read and change the parameter values of a frame.

`frame-parameter frame parameter`

[Function]

This function returns the value of the parameter `parameter` (a symbol) of `frame`. If `frame` is `nil`, it returns the selected frame's parameter. If `frame` has no setting for `parameter`, this function returns `nil`.

`frame-parameters &optional frame`

[Function]

The function `frame-parameters` returns an alist listing all the parameters of `frame` and their values. If `frame` is `nil` or omitted, this returns the selected frame's parameters

`modify-frame-parameters frame alist`

[Function]

This function alters the frame `frame` based on the elements of `alist`. Each element of `alist` has the form `(parm . value)`, where `parm` is a symbol naming a parameter. If you don't mention a parameter in `alist`, its value doesn't change. If `frame` is `nil`, it defaults to the selected frame.

Some parameters are only meaningful for frames on certain kinds of display (see Chapter 30 [Frames], page 785). If `alist` includes parameters that are not meaningful for the `frame`'s display, this function will change its value in the frame's parameter list, but will otherwise ignore it.

When `alist` specifies more than one parameter whose value can affect the new size of `frame`, the final size of the frame may differ according to the toolkit used. For example, specifying that a frame should from now on have a menu and/or tool bar instead of none and simultaneously specifying the new height of the frame will inevitably lead to a recalculation of the frame's height. Conceptually, in such case, this function will try to have the explicit height specification prevail. It cannot be excluded, however, that the addition (or removal) of the menu or tool bar, when eventually performed by the toolkit, will defeat this intention.

Sometimes, binding `frame-inhibit-implied-resize` (see Section 30.3.5 [Implied Frame Resizing], page 801) to a non-`nil` value around calls to this function may fix the problem sketched here. Sometimes, however, exactly such binding may be hit by the problem.

`set-frame-parameter frame parm value`

[Function]

This function sets the frame parameter `parm` to the specified `value`. If `frame` is `nil`, it defaults to the selected frame.

`modify-all-frames-parameters alist`

[Function]

This function alters the frame parameters of all existing frames according to `alist`, then modifies `default-frame-alist` (and, if necessary, `initial-frame-alist`) to apply the same parameter values to frames that will be created henceforth.

30.4.2 Initial Frame Parameters

You can specify the parameters for the initial startup frame by setting `initial-frame-alist` in your init file (see Section 42.1.2 [Init File], page 1258).

`initial-frame-alist`

[User Option]

This variable's value is an alist of parameter values used when creating the initial frame. You can set this variable to specify the appearance of the initial frame without altering subsequent frames. Each element has the form:

`(parameter . value)`

Emacs creates the initial frame before it reads your init file. After reading that file, Emacs checks `initial-frame-alist`, and applies the parameter settings in the altered value to the already created initial frame.

If these settings affect the frame geometry and appearance, you'll see the frame appear with the wrong ones and then change to the specified ones. If that bothers you, you can specify the same geometry and appearance with X resources; those do take effect before the frame is created. See Section “X Resources” in *The GNU Emacs Manual*.

X resource settings typically apply to all frames. If you want to specify some X resources solely for the sake of the initial frame, and you don't want them to apply to subsequent frames, here's how to achieve this. Specify parameters in `default-frame-alist` to override the X resources for subsequent frames; then, to prevent these from affecting the initial frame, specify the same parameters in `initial-frame-alist` with values that match the X resources.

If these parameters include `(minibuffer . nil)`, that indicates that the initial frame should have no minibuffer. In this case, Emacs creates a separate *minibuffer-only frame* as well.

`minibuffer-frame-alist`

[User Option]

This variable's value is an alist of parameter values used when creating an initial minibuffer-only frame (i.e., the minibuffer-only frame that Emacs creates if `initial-frame-alist` specifies a frame with no minibuffer).

`default-frame-alist`

[User Option]

This is an alist specifying default values of frame parameters for all Emacs frames—the first frame, and subsequent frames. When using the X Window System, you can get the same results by means of X resources in many cases.

Setting this variable does not affect existing frames. Furthermore, functions that display a buffer in a separate frame may override the default parameters by supplying their own parameters.

If you invoke Emacs with command-line options that specify frame appearance, those options take effect by adding elements to either `initial-frame-alist` or `default-frame-alist`. Options which affect just the initial frame, such as ‘`--geometry`’ and ‘`--maximized`’, add to `initial-frame-alist`; the others add to `default-frame-alist`. see Section “Command Line Arguments for Emacs Invocation” in *The GNU Emacs Manual*.

30.4.3 Window Frame Parameters

Just what parameters a frame has depends on what display mechanism it uses. This section describes the parameters that have special meanings on some or all kinds of terminals. Of these, `name`, `title`, `height`, `width`, `buffer-list` and `buffer-predicate` provide meaningful information in terminal frames, and `tty-color-mode` is meaningful only for frames on text terminals.

30.4.3.1 Basic Parameters

These frame parameters give the most basic information about the frame. `title` and `name` are meaningful on all terminals.

display The display on which to open this frame. It should be a string of the form ‘`host:dpw.screen`’, just like the `DISPLAY` environment variable. See Section 30.2 [Multiple Terminals], page 787, for more details about display names.

display-type This parameter describes the range of possible colors that can be used in this frame. Its value is `color`, `grayscale` or `mono`.

title If a frame has a non-`nil` title, that title appears in the window system’s title bar at the top of the frame, and also in the mode line of windows in that frame if `mode-line-frame-identification` uses ‘%F’ (see Section 24.4.5 [%-Constructs], page 556). This is normally the case when Emacs is not using a window system, and can only display one frame at a time. When Emacs is using a window system, this parameter, if non-`nil`, overrides the title determined by the `name` parameter and the implicit title calculated according to `frame-title-format`. It also overrides the title determined by `icon-title-format` for iconified frames. See Section 30.6 [Frame Titles], page 821.

name The name of the frame. If you don’t specify a name via this parameter, Emacs sets the frame name automatically, as specified by `frame-title-format` and `icon-title-format`, and that is the frame’s title that will appear on display when Emacs uses a window system (unless the `title` parameter overrides it). If you specify the frame name explicitly when you create the frame, the name is also used (instead of the name of the Emacs executable) when looking up X resources for the frame.

explicit-name If the frame name was specified explicitly when the frame was created, this parameter will be that name. If the frame wasn’t explicitly named, this parameter will be `nil`.

30.4.3.2 Position Parameters

Parameters describing the X- and Y-offsets of a frame are always measured in pixels. For a normal, non-child frame they specify the frame’s outer position (see Section 30.3 [Frame Geometry], page 791) relative to its display’s origin. For a child frame (see Section 30.14 [Child Frames], page 831) they specify the frame’s outer position relative to the native position of the frame’s parent frame. (Note that none of these parameters is meaningful on TTY frames.)

left The position, in pixels, of the left outer edge of the frame with respect to the left edge of the frame’s display or parent frame. It can be specified in one of the following ways.

an integer A positive integer always relates the left edge of the frame to the left edge of its display or parent frame. A negative integer relates the right frame edge to the right edge of the display or parent frame.

(*+ pos*) This specifies the position of the left frame edge relative to the left edge of its display or parent frame. The integer *pos* may be positive or negative; a negative value specifies a position outside the screen or parent frame or on a monitor other than the primary one (for multi-monitor displays).

(*- pos*) This specifies the position of the right frame edge relative to the right edge of the display or parent frame. The integer *pos* may be positive or negative; a negative value specifies a position outside the screen or parent frame or on a monitor other than the primary one (for multi-monitor displays).

a floating-point value

A floating-point value in the range 0.0 to 1.0 specifies the left edge’s offset via the *left position ratio* of the frame—the ratio of the left edge of its outer frame to the width of the frame’s workarea (see Section 30.2 [Multiple Terminals], page 787) or its parent’s native frame (see Section 30.14 [Child Frames], page 831) minus the width of the outer frame. Thus, a left position ratio of 0.0 flushes a frame to the left, a ratio of 0.5 centers it and a ratio of 1.0 flushes it to the right of its display or parent frame. Similarly, the *top position ratio* of a frame is the ratio of the frame’s top position to the height of its workarea or parent frame minus the height of the frame.

Emacs will try to keep the position ratios of a child frame unaltered if that frame has a non-nil **keep-ratio** parameter (see Section 30.4.3.6 [Frame Interaction Parameters], page 812) and its parent frame is resized.

Since the outer size of a frame (see Section 30.3 [Frame Geometry], page 791) is usually unavailable before a frame has been made visible, it is generally not advisable to use floating-point values when creating decorated frames. Floating-point values are more suited for ensuring that an (undecorated) child frame is positioned nicely within the area of its parent frame.

Some window managers ignore program-specified positions. If you want to be sure the position you specify is not ignored, specify a non-nil value for the **user-position** parameter as in the following example:

```
(modify-frame-parameters
  nil '((user-position . t) (left . (+ -4))))
```

In general, it is not a good idea to position a frame relative to the right or bottom edge of its display. Positioning the initial or a new frame is either not

accurate (because the size of the outer frame is not yet fully known before the frame has been made visible) or will cause additional flicker (if the frame has to be repositioned after becoming visible).

Note also, that positions specified relative to the right/bottom edge of a display, workarea or parent frame as well as floating-point offsets are stored internally as integer offsets relative to the left/top edge of the display, workarea or parent frame edge. They are also returned as such by functions like `frame-parameters` and restored as such by the desktop saving routines.

top The screen position of the top (or bottom) edge, in pixels, with respect to the top (or bottom) edge of the display or parent frame. It works just like `left`, except vertically instead of horizontally.

icon-left

The screen position of the left edge of the frame's icon, in pixels, counting from the left edge of the screen. This takes effect when the frame is iconified, if the window manager supports this feature. If you specify a value for this parameter, then you must also specify a value for `icon-top` and vice versa.

icon-top The screen position of the top edge of the frame's icon, in pixels, counting from the top edge of the screen. This takes effect when the frame is iconified, if the window manager supports this feature.

user-position

When you create a frame and specify its screen position with the `left` and `top` parameters, use this parameter to say whether the specified position was user-specified (explicitly requested in some way by a human user) or merely program-specified (chosen by a program). A non-`nil` value says the position was user-specified.

Window managers generally heed user-specified positions, and some heed program-specified positions too. But many ignore program-specified positions, placing the window in a default fashion or letting the user place it with the mouse. Some window managers, including `twm`, let the user specify whether to obey program-specified positions or ignore them.

When you call `make-frame`, you should specify a non-`nil` value for this parameter if the values of the `left` and `top` parameters represent the user's stated preference; otherwise, use `nil`.

z-group This parameter specifies a relative position of the frame's window-system window in the stacking (Z-) order of the frame's display.

If this is `above`, the window-system will display the window that corresponds to the frame above all other window-system windows that do not have the `above` property set. If this is `nil`, the frame's window is displayed below all windows that have the `above` property set and above all windows that have the `below` property set. If this is `below`, the frame's window is displayed below all windows that do not have the `below` property set.

To position the frame above or below a specific other frame use the function `frame-restack` (see Section 30.12 [Raising and Lowering], page 829).

30.4.3.3 Size Parameters

Frame parameters usually specify frame sizes in character units. On graphical displays, the `default` face determines the actual pixel sizes of these character units (see Section 41.12.1 [Face Attributes], page 1164).

width This parameter specifies the width of the frame. It can be specified as in the following ways:

an integer A positive integer specifies the width of the frame’s text area (see Section 30.3 [Frame Geometry], page 791) in characters.

a cons cell If this is a cons cell with the symbol `text-pixels` in its CAR, the CDR of that cell specifies the width of the frame’s text area in pixels.

a floating-point value

A floating-point number between 0.0 and 1.0 can be used to specify the width of a frame via its *width ratio*—the ratio of its outer width (see Section 30.3 [Frame Geometry], page 791) to the width of the frame’s workarea (see Section 30.2 [Multiple Terminals], page 787) or its parent frame’s (see Section 30.14 [Child Frames], page 831) native frame. Thus, a value of 0.5 makes the frame occupy half of the width of its workarea or parent frame, a value of 1.0 the full width. Similarly, the *height ratio* of a frame is the ratio of its outer height to the height of its workarea or its parent’s native frame.

Emacs will try to keep the width and height ratio of a child frame unaltered if that frame has a non-`nil` `keep-ratio` parameter (see Section 30.4.3.6 [Frame Interaction Parameters], page 812) and its parent frame is resized.

Since the outer size of a frame is usually unavailable before a frame has been made visible, it is generally not advisable to use floating-point values when creating decorated frames. Floating-point values are more suited to ensure that a child frame always fits within the area of its parent frame as, for example, when customizing `display-buffer-alist` (see Section 29.13.1 [Choosing Window], page 724) via `display-buffer-in-child-frame`.

Regardless of how this parameter was specified, functions reporting the value of this parameter like `frame-parameters` always report the width of the frame’s text area in characters as an integer rounded, if necessary, to a multiple of the frame’s default character width. That value is also used by the desktop saving routines.

height This parameter specifies the height of the frame. It works just like `width`, except vertically instead of horizontally.

user-size

This does for the size parameters `height` and `width` what the `user-position` parameter (see Section 30.4.3.2 [Position Parameters], page 805) does for the position parameters `top` and `left`.

min-width

This parameter specifies the minimum native width (see Section 30.3 [Frame Geometry], page 791) of the frame, in characters. Normally, the functions that establish a frame’s initial width or resize a frame horizontally make sure that all the frame’s windows, vertical scroll bars, fringes, margins and vertical dividers can be displayed. This parameter, if non-`nil` allows to make a frame narrower than that with the consequence that any components that do not fit will be clipped by the window manager.

min-height

This parameter specifies the minimum native height (see Section 30.3 [Frame Geometry], page 791) of the frame, in characters. Normally, the functions that establish a frame’s initial size or resize a frame make sure that all the frame’s windows, horizontal scroll bars and dividers, mode and header lines, the echo area and the internal menu and tool bar can be displayed. This parameter, if non-`nil` allows to make a frame smaller than that with the consequence that any components that do not fit will be clipped by the window manager.

fullscreen

This parameter specifies whether to maximize the frame’s width, height or both. Its value can be `fullwidth`, `fullheight`, `fullboth`, or `maximized`.¹ A `fullwidth` frame is as wide as possible, a `fullheight` frame is as tall as possible, and a `fullboth` frame is both as wide and as tall as possible. A `maximized` frame is like a “`fullboth`” frame, except that it usually keeps its title bar and the buttons for resizing and closing the frame. Also, maximized frames typically avoid hiding any task bar or panels displayed on the desktop. A “`fullboth`” frame, on the other hand, usually omits the title bar and occupies the entire available screen space.

Full-height and full-width frames are more similar to maximized frames in this regard. However, these typically display an external border which might be absent with maximized frames. Hence the heights of maximized and full-height frames and the widths of maximized and full-width frames often differ by a few pixels.

With some window managers you may have to customize the variable `frame-resize-pixelwise` (see Section 30.3.4 [Frame Size], page 799) in order to make a frame truly appear maximized or full-screen. Moreover, some window managers might not support smooth transition between the various full-screen or maximization states. Customizing the variable `x-frame-normalize-before-maximize` can help to overcome that.

Full-screen on macOS hides both the tool-bar and the menu-bar, however both will be displayed if the mouse pointer is moved to the top of the screen.

fullscreen-restore

This parameter specifies the desired fullscreen state of the frame after invoking the `toggle-frame-fullscreen` command (see Section “Frame Commands” in *The GNU Emacs Manual*) in the “`fullboth`” state. Normally this parameter is

¹ On PGTK frames, setting the values `fullheight` and `fullwidth` has no effect.

installed automatically by that command when toggling the state to fullboth. If, however, you start Emacs in the “fullboth” state, you have to specify the desired behavior in your initial file as, for example

```
(setq default-frame-alist
      '((fullscreen . fullboth)
        (fullscreen-restore . fullheight)))
```

This will give a new frame full height after typing in it F11 for the first time.

fit-frame-to-buffer-margins

This parameter allows to override the value of the option **fit-frame-to-buffer-margins** when fitting this frame to the buffer of its root window with **fit-frame-to-buffer** (see Section 29.5 [Resizing Windows], page 703).

fit-frame-to-buffer-sizes

This parameter allows to override the value of the option **fit-frame-to-buffer-sizes** when fitting this frame to the buffer of its root window with **fit-frame-to-buffer** (see Section 29.5 [Resizing Windows], page 703).

30.4.3.4 Layout Parameters

These frame parameters enable or disable various parts of the frame, or control their sizes.

border-width

The width in pixels of the frame’s outer border (see Section 30.3 [Frame Geometry], page 791).

internal-border-width

The width in pixels of the frame’s internal border (see Section 30.3 [Frame Geometry], page 791).

child-frame-border-width

The width in pixels of the frame’s internal border (see Section 30.3 [Frame Geometry], page 791) if the given frame is a child frame (see Section 30.14 [Child Frames], page 831). If this is **nil**, the value specified by the **internal-border-width** parameter is used instead.

vertical-scroll-bars

Whether the frame has scroll bars (see Section 41.14 [Scroll Bars], page 1195) for vertical scrolling, and which side of the frame they should be on. The possible values are **left**, **right**, and **nil** for no scroll bars.

horizontal-scroll-bars

Whether the frame has scroll bars for horizontal scrolling (**t** and **bottom** mean yes, **nil** means no).

scroll-bar-width

The width of vertical scroll bars, in pixels, or **nil** meaning to use the default width.

scroll-bar-height

The height of horizontal scroll bars, in pixels, or **nil** meaning to use the default height.

left-fringe
right-fringe

The default width of the left and right fringes of windows in this frame (see Section 41.13 [Fringes], page 1189). If either of these is zero, that effectively removes the corresponding fringe.

When you use `frame-parameter` to query the value of either of these two frame parameters, the return value is always an integer. When using `set-frame-parameter`, passing a `nil` value imposes an actual default value of 8 pixels.

right-divider-width

The width (thickness) reserved for the right divider (see Section 41.15 [Window Dividers], page 1198) of any window on the frame, in pixels. A value of zero means to not draw right dividers.

bottom-divider-width

The width (thickness) reserved for the bottom divider (see Section 41.15 [Window Dividers], page 1198) of any window on the frame, in pixels. A value of zero means to not draw bottom dividers.

menu-bar-lines

The number of lines to allocate at the top of the frame for a menu bar (see Section 23.18.5 [Menu Bar], page 516). The default is one if Menu Bar mode is enabled and zero otherwise. See Section “Menu Bars” in *The GNU Emacs Manual*. For an external menu bar (see Section 30.3.1 [Frame Layout], page 791), this value remains unchanged even when the menu bar wraps to two or more lines. In that case, the `menu-bar-size` value returned by `frame-geometry` (see Section 30.3 [Frame Geometry], page 791) allows to derive whether the menu bar actually occupies one or more lines.

tool-bar-lines

The number of lines to use for the tool bar (see Section 23.18.6 [Tool Bar], page 517). The default is one if Tool Bar mode is enabled and zero otherwise. See Section “Tool Bars” in *The GNU Emacs Manual*. This value may change whenever the tool bar wraps (see Section 30.3.1 [Frame Layout], page 791).

tool-bar-position

The position of the tool bar when Emacs was built with GTK+. Its value can be one of `top`, `bottom`, `left`, `right`. The default is `top`.

tab-bar-lines

The number of lines to use for the tab bar (see Section “Tab Bars” in *The GNU Emacs Manual*). The default is one if Tab Bar mode is enabled and zero otherwise. This value may change whenever the tab bar wraps (see Section 30.3.1 [Frame Layout], page 791).

line-spacing

Additional space to leave below each text line, in pixels (a positive integer). See Section 41.11 [Line Height], page 1162, for more information.

no-special-glyphs

If this is non-`nil`, it suppresses the display of any truncation (see Section 41.3 [Truncation], page 1130) and continuation glyphs for all the buffers displayed

by this frame. This is useful to eliminate such glyphs when fitting a frame to its buffer via `fit-frame-to-buffer` (see Section 29.5 [Resizing Windows], page 703). This frame parameter has effect only for GUI frames shown on graphical displays, and only if the fringes are disabled. This parameter is intended as a purely-presentation feature, and in particular should not be used for frames where the user can interactively insert text, or more generally where the cursor is shown. A notable example of frames where this is used is tooltip frames (see Section 41.26 [Tooltips], page 1249).

30.4.3.5 Buffer Parameters

These frame parameters, meaningful on all kinds of terminals, deal with which buffers have been, or should, be displayed in the frame.

`minibuffer`

Whether this frame has its own minibuffer. The value `t` means yes, `nil` means no, `only` means this frame is just a minibuffer. If the value is a minibuffer window (in some other frame), the frame uses that minibuffer.

This parameter takes effect when the frame is created. If specified as `nil`, Emacs will try to set it to the minibuffer window of `default-minibuffer-frame` (see Section 30.9 [Minibuffers and Frames], page 824). For an existing frame, this parameter can be used exclusively to specify another minibuffer window. It is not allowed to change it from a minibuffer window to `t` and vice-versa, or from `t` to `nil`. If the parameter specifies a minibuffer window already, setting it to `nil` has no effect.

The special value `child-frame` means to make a minibuffer-only child frame (see Section 30.14 [Child Frames], page 831) whose parent becomes the frame created. As if specified as `nil`, Emacs will set this parameter to the minibuffer window of the child frame but will not select the child frame after its creation.

`buffer-predicate`

The buffer-predicate function for this frame. The function `other-buffer` uses this predicate (from the selected frame) to decide which buffers it should consider, if the predicate is not `nil`. It calls the predicate with one argument, a buffer, once for each buffer; if the predicate returns a non-`nil` value, it considers that buffer.

`buffer-list`

A list of buffers that have been selected in this frame, ordered most-recently-selected first.

`unsplittable`

If non-`nil`, this frame's window is never split automatically.

30.4.3.6 Frame Interaction Parameters

These parameters supply forms of interactions between different frames.

`parent-frame`

If non-`nil`, this means that this frame is a child frame (see Section 30.14 [Child Frames], page 831), and this parameter specifies its parent frame. If `nil`, this means that this frame is a normal, top-level frame.

delete-before

If non-`nil`, this parameter specifies another frame whose deletion will automatically trigger the deletion of this frame. See Section 30.7 [Deleting Frames], page 822.

mouse-wheel-frame

If non-`nil`, this parameter specifies the frame whose windows will be scrolled whenever the mouse wheel is scrolled with the mouse pointer hovering over this frame, see Section “Mouse Commands” in *The GNU Emacs Manual*.

no-other-frame

If this is non-`nil`, then this frame is not eligible as candidate for the functions `next-frame`, `previous-frame` (see Section 30.8 [Finding All Frames], page 823) and `other-frame`, see Section “Frame Commands” in *The GNU Emacs Manual*.

auto-hide-function

When this parameter specifies a function, that function will be called instead of the function specified by the variable `frame-auto-hide-function` when quitting the frame’s only window (see Section 29.16 [Quitting Windows], page 749) and there are other frames left.

minibuffer-exit

When this parameter is non-`nil`, Emacs will by default make this frame invisible whenever the minibuffer (see Chapter 21 [Minibuffers], page 385) is exited. Alternatively, it can specify the functions `iconify-frame` and `delete-frame`. This parameter is useful to make a child frame disappear automatically (similar to how Emacs deals with a window) when exiting the minibuffer.

keep-ratio

This parameter is currently meaningful for child frames (see Section 30.14 [Child Frames], page 831) only. If it is non-`nil`, then Emacs will try to keep the frame’s size (width and height) ratios (see Section 30.4.3.3 [Size Parameters], page 808) as well as its left and right position ratios (see Section 30.4.3.2 [Position Parameters], page 805) unaltered whenever its parent frame is resized.

If the value of this parameter is `nil`, the frame’s position and size remain unaltered when the parent frame is resized, so the position and size ratios may change. If the value of this parameter is `t`, Emacs will try to preserve the frame’s size and position ratios, hence the frame’s size and position relative to its parent frame may change.

More individual control is possible by using a cons cell: In that case the frame’s width ratio is preserved if the CAR of the cell is either `t` or `width-only`. The height ratio is preserved if the CAR of the cell is either `t` or `height-only`. The left position ratio is preserved if the CDR of the cell is either `t` or `left-only`. The top position ratio is preserved if the CDR of the cell is either `t` or `top-only`.

30.4.3.7 Mouse Dragging Parameters

The parameters described below provide support for resizing a frame by dragging its internal borders with the mouse. They also allow moving a frame with the mouse by dragging the header or tab line of its topmost or the mode line of its bottommost window.

These parameters are mostly useful for child frames (see Section 30.14 [Child Frames], page 831) that come without window manager decorations. If necessary, they can be used for undecorated top-level frames as well.

drag-internal-border

If non-*nil*, the frame can be resized by dragging its internal borders, if present, with the mouse.

drag-with-header-line

If non-*nil*, the frame can be moved with the mouse by dragging the header line of its topmost window.

drag-with-tab-line

If non-*nil*, the frame can be moved with the mouse by dragging the tab line of its topmost window.

drag-with-mode-line

If non-*nil*, the frame can be moved with the mouse by dragging the mode line of its bottommost window. Note that such a frame is not allowed to have its own minibuffer window.

snap-width

A frame that is moved with the mouse will “snap” at the border(s) of the display or its parent frame whenever it is dragged as near to such an edge as the number of pixels specified by this parameter.

top-visible

If this parameter is a number, the top edge of the frame never appears above the top edge of its display or parent frame. Moreover, as many pixels of the frame as specified by that number will remain visible when the frame is moved against any of the remaining edges of its display or parent frame. Setting this parameter is useful to guard against dragging a child frame with a non-*nil* **drag-with-header-line** parameter completely out of the area of its parent frame.

bottom-visible

If this parameter is a number, the bottom edge of the frame never appears below the bottom edge of its display or parent frame. Moreover, as many pixels of the frame as specified by that number will remain visible when the frame is moved against any of the remaining edges of its display or parent frame. Setting this parameter is useful to guard against dragging a child frame with a non-*nil* **drag-with-mode-line** parameter completely out of the area of its parent frame.

30.4.3.8 Window Management Parameters

The following frame parameters control various aspects of the frame’s interaction with the window manager or window system. They have no effect on text terminals.

visibility

The state of visibility of the frame. There are three possibilities: *nil* for invisible, *t* for visible, and *icon* for iconified. See Section 30.11 [Visibility of Frames], page 828.

auto-raise

If non-*nil*, Emacs automatically raises the frame when it is selected. Some window managers do not allow this.

auto-lower

If non-*nil*, Emacs automatically lowers the frame when it is deselected. Some window managers do not allow this.

icon-type

The type of icon to use for this frame. If the value is a string, that specifies a file containing a bitmap to use; *nil* specifies no icon (in which case the window manager decides what to show); any other non-*nil* value specifies the default Emacs icon.

icon-name

The name to use in the icon for this frame, when and if the icon appears. If this is *nil*, the frame's title is used.

window-id

The ID number which the graphical display uses for this frame. Emacs assigns this parameter when the frame is created; changing the parameter has no effect on the actual ID number.

outer-window-id

The ID number of the outermost window-system window in which the frame exists. As with **window-id**, changing this parameter has no actual effect.

wait-for-wm

If non-*nil*, tell Xt to wait for the window manager to confirm geometry changes. Some window managers, including versions of Fvwm2 and KDE, fail to confirm, so Xt hangs. Set this to *nil* to prevent hanging with those window managers.

sticky

If non-*nil*, the frame is visible on all virtual desktops on systems with virtual desktops.

shaded

If non-*nil*, tell the window manager to display the frame in a way that its contents are hidden, leaving only the title bar.

use-frame-synchronization

If non-*nil*, synchronize the frame redisplay with the refresh rate of the monitor to avoid graphics tearing. At present, this is only implemented on Haiku and the X window system inside no-toolkit and X toolkit builds, does not work correctly with toolkit scroll bars, and requires a compositing manager supporting the relevant display synchronization protocols. The **synchronizeResize** X resource must also be set to the string "extended".

inhibit-double-buffering

If non-*nil*, the frame is drawn to the screen without double buffering. Emacs normally attempts to use double buffering, where available, to reduce flicker. Set this property if you experience display bugs or pine for that retro, flicker-y feeling.

skip-taskbar

If non-`nil`, this tells the window manager to remove the frame's icon from the taskbar associated with the frame's display and inhibit switching to the frame's window via the combination `Alt-TAB`. On MS-Windows, iconifying such a frame will "roll in" its window-system window at the bottom of the desktop. Some window managers may not honor this parameter.

no-focus-on-map

If non-`nil`, this means that the frame does not want to receive input focus when it is mapped (see Section 30.11 [Visibility of Frames], page 828). Some window managers may not honor this parameter.

no-accept-focus

If non-`nil`, this means that the frame does not want to receive input focus via explicit mouse clicks or when moving the mouse into it either via `focus-follows-mouse` (see Section 30.10 [Input Focus], page 824) or `mouse-autoselect-window` (see Section 29.25 [Mouse Window Auto-selection], page 773). This may have the unwanted side-effect that a user cannot scroll a non-selected frame with the mouse. Some window managers may not honor this parameter. On Haiku, it also has the side-effect that the window will not be able to receive any keyboard input from the user, not even if the user switches to the frame using the key combination `Alt-TAB`.

undecorated

If non-`nil`, this frame's window-system window is drawn without decorations, like the title, minimize/maximize boxes and external borders. This usually means that the window cannot be dragged, resized, iconified, maximized or deleted with the mouse. If `nil`, the frame's window is usually drawn with all the elements listed above unless their display has been suspended via window manager settings.

Under X, Emacs uses the Motif window manager hints to turn off decorations. Some window managers may not honor these hints.

NS builds consider the tool bar to be a decoration, and therefore hide it on an undecorated frame.

override-redirect

If non-`nil`, this means that this is an *override redirect* frame—a frame not handled by window managers under X. Override redirect frames have no window manager decorations, can be positioned and resized only via Emacs' positioning and resizing functions and are usually drawn on top of all other frames. Setting this parameter has no effect on MS-Windows.

ns-appearance

Only available on macOS, if set to `dark` draw this frame's window-system window using the "vibrant dark" theme, and if set to `light` use the "aqua" theme, otherwise use the system default. The "vibrant dark" theme can be used to set the toolbar and scrollbars to a dark appearance when using an Emacs theme with a dark background.

ns-transparent-titlebar

Only available on macOS, if non-`nil`, set the titlebar and toolbar to be transparent. This effectively sets the background color of both to match the Emacs background color.

30.4.3.9 Cursor Parameters

This frame parameter controls the way the cursor looks.

cursor-type

How to display the cursor. Legitimate values are:

`box` Display a filled box. (This is the default.)

`(box . size)`

Display a filled box. However, display it as a hollow box if point is under masked image larger than `size` pixels in either dimension.

`hollow` Display a hollow box.

`nil` Don't display a cursor.

`bar` Display a vertical bar between characters.

`(bar . width)`

Display a vertical bar `width` pixels wide between characters.

`hbar` Display a horizontal bar.

`(hbar . height)`

Display a horizontal bar `height` pixels high.

The `cursor-type` frame parameter may be overridden by the variables `cursor-type` and `cursor-in-non-selected-windows`:

cursor-type

[User Option]

This buffer-local variable controls how the cursor looks in a selected window showing the buffer. If its value is `t`, that means to use the cursor specified by the `cursor-type` frame parameter. Otherwise, the value should be one of the cursor types listed above, and it overrides the `cursor-type` frame parameter.

cursor-in-non-selected-windows

[User Option]

This buffer-local variable controls how the cursor looks in a window that is not selected. It supports the same values as the `cursor-type` frame parameter; also, `nil` means don't display a cursor in nonselected windows, and `t` (the default) means use a standard modification of the usual cursor type (solid box becomes hollow box, and bar becomes a narrower bar).

x-stretch-cursor

[User Option]

This variable controls the width of the block cursor displayed on extra-wide glyphs such as a tab or a stretch of white space. By default, the block cursor is only as wide as the font's default character, and will not cover all of the width of the glyph under it if that glyph is extra-wide. A non-`nil` value of this variable means draw the block cursor as wide as the glyph under it. The default value is `nil`.

This variable has no effect on text-mode frames, since the text-mode cursor is drawn by the terminal out of Emacs's control.

blink-cursor-alist

[User Option]

This variable specifies how to blink the cursor. Each element has the form (*on-state* . *off-state*). Whenever the cursor type equals *on-state* (comparing using `equal`), the corresponding *off-state* specifies what the cursor looks like when it blinks off. Both *on-state* and *off-state* should be suitable values for the `cursor-type` frame parameter. There are various defaults for how to blink each type of cursor, if the type is not mentioned as an *on-state* here. Changes in this variable do not take effect immediately, only when you specify the `cursor-type` frame parameter.

30.4.3.10 Font and Color Parameters

These frame parameters control the use of fonts and colors.

font-backend

A list of symbols, specifying the *font backends* to use for drawing characters on the frame, in order of priority. In Emacs built without Cairo drawing on X, there are currently three potentially available font backends: `x` (the X core font driver), `xft` (the Xft font driver), and `xfthb` (the Xft font driver with HarfBuzz text shaping). If built with Cairo drawing, there are also three potentially available font backends on X: `x`, `ftcr` (the FreeType font driver on Cairo), and `ftcrhb` (the FreeType font driver on Cairo with HarfBuzz text shaping). When Emacs is built with HarfBuzz, the default font driver is `ftcrhb`, although use of the `ftcr` driver is still possible, but not recommended. On MS-Windows, there are currently three available font backends: `gdi` (the core MS-Windows font driver), `uniscribe` (font driver for OTF and TTF fonts with text shaping by the Uniscribe engine), and `harfbuzz` (font driver for OTF and TTF fonts with HarfBuzz text shaping) (see Section “Windows Fonts” in *The GNU Emacs Manual*). The `harfbuzz` driver is similarly recommended. On Haiku, there can be several font drivers (see Section “Haiku Fonts” in *The GNU Emacs Manual*). On other systems, there is only one available font backend, so it does not make sense to modify this frame parameter.

background-mode

This parameter is either `dark` or `light`, according to whether the background color is a light one or a dark one.

tty-color-mode

This parameter overrides the terminal’s color support as given by the system’s terminal capabilities database in that this parameter’s value specifies the color mode to use on a text terminal. The value can be either a symbol or a number. A number specifies the number of colors to use (and, indirectly, what commands to issue to produce each color). For example, (`tty-color-mode . 8`) specifies use of the ANSI escape sequences for 8 standard text colors. A value of `-1` turns off color support.

If the parameter’s value is a symbol, it specifies a number through the value of `tty-color-mode-alist`, and the associated number is used instead.

screen-gamma

If this is a number, Emacs performs gamma correction which adjusts the brightness of all colors. The value should be the screen gamma of your display.

Usual PC monitors have a screen gamma of 2.2, so color values in Emacs, and in X windows generally, are calibrated to display properly on a monitor with that gamma value. If you specify 2.2 for `screen-gamma`, that means no correction is needed. Other values request correction, designed to make the corrected colors appear on your screen the way they would have appeared without correction on an ordinary monitor with a gamma value of 2.2.

If your monitor displays colors too light, you should specify a `screen-gamma` value smaller than 2.2. This requests correction that makes colors darker. A screen gamma value of 1.5 may give good results for LCD color displays.

alpha This parameter specifies the opacity of the frame, on graphical displays that support variable opacity. It should be an integer between 0 and 100, where 0 means completely transparent and 100 means completely opaque. It can also have a `nil` value, which tells Emacs not to set the frame opacity (leaving it to the window manager).

To prevent the frame from disappearing completely from view, the variable `frame-alpha-lower-limit` defines a lower opacity limit. If the value of the frame parameter is less than the value of this variable, Emacs uses the latter. By default, `frame-alpha-lower-limit` is 20.

The `alpha` frame parameter can also be a cons cell (`active . inactive`), where `active` is the opacity of the frame when it is selected, and `inactive` is the opacity when it is not selected.

Some window systems do not support the `alpha` parameter for child frames (see Section 30.14 [Child Frames], page 831).

alpha-background

Sets the background transparency of the frame. Unlike the `alpha` frame parameter, this only controls the transparency of the background while keeping foreground elements such as text fully opaque. It should be an integer between 0 and 100, where 0 means completely transparent and 100 means completely opaque (default).

The following frame parameters are semi-obsolete in that they are automatically equivalent to particular face attributes of particular faces (see Section “Standard Faces” in *The Emacs Manual*):

font The name of the font for displaying text in the frame. This is a string, either a valid font name for your system or the name of an Emacs fontset (see Section 41.12.11 [Fontsets], page 1182). It is equivalent to the `font` attribute of the `default` face.

foreground-color

The color to use for characters. It is equivalent to the `:foreground` attribute of the `default` face.

background-color

The color to use for the background of characters. It is equivalent to the `:background` attribute of the `default` face.

mouse-color

The color for the mouse pointer. It is equivalent to the `:background` attribute of the `mouse` face.

cursor-color

The color for the cursor that shows point. It is equivalent to the `:background` attribute of the `cursor` face.

border-color

The color for the border of the frame. It is equivalent to the `:background` attribute of the `border` face.

scroll-bar-foreground

If non-`nil`, the color for the foreground of scroll bars. It is equivalent to the `:foreground` attribute of the `scroll-bar` face.

scroll-bar-background

If non-`nil`, the color for the background of scroll bars. It is equivalent to the `:background` attribute of the `scroll-bar` face.

30.4.4 Geometry

Here's how to examine the data in an X-style window geometry specification:

x-parse-geometry geom

[Function]

The function `x-parse-geometry` converts a standard X window geometry string to an alist that you can use as part of the argument to `make-frame`.

The alist describes which parameters were specified in `geom`, and gives the values specified for them. Each element looks like `(parameter . value)`. The possible `parameter` values are `left`, `top`, `width`, and `height`.

For the size parameters, the value must be an integer. The position parameter names `left` and `top` are not totally accurate, because some values indicate the position of the right or bottom edges instead. The `value` possibilities for the position parameters are: an integer, a list `(+ pos)`, or a list `(- pos)`; as previously described (see Section 30.4.3.2 [Position Parameters], page 805).

Here is an example:

```
(x-parse-geometry "35x70+0-0")
⇒ ((height . 70) (width . 35)
    (top - 0) (left . 0))
```

30.5 Terminal Parameters

Each terminal has a list of associated parameters. These *terminal parameters* are mostly a convenient way of storage for terminal-local variables, but some terminal parameters have a special meaning.

This section describes functions to read and change the parameter values of a terminal. They all accept as their argument either a terminal or a frame; the latter means use that frame's terminal. An argument of `nil` means the selected frame's terminal.

terminal-parameters &optional terminal

[Function]

This function returns an alist listing all the parameters of `terminal` and their values.

terminal-parameter *terminal parameter* [Function]

This function returns the value of the parameter *parameter* (a symbol) of *terminal*. If *terminal* has no setting for *parameter*, this function returns `nil`.

set-terminal-parameter *terminal parameter value* [Function]

This function sets the parameter *parameter* of *terminal* to the specified *value*, and returns the previous value of that parameter.

Here's a list of a few terminal parameters that have a special meaning:

background-mode

The classification of the terminal's background color, either `light` or `dark`.

normal-erase-is-backspace

Value is either 1 or 0, depending on whether `normal-erase-is-backspace-mode` is turned on or off on this terminal. See Section “DEL Does Not Delete” in *The Emacs Manual*.

terminal-initiated

After the terminal is initialized, this is set to the terminal-specific initialization function.

tty-mode-set-strings

When present, a list of strings containing escape sequences that Emacs will output while configuring a tty for rendering. Emacs emits these strings only when configuring a terminal: if you want to enable a mode on a terminal that is already active (for example, while in `tty-setup-hook`), explicitly output the necessary escape sequence using `send-string-to-terminal` in addition to adding the sequence to `tty-mode-set-strings`.

tty-mode-reset-strings

When present, a list of strings that undo the effects of the strings in `tty-mode-set-strings`. Emacs emits these strings when exiting, deleting a terminal, or suspending itself.

30.6 Frame Titles

Every frame has a `name` parameter; this serves as the default for the frame title which window systems typically display at the top of the frame. You can specify a name explicitly by setting the `name` frame property.

Normally you don't specify the name explicitly, and Emacs computes the frame name automatically based on a template stored in the variable `frame-title-format`. Emacs recomputes the name each time the frame is redisplayed.

frame-title-format [Variable]

This variable specifies how to compute a name for a frame when you have not explicitly specified one (via the frame's parameters; see Section 30.4.3.1 [Basic Parameters], page 805). The variable's value is actually a mode line construct, just like `mode-line-format`, except that the '%c', '%C', and '%l' constructs are ignored. See Section 24.4.2 [Mode Line Data], page 551.

icon-title-format

[Variable]

This variable specifies how to compute the name for an iconified frame when you have not explicitly specified the frame's name via the frame's parameters. The resulting title appears in the frame's icon itself. If the value is a string, it should be a mode line construct like that of `frame-title-format`. The value can also be `t`, which means to use `frame-title-format` instead; this avoids problems with some window managers and desktop environments, where a change in a frame's title (when a frame is iconified) is interpreted as a request to raise the frame and/or give it input focus. It is also useful if you want the frame's title to be the same no matter if the frame is iconified or not. The default value is a string identical to the default value of `frame-title-format`.

multiple-frames

[Variable]

This variable is set automatically by Emacs. Its value is `t` when there are two or more frames (not counting minibuffer-only frames or invisible frames). The default value of `frame-title-format` uses `multiple-frames` so as to put the buffer name in the frame title only when there is more than one frame.

The value of this variable is not guaranteed to be accurate except while processing `frame-title-format` or `icon-title-format`.

30.7 Deleting Frames

A *live frame* is one that has not been deleted. When a frame is deleted, it is removed from its terminal display, although it may continue to exist as a Lisp object until there are no more references to it.

delete-frame &optional frame force

[Command]

This function deletes the frame `frame`. The argument `frame` must specify a live frame (see below) and defaults to the selected frame.

It first deletes any child frame of `frame` (see Section 30.14 [Child Frames], page 831) and any frame whose `delete-before` frame parameter (see Section 30.4.3.6 [Frame Interaction Parameters], page 812) specifies `frame`. All such deletions are performed recursively; so this step makes sure that no other frames with `frame` as their ancestor will exist. Then, unless `frame` specifies a tooltip, this function runs the hook `delete-frame-functions` (each function getting one argument, `frame`) before actually killing the frame. After actually killing the frame and removing the frame from the frame list, `delete-frame` runs `after-delete-frame-functions`.

Note that a frame cannot be deleted as long as its minibuffer serves as surrogate minibuffer for another frame (see Section 30.9 [Minibuffers and Frames], page 824). Normally, you cannot delete a frame if all other frames are invisible, but if `force` is `non-nil`, then you are allowed to do so.

frame-live-p frame

[Function]

This function returns `non-nil` if the frame `frame` has not been deleted. The possible `non-nil` return values are like those of `framep`. See Chapter 30 [Frames], page 785.

Some window managers provide a command to delete a window. These work by sending a special message to the program that operates the window. When Emacs gets one of these commands, it generates a `delete-frame` event, whose normal definition is a command that calls the function `delete-frame`. See Section 22.7.12 [Misc Events], page 450.

delete-other-frames &optional frame iconify [Command]

This command deletes all frames on *frame*'s terminal, except *frame*. If *frame* uses another frame's minibuffer, that minibuffer frame is left untouched. The argument *frame* must specify a live frame and defaults to the selected frame. Internally, this command works by calling **delete-frame** with *force nil* for all frames that shall be deleted.

This function does not delete any of *frame*'s child frames (see Section 30.14 [Child Frames], page 831). If *frame* is a child frame, it deletes *frame*'s siblings only.

With the prefix argument *iconify*, the frames are iconified rather than deleted.

30.8 Finding All Frames

frame-list [Function]

This function returns a list of all the live frames, i.e., those that have not been deleted. It is analogous to **buffer-list** for buffers, and includes frames on all terminals. The list that you get is newly created, so modifying the list doesn't have any effect on the internals of Emacs.

visible-frame-list [Function]

This function returns a list of just the currently visible frames. See Section 30.11 [Visibility of Frames], page 828. Frames on text terminals always count as visible, even though only the selected one is actually displayed.

frame-list-z-order &optional display [Function]

This function returns a list of Emacs' frames, in Z (stacking) order (see Section 30.12 [Raising and Lowering], page 829). The optional argument *display* specifies which display to poll. *display* should be either a frame or a display name (a string). If omitted or *nil*, that stands for the selected frame's display. It returns *nil* if *display* contains no Emacs frame.

Frames are listed from topmost (first) to bottommost (last). As a special case, if *display* is non-*nil* and specifies a live frame, it returns the child frames of that frame in Z (stacking) order.

This function is not meaningful on text terminals.

next-frame &optional frame minibuf [Function]

This function lets you cycle conveniently through all the frames on a specific terminal from an arbitrary starting point. It returns the frame following *frame*, in the list of all live frames, on *frame*'s terminal. The argument *frame* must specify a live frame and defaults to the selected frame. It never returns a frame whose **no-other-frame** parameter (see Section 30.4.3.6 [Frame Interaction Parameters], page 812) is non-*nil*.

The second argument, *minibuf*, says which frames to consider when deciding what the next frame should be:

nil Consider all frames except minibuffer-only frames.

visible Consider only visible frames.

0 Consider only visible or iconified frames.

a window Consider only the frames using that particular window as their minibuffer window.

anything else Consider all frames.

previous-frame &optional frame minibuf [Function]

Like `next-frame`, but cycles through all frames in the opposite direction.

See also `next-window` and `previous-window`, in Section 29.10 [Cyclic Window Ordering], page 717.

Some Lisp programs need to find one or more frames that satisfy a given criteria. The function `filtered-frame-list` is provided for this purpose.

filtered-frame-list predicate [Function]

This function returns the list of all the live frames which satisfy the specified *predicate*. The argument *predicate* must be a function of one argument, a frame to be tested against the filtering criteria, and should return `non-nil` if the frame satisfies the criteria.

30.9 Minibuffers and Frames

Normally, each frame has its own minibuffer window at the bottom, which is used whenever that frame is selected. You can get that window with the function `minibuffer-window` (see Section 21.11 [Minibuffer Windows], page 418).

However, you can also create a frame without a minibuffer. Such a frame must use the minibuffer window of some other frame. That other frame will serve as *surrogate minibuffer frame* for this frame and cannot be deleted via `delete-frame` (see Section 30.7 [Deleting Frames], page 822) as long as this frame is live.

When you create the frame, you can explicitly specify its minibuffer window (in some other frame) with the `minibuffer` frame parameter (see Section 30.4.3.5 [Buffer Parameters], page 812). If you don't, then the minibuffer is found in the frame which is the value of the variable `default-minibuffer-frame`. Its value should be a frame that does have a minibuffer.

If you use a minibuffer-only frame, you might want that frame to raise when you enter the minibuffer. If so, set the variable `minibuffer-auto-raise` to `t`. See Section 30.12 [Raising and Lowering], page 829.

default-minibuffer-frame [Variable]

This variable specifies the frame to use for the minibuffer window, by default. It does not affect existing frames. It is always local to the current terminal and cannot be buffer-local. See Section 30.2 [Multiple Terminals], page 787.

30.10 Input Focus

At any time, one frame in Emacs is the *selected frame*. The selected window (see Section 29.3 [Selecting Windows], page 696) always resides on the selected frame.

When Emacs displays its frames on several terminals (see Section 30.2 [Multiple Terminals], page 787), each terminal has its own selected frame. But only one of these is the selected

frame: it's the frame that belongs to the terminal from which the most recent input came. That is, when Emacs runs a command that came from a certain terminal, the selected frame is the one of that terminal. Since Emacs runs only a single command at any given time, it needs to consider only one selected frame at a time; this frame is what we call *the selected frame* in this manual. The display on which the selected frame is shown is the *selected frame's display*.

selected-frame

[Function]

This function returns the selected frame.

Some window systems and window managers direct keyboard input to the window object that the mouse is in; others require explicit clicks or commands to *shift the focus* to various window objects. Either way, Emacs automatically keeps track of which frames have focus. To explicitly switch to a different frame from a Lisp function, call **select-frame-set-input-focus**.

The plural “frames” in the previous paragraph is deliberate: while Emacs itself has only one selected frame, Emacs can have frames on many different terminals (recall that a connection to a window system counts as a terminal), and each terminal has its own idea of which frame has input focus. Under the X Window System, where user input is organized into individual “seats” of input, each seat in turn can have its own specific input focus. When you set the input focus to a frame, you set the focus for that frame's terminal on the last seat which interacted with Emacs, but frames on other terminals and seats may still remain focused.

If the input focus is set before any user interaction has occurred on the specified terminal, then the X server picks a random seat (normally the one with the lowest number) and sets the input focus there.

Lisp programs can switch frames temporarily by calling the function **select-frame**. This does not alter the window system's concept of focus; rather, it escapes from the window manager's control until that control is somehow reasserted.

When using a text terminal, only one frame can be displayed at a time on the terminal, so after a call to **select-frame**, the next redisplay actually displays the newly selected frame. This frame remains selected until a subsequent call to **select-frame**. Each frame on a text terminal has a number which appears in the mode line before the buffer name (see Section 24.4.4 [Mode Line Variables], page 554).

select-frame-set-input-focus frame &optional norecord

[Function]

This function selects *frame*, raises it (should it happen to be obscured by other frames) and tries to give it the window system's focus. On a text terminal, the next redisplay displays the new frame on the entire terminal screen. The optional argument *norecord* has the same meaning as for **select-frame** (see below). The return value of this function is not significant.

Ideally, the function described next should focus a frame without also raising it above other frames. Unfortunately, many window-systems or window managers may refuse to comply.

x-focus-frame frame &optional noactivate

[Function]

This function gives *frame* the focus of the X server without necessarily raising it. *frame nil* means use the selected frame. Under X, the optional argument *noactivate*, if

`non-nil`, means to avoid making *frame*'s window-system window the “active” window which should insist a bit more on avoiding to raise *frame* above other frames.

On MS-Windows the `noactivate` argument has no effect. However, if *frame* is a child frame (see Section 30.14 [Child Frames], page 831), this function usually focuses *frame* without raising it above other child frames.

If there is no window system support, this function does nothing.

select-frame *frame* &**optional** *norecord* [Command]

This function selects frame *frame*, temporarily disregarding the focus of the X server if any. The selection of *frame* lasts until the next time the user does something to select a different frame, or until the next time this function is called. (If you are using a window system, the previously selected frame may be restored as the selected frame after return to the command loop, because it still may have the window system's input focus.)

The specified *frame* becomes the selected frame, and its terminal becomes the selected terminal. This function then calls `select-window` as a subroutine, passing the window selected within *frame* as its first argument and *norecord* as its second argument (hence, if *norecord* is `non-nil`, this avoids changing the order of recently selected windows and the buffer list). See Section 29.3 [Selecting Windows], page 696.

This function returns *frame*, or `nil` if *frame* has been deleted.

In general, you should never use `select-frame` in a way that could switch to a different terminal without switching back when you're done.

Emacs cooperates with the window system by arranging to select frames as the server and window manager request. When a window system informs Emacs that one of its frames has been selected, Emacs internally generates a *focus-in* event. When an Emacs frame is displayed on a text-terminal emulator, such as `xterm`, which supports reporting of focus-change notification, the *focus-in* and *focus-out* events are available even for text-mode frames. Focus events are normally handled by `handle-focus-in`.

handle-focus-in *event* [Command]

This function handles focus-in events from window systems and terminals that support explicit focus notifications. It updates the per-frame focus flags that `frame-focus-state` queries and calls `after-focus-change-function`. In addition, it generates a `switch-frame` event in order to switch the Emacs notion of the selected frame to the frame most recently focused in some terminal. It's important to note that this switching of the Emacs selected frame to the most recently focused frame does not mean that other frames do not continue to have the focus in their respective terminals. Do not invoke this function yourself: instead, attach logic to `after-focus-change-function`.

handle-switch-frame *frame* [Command]

This function handles a switch-frame event, which Emacs generates for itself upon focus notification or under various other circumstances involving an input event arriving at a different frame from the last event. Do not invoke this function yourself.

redirect-frame-focus *frame* &**optional** *focus-frame* [Function]

This function redirects focus from *frame* to *focus-frame*. This means that *focus-frame* will receive subsequent keystrokes and events intended for *frame*. After such an

event, the value of `last-event-frame` will be *focus-frame*. Also, switch-frame events specifying *frame* will instead select *focus-frame*.

If *focus-frame* is omitted or `nil`, that cancels any existing redirection for *frame*, which therefore once again receives its own events.

One use of focus redirection is for frames that don't have minibuffers. These frames use minibuffers on other frames. Activating a minibuffer on another frame redirects focus to that frame. This puts the focus on the minibuffer's frame, where it belongs, even though the mouse remains in the frame that activated the minibuffer.

Selecting a frame can also change focus redirections. Selecting frame `bar`, when `foo` had been selected, changes any redirections pointing to `foo` so that they point to `bar` instead. This allows focus redirection to work properly when the user switches from one frame to another using `select-window`.

This means that a frame whose focus is redirected to itself is treated differently from a frame whose focus is not redirected. `select-frame` affects the former but not the latter.

The redirection lasts until `redirect-frame-focus` is called to change it.

`frame-focus-state frame`

[Function]

This function retrieves the last known focus state of *frame*.

It returns `nil` if the frame is known not to be focused, `t` if the frame is known to be focused, or `unknown` if Emacs does not know the focus state of the frame. (You may see this last state in TTY frames running on terminals that do not support explicit focus notifications.)

`after-focus-change-function`

[Variable]

This function is called with no arguments when Emacs notices that a frame may have gotten or lost focus. Focus events are delivered asynchronously, and may not be delivered in the expected order, so code that wants to do something depending on the state of focused frames have go through all the frames and check.

For instance, here's a simple example function that sets the background color based on whether the frame has focus or not:

```
(add-function :after after-focus-change-function
             #'my-change-background)
(defun my-change-background ()
  (dolist (frame (frame-list))
    (pcase (frame-focus-state frame)
      (`t (set-face-background 'default "black" frame))
      (`nil (set-face-background 'default "#404040" frame)))))
```

Multiple frames may appear to have input focus simultaneously due to focus event delivery differences, the presence of multiple Emacs terminals, and other factors, and code should be robust in the face of this situation.

Depending on window system, focus events may also be delivered repeatedly and with different focus states before settling to the expected values. Code relying on focus notifications should “debounce” any user-visible updates arising from focus changes, perhaps by deferring work until redisplay.

This function may be called in arbitrary contexts, including from inside `read-event`, so take the same care as you might when writing a process filter.

focus-follows-mouse

[User Option]

This option informs Emacs whether and how the window manager transfers focus when you move the mouse pointer into a frame. It can have three meaningful values:

nil The default value `nil` should be used when your window manager follows a “click-to-focus” policy where you have to click the mouse inside of a frame in order for that frame to gain focus.

t The value `t` should be used when your window manager has the focus automatically follow the position of the mouse pointer but a frame that gains focus is not raised automatically and may even remain occluded by other window-system windows.

auto-raise

The value `auto-raise` should be used when your window manager has the focus automatically follow the position of the mouse pointer and a frame that gains focus is raised automatically.

If this option is `non-nil`, Emacs moves the mouse pointer to the frame selected by `select-frame-set-input-focus`. That function is used by a number of commands like, for example, `other-frame` and `pop-to-buffer`.

The distinction between the values `t` and `auto-raise` is not needed for “normal” frames because the window manager usually takes care of raising them. It is useful to automatically raise child frames via `mouse-autoselect-window` (see Section 29.25 [Mouse Window Auto-selection], page 773).

Note that this option does not distinguish “sloppy” focus (where the frame that previously had focus retains focus as long as the mouse pointer does not move into another window-system window) from “strict” focus (where a frame immediately loses focus when it’s left by the mouse pointer). Neither does it recognize whether your window manager supports delayed focusing or auto-raising where you can explicitly specify the time until a new frame gets focus or is auto-raised.

You can supply a “focus follows mouse” policy for individual Emacs windows by customizing the variable `mouse-autoselect-window` (see Section 29.25 [Mouse Window Auto-selection], page 773).

30.11 Visibility of Frames

A frame on a graphical display may be *visible*, *invisible*, or *iconified*. If it is visible, its contents are displayed in the usual manner. If it is iconified, its contents are not displayed, but there is a little icon somewhere to bring the frame back into view (some window managers refer to this state as *minimized* rather than *iconified*, but from Emacs’ point of view they are the same thing). If a frame is invisible, it is not displayed at all.

The concept of visibility is strongly related to that of (un-)mapped frames. A frame (or, more precisely, its window-system window) is and becomes *mapped* when it is displayed for the first time and whenever it changes its state of visibility from *iconified* or *invisible*

to **visible**. Conversely, a frame is and becomes *unmapped* whenever it changes its status from **visible** to **iconified** or **invisible**.

Visibility is meaningless on text terminals, since only the selected frame is actually displayed in any case.

frame-visible-p &optional *frame*

[Function]

This function returns the visibility status of frame *frame*. The value is **t** if *frame* is visible, **nil** if it is invisible, and **icon** if it is iconified.

On a text terminal, all frames are considered visible for the purposes of this function, even though only one frame is displayed. See Section 30.12 [Raising and Lowering], page 829.

iconify-frame &optional *frame*

[Command]

This function iconifies frame *frame*. If you omit *frame*, it iconifies the selected frame. This usually makes all child frames of *frame* (and their descendants) invisible (see Section 30.14 [Child Frames], page 831).

make-frame-visible &optional *frame*

[Command]

This function makes frame *frame* visible. If you omit *frame*, it makes the selected frame visible. This does not raise the frame, but you can do that with **raise-frame** if you wish (see Section 30.12 [Raising and Lowering], page 829).

Making a frame visible usually makes all its child frames (and their descendants) visible as well (see Section 30.14 [Child Frames], page 831).

make-frame-invisible &optional *frame force*

[Command]

This function makes frame *frame* invisible. If you omit *frame*, it makes the selected frame invisible. Usually, this makes all child frames of *frame* (and their descendants) invisible too (see Section 30.14 [Child Frames], page 831).

Unless *force* is **non-nil**, this function refuses to make *frame* invisible if all other frames are invisible.

The visibility status of a frame is also available as a frame parameter. You can read or change it as such. See Section 30.4.3.8 [Management Parameters], page 814. The user can also iconify and deiconify frames with the window manager. This happens below the level at which Emacs can exert any control, but Emacs does provide events that you can use to keep track of such changes. See Section 22.7.12 [Misc Events], page 450.

x-double-buffered-p &optional *frame*

[Function]

This function returns **non-nil** if *frame* is currently being rendered with double buffering. *frame* defaults to the selected frame.

30.12 Raising, Lowering and Restacking Frames

Most window systems use a desktop metaphor. Part of this metaphor is the idea that system-level windows (representing, e.g., Emacs frames) are stacked in a notional third dimension perpendicular to the screen surface. The order induced by stacking is total and usually referred to as stacking (or Z-) order. Where the areas of two windows overlap, the one higher up in that order will (partially) cover the one underneath.

You can *raise* a frame to the top of that order or *lower* a frame to its bottom by using the functions `raise-frame` and `lower-frame`. You can *restack* a frame directly above or below another frame using the function `frame-restack`.

Note that all functions described below will respect the adherence of frames (and all other window-system windows) to their respective z-group (see Section 30.4.3.2 [Position Parameters], page 805). For example, you usually cannot lower a frame below that of the desktop window and you cannot raise a frame whose `z-group` parameter is `nil` above the window-system's taskbar or tooltip window.

`raise-frame &optional frame`

[Command]

This function raises frame `frame` (default, the selected frame) above all other frames belonging to the same or a lower z-group as `frame`. If `frame` is invisible or iconified, this makes it visible. If `frame` is a child frame (see Section 30.14 [Child Frames], page 831), this raises `frame` above all other child frames of its parent.

`lower-frame &optional frame`

[Command]

This function lowers frame `frame` (default, the selected frame) below all other frames belonging to the same or a higher z-group as `frame`. If `frame` is a child frame (see Section 30.14 [Child Frames], page 831), this lowers `frame` below all other child frames of its parent.

`frame-restack frame1 frame2 &optional above`

[Function]

This function restacks `frame1` below `frame2`. This implies that if both frames are visible and their display areas overlap, `frame2` will (partially) obscure `frame1`. If the optional third argument `above` is non-`nil`, this function restacks `frame1` above `frame2`. This means that if both frames are visible and their display areas overlap, `frame1` will (partially) obscure `frame2`.

Technically, this function may be thought of as an atomic action performed in two steps: The first step removes `frame1`'s window-system window from the display. The second step reinserts `frame1`'s window into the display below (above if `above` is true) that of `frame2`. Hence the position of `frame2` in its display's Z (stacking) order relative to all other frames excluding `frame1` remains unaltered.

Some window managers may refuse to restack windows.

Note that the effect of restacking will only hold as long as neither of the involved frames is iconified or made invisible. You can use the `z-group` (see Section 30.4.3.2 [Position Parameters], page 805) frame parameter to add a frame to a group of frames permanently shown above or below other frames. As long as a frame belongs to one of these groups, restacking it will only affect its relative stacking position within that group. The effect of restacking frames belonging to different z-groups is undefined. You can list frames in their current stacking order with the function `frame-list-z-order` (see Section 30.8 [Finding All Frames], page 823).

`minibuffer-auto-raise`

[User Option]

If this is non-`nil`, activation of the minibuffer raises the frame that the minibuffer window is in.

On window systems, you can also enable auto-raising (on frame selection) or auto-lowering (on frame deselection) using frame parameters. See Section 30.4.3.8 [Management Parameters], page 814.

The concept of raising and lowering frames also applies to text terminal frames. On each text terminal, only the top frame is displayed at any one time.

tty-top-frame &optional terminal [Function]

This function returns the top frame on *terminal*. *terminal* should be a terminal object, a frame (meaning that frame's terminal), or `nil` (meaning the selected frame's terminal). If it does not refer to a text terminal, the return value is `nil`.

30.13 Frame Configurations

A *frame configuration* records the current arrangement of frames, all their properties, and the window configuration of each one. (See Section 29.26 [Window Configurations], page 774.)

current-frame-configuration [Function]

This function returns a frame configuration list that describes the current arrangement of frames and their contents.

set-frame-configuration configuration &optional nodelete [Function]

This function restores the state of frames described in *configuration*. However, this function does not restore deleted frames.

Ordinarily, this function deletes all existing frames not listed in *configuration*. But if *nodelete* is non-`nil`, the unwanted frames are iconified instead.

30.14 Child Frames

Child frames are objects halfway between windows (see Chapter 29 [Windows], page 690) and “normal” frames. Like windows, they are attached to an owning frame. Unlike windows, they may overlap each other—changing the size or position of one child frame does not change the size or position of any of its sibling child frames.

By design, operations to make or modify child frames are implemented with the help of frame parameters (see Section 30.4 [Frame Parameters], page 802) without any specialized functions or customizable variables. Note that child frames are meaningful on graphical terminals only.

To create a new child frame or to convert a normal frame into a child frame, set that frame's `parent-frame` parameter (see Section 30.4.3.6 [Frame Interaction Parameters], page 812) to that of an already existing frame. The frame specified by that parameter will then be the frame's parent frame as long as the parameter is not changed or reset. Technically, this makes the child frame's window-system window a child window of the parent frame's window-system window.

The `parent-frame` parameter can be changed at any time. Setting it to another frame reparents the child frame. Setting it to another child frame makes the frame a *nested* child frame. Setting it to `nil` restores the frame's status as a top-level frame—a frame whose window-system window is a child of its display's root window.²

² On Haiku, child frames are only visible when a parent frame is active, owing to a limitation of the Haiku windowing system. Owing to the same limitation, child frames are only guaranteed to appear above

Since child frames can be arbitrarily nested, a frame can be both a child and a parent frame. Also, the relative roles of child and parent frame may be reversed at any time (though it's usually a good idea to keep the size of a child frame sufficiently smaller than that of its parent). An error will be signaled for the attempt to make a frame an ancestor of itself.

Most window-systems clip a child frame at the native edges (see Section 30.3 [Frame Geometry], page 791) of its parent frame—everything outside these edges is usually invisible. A child frame's `left` and `top` parameters specify a position relative to the top-left corner of its parent's native frame. When the parent frame is resized, this position remains conceptually unaltered.

NS builds do not clip child frames at the parent frame's edges, allowing them to be positioned so they do not obscure the parent frame while still being visible themselves.

Usually, moving a parent frame moves along all its child frames and their descendants as well, keeping their relative positions unaltered. Note that the hook `move-frame-functions` (see Section 30.3.3 [Frame Position], page 798) is run for a child frame only when the position of the child frame relative to its parent frame changes.

When a parent frame is resized, its child frames conceptually retain their previous sizes and their positions relative to the left upper corner of the parent. This means that a child frame may become (partially) invisible when its parent frame shrinks. The parameter `keep-ratio` (see Section 30.4.3.6 [Frame Interaction Parameters], page 812) can be used to resize and reposition a child frame proportionally whenever its parent frame is resized. This may avoid obscuring parts of a frame when its parent frame is shrunk.

A visible child frame always appears on top of its parent frame thus obscuring parts of it, except on NS builds where it may be positioned beneath the parent. This is comparable to the window-system window of a top-level frame which also always appears on top of its parent window—the desktop's root window. When a parent frame is iconified or made invisible (see Section 30.11 [Visibility of Frames], page 828), its child frames are made invisible. When a parent frame is deiconified or made visible, its child frames are made visible.

When a parent frame is about to be deleted (see Section 30.7 [Deleting Frames], page 822), its child frames are recursively deleted before it. There is one exception to this rule: When the child frame serves as a surrogate minibuffer frame (see Section 30.9 [Minibuffers and Frames], page 824) for another frame, it is retained until the parent frame has been deleted. If, at this time, no remaining frame uses the child frame as its minibuffer frame, Emacs will try to delete the child frame too. If that deletion fails for whatever reason, the child frame is made a top-level frame.

Whether a child frame can have a menu or tool bar is window-system or window manager dependent. Most window-systems explicitly disallow menu bars for child frames. It seems advisable to disable both, menu and tool bars, via the frame's initial parameters settings.

Usually, child frames do not exhibit window manager decorations like a title bar or external borders (see Section 30.3 [Frame Geometry], page 791). When the child frame does not show a menu or tool bar, any other of the frame's borders (see Section 30.4.3.4 [Layout Parameters], page 810) can be used instead of the external borders.

their top-level parent; that is to say, the top-most frame in the hierarchy, which does not have a parent frame.

In particular, under X (but not when building with GTK+), the frame's outer border can be used. On MS-Windows, specifying a non-zero outer border width will show a one-pixel wide external border. Under all window-systems, the internal border can be used. In either case, it's advisable to disable a child frame's window manager decorations with the `undecorated` frame parameter (see Section 30.4.3.8 [Management Parameters], page 814).

To resize or move an undecorated child frame with the mouse, special frame parameters (see Section 30.4.3.7 [Mouse Dragging Parameters], page 813) have to be used. The internal border of a child frame, if present, can be used to resize the frame with the mouse, provided that frame has a non-nil `drag-internal-border` parameter. If set, the `snap-width` parameter indicates the number of pixels where the frame *snaps* at the respective edge or corner of its parent frame.

There are two ways to drag an entire child frame with the mouse: The `drag-with-mode-line` parameter, if non-nil, allows to drag a frame without minibuffer window (see Section 21.11 [Minibuffer Windows], page 418) via the mode line area of its bottommost window. The `drag-with-header-line` parameter, if non-nil, allows to drag the frame via the header line area of its topmost window.

In order to give a child frame a draggable header or mode line, the window parameters `mode-line-format` and `header-line-format` are handy (see Section 29.27 [Window Parameters], page 776). These allow to remove an unwanted mode line (when `drag-with-header-line` is chosen) and to remove mouse-sensitive areas which might interfere with frame dragging.

When the user drags a frame with a mouse and overshoots, it's easy to drag a frame out of the screen area of its parent. Retrieving such a frame can be hairy once the mouse button has been released. To prevent such a situation, it is advisable to set the frame's `top-visible` or `bottom-visible` parameter (see Section 30.4.3.7 [Mouse Dragging Parameters], page 813).

Set the `top-visible` parameter of a child frame to a number when you intend to allow the user dragging that frame by its header line. Setting `top-visible` to a number inhibits dragging the top edge of the child frame above the top edge of its parent. Set the `bottom-visible` parameter to a number when you intend to drag that frame via its mode line; this inhibits dragging the bottom edge of the child frame beneath the bottom edge of its parent. In either case, that number also specifies width and height (in pixels) of the area of the child frame that remains visible during dragging.

When a child frame is used for displaying a buffer via `display-buffer-in-child-frame` (see Section 29.13.2 [Buffer Display Action Functions], page 726), the frame's `auto-hide-function` parameter (see Section 30.4.3.6 [Frame Interaction Parameters], page 812) can be set to a function, in order to appropriately deal with the frame when the window displaying the buffer shall be quit.

When a child frame is used during minibuffer interaction, for example, to display completions in a separate window, the `minibuffer-exit` parameter (see Section 30.4.3.6 [Frame Interaction Parameters], page 812) is useful in order to deal with the frame when the minibuffer is exited.

The behavior of child frames deviates from that of top-level frames in a number of other ways as well. Here we sketch a few of them:

- The semantics of maximizing and iconifying child frames is highly window-system dependent. As a rule, applications should never invoke these operations on child frames.

By default, invoking `iconify-frame` on a child frame will try to iconify the top-level frame corresponding to that child frame instead. To obtain a different behavior, users may customize the option `iconify-child-frame` described below.

- Raising, lowering and restacking child frames (see Section 30.12 [Raising and Lowering], page 829) or changing the `z-group` (see Section 30.4.3.2 [Position Parameters], page 805) of a child frame changes only the stacking order of child frames with the same parent.
- Many window-systems are not able to change the opacity (see Section 30.4.3.10 [Font and Color Parameters], page 818) of child frames.
- Transferring focus from a child frame to an ancestor that is not its parent by clicking with the mouse in a visible part of that ancestor's window may fail with some window-systems. You may have to click into the direct parent's window-system window first.
- Window managers might not bother to extend their focus follows mouse policy to child frames. Customizing `mouse-autoselect-window` can help in this regard (see Section 29.25 [Mouse Window Auto-selection], page 773).
- Dropping (see Section 30.22 [Drag and Drop], page 841) on child frames is not guaranteed to work on all window-systems. Some will drop the object on the parent frame or on some ancestor instead.

The following two functions can be useful when working with child and parent frames:

frame-parent &optional frame

[Function]

This function returns the parent frame of *frame*. The parent frame of *frame* is the Emacs frame whose window-system window is the parent window of *frame*'s window-system window. If such a frame exists, *frame* is considered a child frame of that frame.

This function returns `nil` if *frame* has no parent frame.

frame-ancestor-p ancestor descendant

[Function]

This function returns non-`nil` if *ancestor* is an ancestor of *descendant*. *ancestor* is an ancestor of *descendant* when it is either *descendant*'s parent frame or it is an ancestor of *descendant*'s parent frame. Both, *ancestor* and *descendant* must specify live frames.

Note also the function `window-largest-empty-rectangle` (see Section 29.24 [Coordinates and Windows], page 769) which can be used to inscribe a child frame in the largest empty area of an existing window. This can be useful to avoid that a child frame obscures any text shown in that window.

Customizing the following option can be useful to tweak the behavior of `iconify-frame` for child frames.

iconify-child-frame

[User Option]

This option tells Emacs how to proceed when it is asked to iconify a child frame. If it is `nil`, `iconify-frame` will do nothing when invoked on a child frame. If it is `iconify-top-level`, Emacs will try to iconify the top-level frame that is the ancestor of this child frame instead. If it is `make-invisible`, Emacs will try to make this child frame invisible instead of iconifying it.

Any other value means to try iconifying the child frame. Since such an attempt may not be honored by all window managers and can even lead to making the child frame unresponsive to user actions, the default is to iconify the top level frame instead.

30.15 Mouse Tracking

Sometimes it is useful to *track* the mouse, which means to display something to indicate where the mouse is and move the indicator as the mouse moves. For efficient mouse tracking, you need a way to wait until the mouse actually moves.

The convenient way to track the mouse is to ask for events to represent mouse motion. Then you can wait for motion by waiting for an event. In addition, you can easily handle any other sorts of events that may occur. That is useful, because normally you don't want to track the mouse forever—only until some other event, such as the release of a button.

track-mouse *body*... [Macro]

This macro executes *body*, with generation of mouse motion events enabled. Typically, *body* would use **read-event** to read the motion events and modify the display accordingly. See Section 22.7.8 [Motion Events], page 447, for the format of mouse motion events.

The value of **track-mouse** is that of the last form in *body*. You should design *body* to return when it sees the up-event that indicates the release of the button, or whatever kind of event means it is time to stop tracking. Its value also controls how mouse events are reported while a mouse button is held down: if it is **dragging** or **drag-source**, the motion events are reported relative to the frame underneath the pointer. If there is no such frame, the events will be reported relative to the frame the mouse buttons were first pressed on. In addition, the **posn-window** of the mouse position list will be **nil** if the value is **drag-source**. This is useful to determine if a frame is not directly visible underneath the mouse pointer.

The **track-mouse** macro causes Emacs to generate mouse motion events by binding the variable **track-mouse** to a non-**nil** value. If that variable has the special value **dragging**, it additionally instructs the display engine to refrain from changing the shape of the mouse pointer. This is desirable in Lisp programs that require mouse dragging across large portions of Emacs display, which might otherwise cause the mouse pointer to change its shape according to the display portion it hovers on (see Section 30.19 [Pointer Shape], page 839). Therefore, Lisp programs that need the mouse pointer to retain its original shape during dragging should bind **track-mouse** to the value **dragging** at the beginning of their *body*.

The usual purpose of tracking mouse motion is to indicate on the screen the consequences of pushing or releasing a button at the current position.

In many cases, you can avoid the need to track the mouse by using the **mouse-face** text property (see Section 33.19.4 [Special Properties], page 924). That works at a much lower level and runs more smoothly than Lisp-level mouse tracking.

30.16 Mouse Position

The functions **mouse-position** and **set-mouse-position** give access to the current position of the mouse.

mouse-position [Function]

This function returns a description of the position of the mouse. The value looks like (**frame** *x* . *y*), where *x* and *y* are integers giving the (possibly rounded) position

in multiples of the default character size of *frame* (see Section 30.3.2 [Frame Font], page 797) relative to the native position of *frame* (see Section 30.3 [Frame Geometry], page 791).

mouse-position-function

[Variable]

If non-*nil*, the value of this variable is a function for `mouse-position` to call. `mouse-position` calls this function just before returning, with its normal return value as the sole argument, and it returns whatever this function returns to it.

This abnormal hook exists for the benefit of packages like `xt-mouse.el` that need to do mouse handling at the Lisp level.

tty-menu-calls-mouse-position-function

[Variable]

If non-*nil*, TTY menus will call `mouse-position-function` as described above. This exists for cases where `mouse-position-function` is not safe to be called by the TTY menus, such as if it could trigger redisplay.

set-mouse-position frame x y

[Function]

This function warps the mouse to position *x*, *y* in frame *frame*. The arguments *x* and *y* are integers, giving the position in multiples of the default character size of *frame* (see Section 30.3.2 [Frame Font], page 797) relative to the native position of *frame* (see Section 30.3 [Frame Geometry], page 791).

The resulting mouse position is constrained to the native frame of *frame*. If *frame* is not visible, this function does nothing. The return value is not significant.

mouse-pixel-position

[Function]

This function is like `mouse-position` except that it returns coordinates in units of pixels rather than units of characters.

set-mouse-pixel-position frame x y

[Function]

This function warps the mouse like `set-mouse-position` except that *x* and *y* are in units of pixels rather than units of characters.

The resulting mouse position is not constrained to the native frame of *frame*. If *frame* is not visible, this function does nothing. The return value is not significant.

On a graphical terminal the following two functions allow the absolute position of the mouse cursor to be retrieved and set.

mouse-absolute-pixel-position

[Function]

This function returns a cons cell (*x* . *y*) of the coordinates of the mouse cursor position in pixels, relative to a position (0, 0) of the selected frame's display.

set-mouse-absolute-pixel-position x y

[Function]

This function moves the mouse cursor to the position (*x*, *y*). The coordinates *x* and *y* are interpreted in pixels relative to a position (0, 0) of the selected frame's display.

The following function can tell whether the mouse cursor is currently visible on a frame:

frame-pointer-visible-p &optional frame

[Function]

This predicate function returns *non-nil* if the mouse pointer displayed on *frame* is visible; otherwise it returns *nil*. *frame* omitted or *nil* means the selected frame. This is useful when `make-pointer-invisible` is set to *t*: it allows you to know if the pointer has been hidden. See Section “Mouse Avoidance” in *The Emacs Manual*.

30.17 Pop-Up Menus

A Lisp program can pop up a menu so that the user can choose an alternative with the mouse. On a text terminal, if the mouse is not available, the user can choose an alternative using the keyboard motion keys—*C-n*, *C-p*, or up- and down-arrow keys.

`x-popup-menu position menu` [Function]

This function displays a pop-up menu and returns an indication of what selection the user makes.

The argument *position* specifies where on the screen to put the top left corner of the menu. It can be either a mouse button event (which says to put the menu where the user actuated the button) or a list of this form:

`((xoffset yoffset) window)`

where *xoffset* and *yoffset* are coordinates, measured in pixels, counting from the top left corner of *window*. *window* may be a window or a frame.

If *position* is `t`, it means to use the current mouse position (or the top-left corner of the frame if the mouse is not available on a text terminal). If *position* is `nil`, it means to precompute the key binding equivalents for the keymaps specified in *menu*, without actually displaying or popping up the menu.

The argument *menu* says what to display in the menu. It can be a keymap or a list of keymaps (see Section 23.18 [Menu Keymaps], page 510). In this case, the return value is the list of events corresponding to the user's choice. This list has more than one element if the choice occurred in a submenu. (Note that `x-popup-menu` does not actually execute the command bound to that sequence of events.) On text terminals and toolkits that support menu titles, the title is taken from the prompt string of *menu* if *menu* is a keymap, or from the prompt string of the first keymap in *menu* if it is a list of keymaps (see Section 23.18.1 [Defining Menus], page 510).

Alternatively, *menu* can have the following form:

`(title pane1 pane2...)`

where each pane is a list of form

`(title item1 item2...)`

Each *item* should be a cons cell, `(line . value)`, where *line* is a string and *value* is the value to return if that *line* is chosen. Unlike in a menu keymap, a `nil` value does not make the menu item non-selectable. Alternatively, each *item* can be a string rather than a cons cell; this makes a non-selectable menu item.

If the user gets rid of the menu without making a valid choice, for instance by clicking the mouse away from a valid choice or by typing *C-g*, then this normally results in a quit and `x-popup-menu` does not return. But if *position* is a mouse button event (indicating that the user invoked the menu with the mouse) then no quit occurs and `x-popup-menu` returns `nil`.

Usage note: Don't use `x-popup-menu` to display a menu if you could do the job with a prefix key defined with a menu keymap. If you use a menu keymap to implement a menu, *C-h c* and *C-h a* can see the individual items in that menu and provide help for them. If instead you implement the menu by defining a command that calls `x-popup-menu`, the help

facilities cannot know what happens inside that command, so they cannot give any help for the menu's items.

The menu bar mechanism, which lets you switch between submenus by moving the mouse, cannot look within the definition of a command to see that it calls `x-popup-menu`. Therefore, if you try to implement a submenu using `x-popup-menu`, it cannot work with the menu bar in an integrated fashion. This is why all menu bar submenus are implemented with menu keymaps within the parent menu, and never with `x-popup-menu`. See Section 23.18.5 [Menu Bar], page 516.

If you want a menu bar submenu to have contents that vary, you should still use a menu keymap to implement it. To make the contents vary, add a hook function to `menu-bar-update-hook` to update the contents of the menu keymap as necessary.

`x-pre-popup-menu-hook`

[Variable]

A normal hook run immediately before a pop-up menu is displayed, either directly by calling `x-popup-menu`, or through a menu keymap. It won't be called if `x-popup-menu` returns for some other reason without displaying a pop-up menu.

30.18 Dialog Boxes

A dialog box is a variant of a pop-up menu—it looks a little different, it always appears in the center of a frame, and it has just one level and one or more buttons. The main use of dialog boxes is for asking questions that the user can answer with “yes”, “no”, and a few other alternatives. With a single button, they can also force the user to acknowledge important information. The functions `y-or-n-p` and `yes-or-no-p` use dialog boxes instead of the keyboard, when called from commands invoked by mouse clicks.

`x-popup-dialog` *position* *contents* &optional *header*

[Function]

This function displays a pop-up dialog box and returns an indication of what selection the user makes. The argument *contents* specifies the alternatives to offer; it has this format:

```
(title (string . value)...)
```

which looks like the list that specifies a single pane for `x-popup-menu`.

The return value is *value* from the chosen alternative.

As for `x-popup-menu`, an element of the list may be just a string instead of a cons cell (*string* . *value*). That makes a box that cannot be selected.

If `nil` appears in the list, it separates the left-hand items from the right-hand items; items that precede the `nil` appear on the left, and items that follow the `nil` appear on the right. If you don't include a `nil` in the list, then approximately half the items appear on each side.

Dialog boxes always appear in the center of a frame; the argument *position* specifies which frame. The possible values are as in `x-popup-menu`, but the precise coordinates or the individual window don't matter; only the frame matters.

If *header* is non-`nil`, the frame title for the box is ‘Information’, otherwise it is ‘Question’. The former is used for `message-box` (see [message-box], page 1134). (On text terminals, the box title is not displayed.)

In some configurations, Emacs cannot display a real dialog box; so instead it displays the same items in a pop-up menu in the center of the frame.

If the user gets rid of the dialog box without making a valid choice, for instance using the window manager, then this produces a quit and `x-popup-dialog` does not return.

30.19 Pointer Shape

You can specify the mouse pointer style for particular text or images using the `pointer` text property, and for images with the `:pointer` and `:map` image properties. The values you can use in these properties are in the table below. The actual shapes may vary between systems; the descriptions are examples.

`text`

`nil` The usual mouse pointer style used over text (an “I”-like shape).

`arrow`

`vdrag`

`modeline` An arrow that points north-west.

`hand` A hand that points upwards.

`hdrag` A right-left arrow.

`nhdrag` An up-down arrow.

`hourglass`

A rotating ring.

Over void parts of the window (parts that do not correspond to any of the buffer contents), the mouse pointer usually uses the `arrow` style, but you can specify a different style (one of those above) by setting `void-text-area-pointer`.

`void-text-area-pointer`

[User Option]

This variable specifies the mouse pointer style for void text areas. These include the areas after the end of a line or below the last line in the buffer. The default is to use the `arrow` (non-text) pointer style.

When using some window systems, you can specify what the `text` pointer style really looks like by setting the variable `x-pointer-shape`.

`x-pointer-shape`

[Variable]

This variable specifies the pointer shape to use ordinarily in the Emacs frame, for the `text` pointer style.

`x-sensitive-text-pointer-shape`

[Variable]

This variable specifies the pointer shape to use when the mouse is over mouse-sensitive text.

These variables affect newly created frames. They do not normally affect existing frames; however, if you set the mouse color of a frame, that also installs the current value of those two variables. See Section 30.4.3.10 [Font and Color Parameters], page 818.

The values you can use, to specify either of these pointer shapes, are defined in the file `lisp/term/x-win.el`. Use `M-x apropos RET x-pointer RET` to see a list of them.

30.20 Window System Selections

In window systems, such as X, data can be transferred between different applications by means of *selections*. X defines an arbitrary number of *selection types*, each of which can store its own data; however, only three are commonly used: the *clipboard*, *primary selection*, and *secondary selection*. Other window systems support only the clipboard. See Section “Cut and Paste” in *The GNU Emacs Manual*, for Emacs commands that make use of these selections. This section documents the low-level functions for reading and setting window-system selections.

gui-set-selection type data [Command]

This function sets a window-system selection. It takes two arguments: a selection type *type*, and the value to assign to it, *data*.

type should be a symbol; it is usually one of PRIMARY, SECONDARY or CLIPBOARD. These are symbols with upper-case names, in accord with X Window System conventions. If *type* is nil, that stands for PRIMARY.

If *data* is nil, it means to clear out the selection. Otherwise, *data* may be a string, a symbol, an integer, an overlay, or a cons of two markers pointing to the same buffer. An overlay or a pair of markers stands for text in the overlay or between the markers. The argument *data* may also be a vector of valid non-vector selection values.

If *data* is a string, then its text properties can specify values used for individual data types. For example, if *data* has a property named text/uri-list, then a call to **gui-get-selection** with the data type text/uri-list will result in the value of that property being used instead of *data* itself.

This function returns *data*.

gui-get-selection &optional type data-type [Function]

This function accesses selections set up by Emacs or by other programs. It takes two optional arguments, *type* and *data-type*. The default for *type*, the selection type, is PRIMARY.

The *data-type* argument specifies the form of data conversion to use, to convert the raw data obtained from another program into Lisp data. Meaningful values include TEXT, STRING, UTF8_STRING, TARGETS, LENGTH, DELETE, FILE_NAME, CHARACTER_POSITION, NAME, LINE_NUMBER, COLUMN_NUMBER, OWNER_OS, HOST_NAME, USER, CLASS, ATOM, and INTEGER. (These are symbols with upper-case names in accord with X conventions.) The default for *data-type* is STRING. Window systems other than X usually support only a small subset of these types, in addition to STRING.

selection-coding-system [User Option]

This variable specifies the coding system to use when reading and writing selections or the clipboard. See Section 34.10 [Coding Systems], page 976. The default is compound-text-with-extensions, which converts to the text representation that X11 normally uses.

When Emacs runs on MS-Windows, it does not implement X selections in general, but it does support the clipboard. **gui-get-selection** and **gui-set-selection** on MS-Windows support the text data type only; if the clipboard holds other types of data, Emacs treats the clipboard as empty. The supported data type is STRING.

For backward compatibility, there are obsolete aliases `x-get-selection` and `x-set-selection`, which were the names of `gui-get-selection` and `gui-set-selection` before Emacs 25.1.

30.21 Yanking Media

If you choose, for instance, “Copy Image” in a web browser, that image is put onto the clipboard, and Emacs can access it via `gui-get-selection`. But in general, inserting image data into an arbitrary buffer isn’t very useful—you can’t really do much with it by default.

So Emacs has a system to let modes register handlers for these “complicated” selections.

yank-media-handler *types handler* [Function]

types can be a MIME media type symbol, a regexp to match these, or a list of these symbols and regexps. For instance:

```
(yank-media-handler 'text/html #'my-html-handler)
(yank-media-handler "image/.*" #'my-image-handler)
```

A mode can register as many handlers as required.

The *handler* function is called with two parameters: The MIME media type symbol and the data (as a string). The handler should then insert the object into the buffer, or save it, or do whatever is appropriate for the mode.

The `yank-media` command will consult the registered handlers in the current buffer, compare that with the available media types on the clipboard, and then pass on the matching selection to the handler (if any). If there’s more than one matching selection, the user is queried first.

The `yank-media-types` command can be used to explore the clipboard/primary selection. It lists all the media types that are currently available, and can be handy when creating handlers—to see what data is actually available. Some applications put a surprising amount of different data types on the clipboard.

30.22 Drag and Drop

When the user drops something from another application over Emacs, Emacs will try to insert any text and open any URL that was dropped. If text was dropped, then it will always be inserted at the location of the mouse pointer where the drop happened, or saved in the kill ring if insertion failed, which could happen if the buffer was read-only. If a URL was dropped instead, then Emacs will first try to call an appropriate handler function by matching the URL against regexps defined in the variable `dnd-protocol-alist`, and then against those defined in the variables `browse-url-handlers` and `browse-url-default-handlers`. Should no suitable handler be located, Emacs will fall back to inserting the URL as plain text.

dnd-protocol-alist [Variable]

This variable is a list of cons cells of the form `(pattern . action)`. *pattern* is a regexp that URLs are matched against after being dropped. *action* is a function that is called with two arguments, should a URL being dropped match *pattern*: the URL being dropped, and the action being performed for the drop, which is one of the symbols `copy`, `move`, `link`, `private` or `ask`.

If *action* is *private*, then it means the program that initiated the drop wants Emacs to perform an unspecified action with the URL; a reasonable action to perform in that case is to open the URL or copy its contents into the current buffer. Otherwise, *action* has the same meaning as the *action* argument to `dnd-begin-file-drag`.

Emacs implements receiving text and URLs individually for each window system, and does not by default support receiving other kinds of data as drops. To support receiving other kinds of data, use the X-specific interface described below.

When a user drags something from another application over Emacs under the X Window System, that other application expects Emacs to tell it if Emacs understands the data being dragged. The function in the variable `x-dnd-test-function` is called by Emacs to determine what to reply to any such inquiry. The default value is `x-dnd-default-test-function`, which accepts drops if the type of the data to be dropped is present in `x-dnd-known-types`. Changing the variables `x-dnd-test-function` and `x-dnd-known-types` can make Emacs accept or reject drops based on some other criteria.

If you want to change the way Emacs receives drops of different data types, or you want to enable it to understand a new type, change the variable `x-dnd-types-alist`. Doing so correctly requires detailed knowledge of what data types other applications use for drag and drop.

These data types are typically implemented as special data types that can be obtained from an X selection provided by the other application. In most cases, they are either the same data types that are typically accepted by `gui-set-selection`, or MIME types, depending on the specific drag-and-drop protocol being used. For example, the data type used for plain text may be either "`STRING`" or "`text/plain`".

When Emacs runs on X window system, it supports the X Direct Save (XDS) protocol, which allows users to save a file by dragging and dropping it onto an Emacs window, such as a Dired window. To comply with the unique requirements of XDS, these drag-and-drop requests are processed specially: instead of being handled according to `x-dnd-types-alist`, they are handled by the *direct-save function* that is the value of the variable `x-dnd-direct-save-function`. The value should be a function of two arguments, *need-name* and *filename*. The XDS protocol uses a two-step procedure for dragging files:

1. The application from which the file is dragged asks Emacs to provide the full file name under which to save the file. For this purpose, the direct-save function is called with its first argument *need-name* `non-nil`, and the second argument *filename* set to the basename of the file to be saved. It should return the fully-expanded absolute file name under which to save the file. For example, if a file is dragged to a Dired window, the natural directory for the file is the directory of the file shown at location of the drop. If saving the file is not possible for some reason, the function should return `nil`, which will cancel the drag-and-drop operation.
2. The application from which the file is dragged saves the file under the name returned by the first call to the direct-save function. If it succeeds in saving the file, the direct-save function is called again, this time with the first argument *need-name* set to `nil` and the second argument *filename* set to the full absolute name of the saved file. The function is then expected to do whatever is needed given the fact that file was saved. For example, Dired should update the directory on display by showing the new file there.

The default value of `x-dnd-direct-save-function` is `x-dnd-save-direct`.

x-dnd-save-direct *need-name filename* [Function]

When called with the *need-name* argument `non-nil`, this function prompts the user for the absolute file name under which it should be saved. If the specified file already exists, it additionally asks the user whether to overwrite it, and returns the absolute file name only if the user confirms the overwriting.

When called with the *need-name* argument `nil`, it reverts the *Dired* listing if the current buffer is in *Dired* mode or one of its descendants, and otherwise visits the file by calling `find-file` (see Section 26.1.1 [Visiting Functions], page 608).

x-dnd-save-direct-immediately *need-name filename* [Function]

This function works like `x-dnd-save-direct`, but when called with its *need-name* argument `non-nil`, it doesn't prompt the user for the full name of the file to be saved; instead, it returns its argument *filename* expanded against the current buffer's default directory (see Section 26.9.4 [File Name Expansion], page 639). (It still asks for confirmation if a file by that name already exists in the default directory.)

On capable window systems, Emacs also supports dragging contents from its frames to windows of other applications.

dnd-begin-text-drag *text &optional frame action allow-same-frame* [Function]

This function begins dragging text from *frame* to another program (known as the *drop target*), and returns the result of drag-and-drop operation when the text is dropped or the drag-and-drop operation is canceled. *text* is the text that will be inserted by the drop target.

action must be one of the symbols `copy` or `move`, where `copy` means that *text* should be inserted by the drop target, and `move` means the same as `copy`, but in addition the caller may have to delete *text* from its source as explained below.

frame is the frame where the mouse is currently held down, or `nil`, which means to use the selected frame. This function may return immediately if no mouse buttons are held down, so it should be only called immediately after a `down-mouse-1` or similar event (see Section 22.7.3 [Mouse Events], page 442), with *frame* set to the frame where that event was generated (see Section 22.7.4 [Click Events], page 442).

allow-same-frame specifies whether or not drops on top of *frame* itself are to be ignored.

The return value specifies the action that the drop target actually performed, and optionally what the caller should do. It can be one of the following symbols:

<code>copy</code>	The drop target inserted the dropped text.
<code>move</code>	The drop target inserted the dropped text, but in addition the caller should delete <i>text</i> from wherever it originated, such as its buffer.
<code>private</code>	The drop target performed some other unspecified action.
<code>nil</code>	The drag-and-drop operation was canceled.

dnd-begin-file-drag *file &optional frame action allow-same-frame* [Function]

This function begins dragging *file* from *frame* to another program, and returns the result of the drag-and-drop operation when the file is dropped or the drag-and-drop operation is canceled.

If *file* is a remote file, then a temporary copy will be made.

action must be one of the symbols `copy`, `move` or `link`, where `copy` means that *file* should be opened or copied by the drop target, `move` means the drop target should move the file to another location, and `link` means the drop target should create a symbolic link to *file*. It is an error to specify `link` as the action if *file* is a remote file. `frame` and `allow-same-frame` have the same meaning as in `dnd-begin-text-drag`.

The return value is the action that the drop target actually performed, which can be one of the following symbols:

<code>copy</code>	The drop target opened or copied <i>file</i> to a different location.
<code>move</code>	The drop target moved <i>file</i> to a different location.
<code>link</code>	The drop target (usually a file manager) created a symbolic link to <i>file</i> .
<code>private</code>	The drop target performed some other unspecified action.
<code>nil</code>	The drag-and-drop operation was canceled.

dnd-begin-drag-files *files* &optional *frame* *action* [Function]
allow-same-frame

This function is like `dnd-begin-file-drag`, except that *files* is a list of files. If the drop target doesn't support dropping multiple files, then the first file will be used instead.

dnd-direct-save *file* *name* &optional *frame* *allow-same-frame* [Function]
This function is similar to `dnd-begin-file-drag` (with the default action of `copy`), but instead of specifying the action you specify the name of the copy created by the target program in *name*.

The high-level interfaces described above are implemented on top of a lower-level primitive. If you need to drag content other than files or text, use the low-level interface `x-begin-drag` instead. However, using it will require detailed knowledge of the data types and actions used by the programs to transfer content via drag-and-drop on each platform you want to support.

x-begin-drag *targets* &optional *action* *frame* *return-frame* [Function]
allow-current-frame *follow-tooltip*

This function begins a drag from *frame*, and returns when the drag-and-drop operation ends, either because the drop was successful, or because the drop was rejected. The drop occurs when all mouse buttons are released on top of an X window other than *frame* (the *drop target*), or any X window if *allow-current-frame* is non-*nil*. If no mouse buttons are held down when the drag-and-drop operation begins, this function may immediately return *nil*.

targets is a list of strings describing selection targets, much like the *data-type* argument to `gui-get-selection`, that the drop target can request from Emacs (see Section 30.20 [Window System Selections], page 840).

action is a symbol describing the action recommended to the target. It can either be `XdndActionCopy`, which means to copy the contents of the selection `XdndSelection` to the drop target; or `XdndActionMove`, which means copy as with `XdndActionCopy`,

and in addition the caller should delete whatever was stored in that selection after copying it.

action may also be an alist which associates between symbols describing the available actions, and strings that the drop target is expected to present to the user to choose between the available actions.

If *return-frame* is non-*nil* and the mouse moves over an Emacs frame after first moving out of *frame*, then the frame to which the mouse moves will be returned immediately. If *return-frame* is the symbol **now**, then any frame underneath the mouse pointer will be returned without waiting for the mouse to first move out of *frame*. *return-frame* is useful when you want to treat dragging content from one frame to another specially, while also being able to drag content to other programs, but it is not guaranteed to work on all systems and with all window managers.

If *follow-tooltip* is non-*nil*, the position of any tooltip (such as one shown by `tooltip-show`) will follow the location of the mouse pointer whenever it moves during the drag-and-drop operation. The tooltip will be hidden once all mouse buttons are released.

If the drop was rejected or no drop target was found, this function returns *nil*. Otherwise, it returns a symbol describing the action the target chose to perform, which can differ from *action* if that isn't supported by the drop target. **XdndActionPrivate** is also a valid return value in addition to **XdndActionCopy** and **XdndActionMove**; it means that the drop target chose to perform an unspecified action, and no further processing is required by the caller.

The caller must cooperate with the target to fully perform the action chosen by the target. For example, callers should delete the buffer text that was dragged if this function returns **XdndActionMove**.

On X Windows, several different drag-and-drop protocols are supported by **x-begin-drag**. When dragging content that is known to not be supported by a specific drag-and-drop protocol, it might be desirable to turn that protocol off, by changing the values of the following variables:

x-dnd-disable-motif-protocol [Variable]

When this is non-*nil*, the Motif drag and drop protocols are disabled, and dropping onto programs that only understand them will not work.

x-dnd-use-offix-drop [Variable]

When this is *nil*, the OffIX (old KDE) drag and drop protocol is disabled. When this is the symbol **files**, the OffIX protocol will only be used if "FILE_NAME" is one of the targets given to **x-begin-drag**. Any other value means to use the OffIX protocol to drop all supported content.

x-dnd-use-unsupported-drop [Variable]

When one of the "STRING", "UTF8_STRING", "COMPOUND_TEXT" or "TEXT" targets is present in the list given to **x-begin-drag**, Emacs will try to use synthesized mouse events and the primary selection to insert the text if the drop target doesn't support any drag-and-drop protocol at all.

A side effect is that Emacs will become the owner of the primary selection upon such a drop. If that is not desired, then the drop emulation can be disabled by setting this variable to `nil`.

30.23 Color Names

A color name is text (usually in a string) that specifies a color. Symbolic names such as ‘`black`’, ‘`white`’, ‘`red`’, etc., are allowed; use `M-x list-colors-display` to see a list of defined names. You can also specify colors numerically in forms such as ‘`#rgb`’ and ‘`RGB:r/g/b`’, where `r` specifies the red level, `g` specifies the green level, and `b` specifies the blue level. You can use either one, two, three, or four hex digits for `r`; then you must use the same number of hex digits for all `g` and `b` as well, making either 3, 6, 9 or 12 hex digits in all. (See the documentation of the X Window System for more details about numerical RGB specification of colors.)

These functions provide a way to determine which color names are valid, and what they look like. In some cases, the value depends on the *selected frame*, as described below; see Section 30.10 [Input Focus], page 824, for the meaning of the term “selected frame”.

To read user input of color names with completion, use `read-color` (see Section 21.6.4 [High-Level Completion], page 402).

color-defined-p *color &optional frame* [Function]

This function reports whether a color name is meaningful. It returns `t` if so; otherwise, `nil`. The argument *frame* says which frame’s display to ask about; if *frame* is omitted or `nil`, the selected frame is used.

Note that this does not tell you whether the display you are using really supports that color. When using X, you can ask for any defined color on any kind of display, and you will get some result—typically, the closest it can do. To determine whether a frame can really display a certain color, use `color-supported-p` (see below).

This function used to be called `x-color-defined-p`, and that name is still supported as an alias.

defined-colors *&optional frame* [Function]

This function returns a list of the color names that are defined and supported on frame *frame* (default, the selected frame). If *frame* does not support colors, the value is `nil`.

This function used to be called `x-defined-colors`, and that name is still supported as an alias.

color-supported-p *color &optional frame background-p* [Function]

This returns `t` if *frame* can really display the color *color* (or at least something close to it). If *frame* is omitted or `nil`, the question applies to the selected frame.

Some terminals support a different set of colors for foreground and background. If *background-p* is non-`nil`, that means you are asking whether *color* can be used as a background; otherwise you are asking whether it can be used as a foreground.

The argument *color* must be a valid color name.

color-gray-p *color &optional frame* [Function]

This returns `t` if *color* is a shade of gray, as defined on *frame*'s display. If *frame* is omitted or `nil`, the question applies to the selected frame. If *color* is not a valid color name, this function returns `nil`.

color-values *color &optional frame* [Function]

This function returns a value that describes what *color* should ideally look like on *frame*. If *color* is defined, the value is a list of three integers, which give the amount of red, the amount of green, and the amount of blue. Each integer ranges in principle from 0 to 65535, but some displays may not use the full range. This three-element list is called the *rgb values* of the color.

If *color* is not defined, the value is `nil`.

```
(color-values "black")
  ⇒ (0 0 0)
(color-values "white")
  ⇒ (65535 65535 65535)
(color-values "red")
  ⇒ (65535 0 0)
(color-values "pink")
  ⇒ (65535 49344 52171)
(color-values "hungry")
  ⇒ nil
```

The color values are returned for *frame*'s display. If *frame* is omitted or `nil`, the information is returned for the selected frame's display. If the frame cannot display colors, the value is `nil`.

This function used to be called `x-color-values`, and that name is still supported as an alias.

color-name-to-rgb *color &optional frame* [Function]

This function does the same as `color-values`, but it returns color values as floating-point numbers between 0.0 and 1.0 inclusive.

color-dark-p *rgb* [Function]

This function returns non-`nil` if the color described by its RGB triplet *rgb* is more readable against white background than against dark background. The argument *rgb* should be a list of the form `(r g b)`, with each component a floating-point number in the range 0.0 to 1.0 inclusive. You can use `color-name-to-rgb` to convert a color's name to such a list.

30.24 Text Terminal Colors

Text terminals usually support only a small number of colors, and the computer uses small integers to select colors on the terminal. This means that the computer cannot reliably tell what the selected color looks like; instead, you have to inform your application which small integers correspond to which colors. However, Emacs does know the standard set of colors and will try to use them automatically.

The functions described in this section control how terminal colors are used by Emacs.

Several of these functions use or return *rgb* values, described in Section 30.23 [Color Names], page 846.

These functions accept a display (either a frame or the name of a terminal) as an optional argument. We hope in the future to make Emacs support different colors on different text terminals; then this argument will specify which terminal to operate on (the default being the selected frame’s terminal; see Section 30.10 [Input Focus], page 824). At present, though, the *frame* argument has no effect.

tty-color-define *name number &optional rgb frame* [Function]

This function associates the color name *name* with color number *number* on the terminal.

The optional argument *rgb*, if specified, is an *rgb* value, a list of three numbers that specify what the color actually looks like. If you do not specify *rgb*, then this color cannot be used by **tty-color-approximate** to approximate other colors, because Emacs will not know what it looks like.

tty-color-clear *&optional frame* [Function]

This function clears the table of defined colors for a text terminal.

tty-color-alist *&optional frame* [Function]

This function returns an alist recording the known colors supported by a text terminal.

Each element has the form (*name number . rgb*) or (*name number*). Here, *name* is the color name, *number* is the number used to specify it to the terminal. If present, *rgb* is a list of three color values (for red, green, and blue) that says what the color actually looks like.

tty-color-approximate *rgb &optional frame* [Function]

This function finds the closest color, among the known colors supported for *display*, to that described by the *rgb* value *rgb* (a list of color values). The return value is an element of **tty-color-alist**.

tty-color-translate *color &optional frame* [Function]

This function finds the closest color to *color* among the known colors supported for *display* and returns its index (an integer). If the name *color* is not defined, the value is *nil*.

30.25 X Resources

This section describes some of the functions and variables for querying and using X resources, or their equivalent on your operating system. See Section “X Resources” in *The GNU Emacs Manual*, for more information about X resources.

x-get-resource *attribute class &optional component subclass* [Function]

The function **x-get-resource** retrieves a resource value from the X Window defaults database.

Resources are indexed by a combination of a *key* and a *class*. This function searches using a key of the form ‘*instance.attribute*’ (where *instance* is the name under which Emacs was invoked), and using ‘*Emacs.class*’ as the class.

The optional arguments *component* and *subclass* add to the key and the class, respectively. You must specify both of them or neither. If you specify them, the key is ‘*instance.component.attribute*’, and the class is ‘*Emacs.class.subclass*’.

x-resource-class [Variable]

This variable specifies the application name that `x-get-resource` should look up. The default value is “`Emacs`”. You can examine X resources for other application names by binding this variable to some other string, around a call to `x-get-resource`.

x-resource-name [Variable]

This variable specifies the instance name that `x-get-resource` should look up. The default value is the name Emacs was invoked with, or the value specified with the ‘`-name`’ or ‘`-rn`’ switches.

To illustrate some of the above, suppose that you have the line:

```
xterm.vt100.background: yellow
```

in your X resources file (whose name is usually `~/.Xdefaults` or `~/.Xresources`). Then:

```
(let ((x-resource-class "XTerm") (x-resource-name "xterm"))
  (x-get-resource "vt100.background" "VT100.Background"))
  ⇒ "yellow"
(let ((x-resource-class "XTerm") (x-resource-name "xterm"))
  (x-get-resource "background" "VT100" "vt100" "Background"))
  ⇒ "yellow"
```

inhibit-x-resources [Variable]

If this variable is non-`nil`, Emacs does not look up X resources, and X resources do not have any effect when creating new frames.

30.26 Display Feature Testing

The functions in this section describe the basic capabilities of a particular display. Lisp programs can use them to adapt their behavior to what the display can do. For example, a program that ordinarily uses a popup menu could use the minibuffer if popup menus are not supported.

The optional argument *display* in these functions specifies which display to ask the question about. It can be a display name, a frame (which designates the display that frame is on), or `nil` (which refers to the selected frame’s display, see Section 30.10 [Input Focus], page 824).

See Section 30.23 [Color Names], page 846, Section 30.24 [Text Terminal Colors], page 847, for other functions to obtain information about displays.

display-popup-menus-p &optional display [Function]

This function returns `t` if popup menus are supported on *display*, `nil` if not. Support for popup menus requires that the mouse be available, since the menu is popped up by clicking the mouse on some portion of the Emacs display.

display-graphic-p &optional display [Function]

This function returns `t` if *display* is a graphic display capable of displaying several frames and several different fonts at once. This is true for displays that use a window system such as X, and false for text terminals.

display-mouse-p &optional display [Function]

This function returns t if *display* has a mouse available, nil if not.

display-color-p &optional display [Function]

This function returns t if the screen is a color screen. It used to be called *x-display-color-p*, and that name is still supported as an alias.

display-grayscale-p &optional display [Function]

This function returns t if the screen can display shades of gray. (All color displays can do this.)

display-supports-face-attributes-p attributes &optional display [Function]

This function returns non-nil if all the face attributes in *attributes* are supported (see Section 41.12.1 [Face Attributes], page 1164).

The definition of “supported” is somewhat heuristic, but basically means that a face containing all the attributes in *attributes*, when merged with the default face for display, can be represented in a way that’s

1. different in appearance than the default face, and
2. close in spirit to what the attributes specify, if not exact.

Point (2) implies that a :weight black attribute will be satisfied by any display that can display bold, as will :foreground "yellow" as long as some yellowish color can be displayed, but :slant italic will *not* be satisfied by the tty display code’s automatic substitution of a dim face for italic.

display-selections-p &optional display [Function]

This function returns t if *display* supports selections. Windowed displays normally support selections, but they may also be supported in some other cases.

display-images-p &optional display [Function]

This function returns t if *display* can display images. Windowed displays ought in principle to handle images, but some systems lack the support for that. On a display that does not support images, Emacs cannot display a tool bar.

display-screens &optional display [Function]

This function returns the number of screens associated with the display.

display-pixel-height &optional display [Function]

This function returns the height of the screen in pixels. On a character terminal, it gives the height in characters.

For graphical terminals, note that on multi-monitor setups this refers to the pixel height for all physical monitors associated with *display*. See Section 30.2 [Multiple Terminals], page 787.

display-pixel-width &optional display [Function]

This function returns the width of the screen in pixels. On a character terminal, it gives the width in characters.

For graphical terminals, note that on multi-monitor setups this refers to the pixel width for all physical monitors associated with *display*. See Section 30.2 [Multiple Terminals], page 787.

display-mm-height &optional display [Function]

This function returns the height of the screen in millimeters, or `nil` if Emacs cannot get that information.

For graphical terminals, note that on multi-monitor setups this refers to the height for all physical monitors associated with *display*. See Section 30.2 [Multiple Terminals], page 787.

display-mm-width &optional display [Function]

This function returns the width of the screen in millimeters, or `nil` if Emacs cannot get that information.

For graphical terminals, note that on multi-monitor setups this refers to the width for all physical monitors associated with *display*. See Section 30.2 [Multiple Terminals], page 787.

display-mm-dimensions-alist [User Option]

This variable allows the user to specify the dimensions of graphical displays returned by `display-mm-height` and `display-mm-width` in case the system provides incorrect values.

display-backing-store &optional display [Function]

This function returns the backing store capability of the display. Backing store means recording the pixels of windows (and parts of windows) that are not exposed, so that when exposed they can be displayed very quickly.

Values can be the symbols `always`, `when-mapped`, or `not-useful`. The function can also return `nil` when the question is inapplicable to a certain kind of display.

display-save-under &optional display [Function]

This function returns non-`nil` if the display supports the SaveUnder feature. That feature is used by pop-up windows to save the pixels they obscure, so that they can pop down quickly.

display-planes &optional display [Function]

This function returns the number of planes the display supports. This is typically the number of bits per pixel. For a tty display, it is log to base two of the number of colors supported.

display-visual-class &optional display [Function]

This function returns the visual class for the screen. The value is one of the symbols `static-gray` (a limited, unchangeable number of grays), `gray-scale` (a full range of grays), `static-color` (a limited, unchangeable number of colors), `pseudo-color` (a limited number of colors), `true-color` (a full range of colors), and `direct-color` (a full range of colors).

display-color-cells &optional display [Function]

This function returns the number of color cells the screen supports.

These functions obtain additional information about the window system in use where Emacs shows the specified *display*. (Their names begin with `x-` for historical reasons.)

x-server-version &optional display [Function]

This function returns the list of version numbers of the GUI window system running on *display*, such as the X server on GNU and Unix systems. The value is a list of three integers: the major and minor version numbers of the protocol, and the distributor-specific release number of the window system software itself. On GNU and Unix systems, these are normally the version of the X protocol and the distributor-specific release number of the X server software. On MS-Windows, this is the version of the Windows OS.

x-server-vendor &optional display [Function]

This function returns the vendor that provided the window system software (as a string). On GNU and Unix systems this really means whoever distributes the X server. On MS-Windows this is the vendor ID string of the Windows OS (Microsoft).

When the developers of X labeled software distributors as “vendors”, they showed their false assumption that no system could ever be developed and distributed non-commercially.

31 Positions

A *position* is the index of a character in the text of a buffer. More precisely, a position identifies the place between two characters (or before the first character, or after the last character), so we can speak of the character before or after a given position. However, we often speak of the character “at” a position, meaning the character after that position.

Positions are usually represented as integers starting from 1, but can also be represented as *markers*—special objects that relocate automatically when text is inserted or deleted so they stay with the surrounding characters. Functions that expect an argument to be a position (an integer), but accept a marker as a substitute, normally ignore which buffer the marker points into; they convert the marker to an integer, and use that integer, exactly as if you had passed the integer as the argument, even if the marker points to the wrong buffer. A marker that points nowhere cannot convert to an integer; using it instead of an integer causes an error. See Chapter 32 [Markers], page 869.

See also the field feature (see Section 33.19.9 [Fields], page 936), which provides functions that are used by many cursor-motion commands.

31.1 Point

Point is a special buffer position used by many editing commands, including the self-inserting typed characters and text insertion functions. Other commands move point through the text to allow editing and insertion at different places.

Like other positions, point designates a place between two characters (or before the first character, or after the last character), rather than a particular character. Usually terminals display the cursor over the character that immediately follows point; point is actually before the character on which the cursor sits.

The value of point is a number no less than 1, and no greater than the buffer size plus 1. If narrowing is in effect (see Section 31.4 [Narrowing], page 865), then point is constrained to fall within the accessible portion of the buffer (possibly at one end of it).

Each buffer has its own value of point, which is independent of the value of point in other buffers. Each window also has a value of point, which is independent of the value of point in other windows on the same buffer. This is why point can have different values in various windows that display the same buffer. When a buffer appears in only one window, the buffer’s point and the window’s point normally have the same value, so the distinction is rarely important. See Section 29.19 [Window Point], page 758, for more details.

point [Function]

This function returns the value of point in the current buffer, as an integer.

```
(point)
⇒ 175
```

point-min [Function]

This function returns the minimum accessible value of point in the current buffer. This is normally 1, but if narrowing is in effect, it is the position of the start of the region that you narrowed to. (See Section 31.4 [Narrowing], page 865.)

point-max

[Function]

This function returns the maximum accessible value of point in the current buffer. This is $(1+ (\text{buffer-size}))$, unless narrowing is in effect, in which case it is the position of the end of the region that you narrowed to. (See Section 31.4 [Narrowing], page 865.)

buffer-end flag

[Function]

This function returns `(point-max)` if *flag* is greater than 0, `(point-min)` otherwise. The argument *flag* must be a number.

buffer-size &optional buffer

[Function]

This function returns the total number of characters in the current buffer. In the absence of any narrowing (see Section 31.4 [Narrowing], page 865), `point-max` returns a value one larger than this.

If you specify a buffer, *buffer*, then the value is the size of *buffer*.

```
(buffer-size)
  ⇒ 35
(point-max)
  ⇒ 36
```

31.2 Motion

Motion functions change the value of point, either relative to the current value of point, relative to the beginning or end of the buffer, or relative to the edges of the selected window. See Section 31.1 [Point], page 853.

31.2.1 Motion by Characters

These functions move point based on a count of characters. `goto-char` is the fundamental primitive; the other functions use that.

goto-char position

[Command]

This function sets point in the current buffer to the value *position*.

If narrowing is in effect, *position* still counts from the beginning of the buffer, but point cannot go outside the accessible portion. If *position* is out of range, `goto-char` moves point to the beginning or the end of the accessible portion.

When this function is called interactively, *position* is the numeric prefix argument, if provided; otherwise it is read from the minibuffer.

`goto-char` returns *position*.

forward-char &optional count

[Command]

This function moves point *count* characters forward, towards the end of the buffer (or backward, towards the beginning of the buffer, if *count* is negative). If *count* is `nil`, the default is 1.

If this attempts to move past the beginning or end of the buffer (or the limits of the accessible portion, when narrowing is in effect), it signals an error with error symbol `beginning-of-buffer` or `end-of-buffer`.

In an interactive call, *count* is the numeric prefix argument.

backward-char &optional count [Command]

This is just like `forward-char` except that it moves in the opposite direction.

31.2.2 Motion by Words

The functions for parsing words described below use the syntax table and `char-script-table` to decide whether a given character is part of a word. See Chapter 36 [Syntax Tables], page 1022, and see Section 34.6 [Character Properties], page 968.

forward-word &optional count [Command]

This function moves point forward *count* words (or backward if *count* is negative). If *count* is omitted or `nil`, it defaults to 1. In an interactive call, *count* is specified by the numeric prefix argument.

“Moving one word” means moving until point crosses a word-constituent character, which indicates the beginning of a word, and then continue moving until the word ends. By default, characters that begin and end words, known as word boundaries, are defined by the current buffer’s syntax table (see Section 36.2.1 [Syntax Class Table], page 1023), but modes can override that by setting up a suitable `find-word-boundary-function-table`, described below. Characters that belong to different scripts (as defined by `char-script-table`), also define a word boundary (see Section 34.6 [Character Properties], page 968). In any case, this function cannot move point past the boundary of the accessible portion of the buffer, or across a field boundary (see Section 33.19.9 [Fields], page 936). The most common case of a field boundary is the end of the prompt in the minibuffer.

If it is possible to move *count* words, without being stopped prematurely by the buffer boundary or a field boundary, the value is `t`. Otherwise, the return value is `nil` and point stops at the buffer boundary or field boundary.

If `inhibit-field-text-motion` is non-`nil`, this function ignores field boundaries.

backward-word &optional count [Command]

This function is just like `forward-word`, except that it moves backward until encountering the front of a word, rather than forward.

words-include-escapes [User Option]

This variable affects the behavior of `forward-word` and `backward-word`, and everything that uses them. If it is non-`nil`, then characters in the escape and character-quote syntax classes count as part of words. Otherwise, they do not.

inhibit-field-text-motion [Variable]

If this variable is non-`nil`, certain motion functions including `forward-word`, `forward-sentence`, and `forward-paragraph` ignore field boundaries.

find-word-boundary-function-table [Variable]

This variable affects the behavior of `forward-word` and `backward-word`, and everything that uses them. Its value is a char-table (see Section 6.6 [Char-Tables], page 119) of functions to search for word boundaries. If a character has a non-`nil` entry in this table, then when a word starts or ends with that character, the corresponding function will be called with 2 arguments: *pos* and *limit*. The function should return the position of the other word boundary. Specifically, if *pos* is smaller than *limit*, then

pos is at the beginning of a word, and the function should return the position after the last character of the word; otherwise, *pos* is at the last character of a word, and the function should return the position of that word's first character.

forward-word-strictly &optional count [Function]

This function is like `forward-word`, but it is not affected by `find-word-boundary-function-table`. Lisp programs that should not change behavior when word movement is modified by modes which set that table, such as `subword-mode`, should use this function instead of `forward-word`.

backward-word-strictly &optional count [Function]

This function is like `backward-word`, but it is not affected by `find-word-boundary-function-table`. Like with `forward-word-strictly`, use this function instead of `backward-word` when movement by words should only consider syntax tables.

31.2.3 Motion to an End of the Buffer

To move point to the beginning of the buffer, write:

```
(goto-char (point-min))
```

Likewise, to move to the end of the buffer, use:

```
(goto-char (point-max))
```

Here are two commands that users use to do these things. They are documented here to warn you not to use them in Lisp programs, because they set the mark and display messages in the echo area.

beginning-of-buffer &optional n [Command]

This function moves point to the beginning of the buffer (or the limits of the accessible portion, when narrowing is in effect), setting the mark at the previous position (except in Transient Mark mode, if the mark is already active, it does not set the mark.)

If *n* is non-`nil`, then it puts point *n* tenths of the way from the beginning of the accessible portion of the buffer. In an interactive call, *n* is the numeric prefix argument, if provided; otherwise *n* defaults to `nil`.

Warning: Don't use this function in Lisp programs!

end-of-buffer &optional n [Command]

This function moves point to the end of the buffer (or the limits of the accessible portion, when narrowing is in effect), setting the mark at the previous position (except in Transient Mark mode when the mark is already active). If *n* is non-`nil`, then it puts point *n* tenths of the way from the end of the accessible portion of the buffer.

In an interactive call, *n* is the numeric prefix argument, if provided; otherwise *n* defaults to `nil`.

Warning: Don't use this function in Lisp programs!

31.2.4 Motion by Text Lines

Text lines are portions of the buffer delimited by newline characters, which are regarded as part of the previous line. The first text line begins at the beginning of the buffer, and the last text line ends at the end of the buffer whether or not the last character is a newline.

The division of the buffer into text lines is not affected by the width of the window, by line continuation in display, or by how tabs and control characters are displayed.

beginning-of-line &optional count

[Command]

This function moves point to the beginning of the current line. With an argument *count* not `nil` or `1`, it moves forward *count*–`1` lines and then to the beginning of the line.

This function does not move point across a field boundary (see Section 33.19.9 [Fields], page 936) unless doing so would move beyond there to a different line; therefore, if *count* is `nil` or `1`, and point starts at a field boundary, point does not move. To ignore field boundaries, either bind `inhibit-field-text-motion` to `t`, or use the `forward-line` function instead. For instance, `(forward-line 0)` does the same thing as `(beginning-of-line)`, except that it ignores field boundaries.

If this function reaches the end of the buffer (or of the accessible portion, if narrowing is in effect), it positions point there. No error is signaled.

line-beginning-position &optional count

[Function]

Return the position that `(beginning-of-line count)` would move to.

end-of-line &optional count

[Command]

This function moves point to the end of the current line. With an argument *count* not `nil` or `1`, it moves forward *count*–`1` lines and then to the end of the line.

This function does not move point across a field boundary (see Section 33.19.9 [Fields], page 936) unless doing so would move beyond there to a different line; therefore, if *count* is `nil` or `1`, and point starts at a field boundary, point does not move. To ignore field boundaries, bind `inhibit-field-text-motion` to `t`.

If this function reaches the end of the buffer (or of the accessible portion, if narrowing is in effect), it positions point there. No error is signaled.

line-end-position &optional count

[Function]

Return the position that `(end-of-line count)` would move to.

pos-bol &optional count

[Function]

Like `line-beginning-position`, but ignores fields (and is more efficient).

pos-eol &optional count

[Function]

Like `line-end-position`, but ignores fields (and is more efficient).

forward-line &optional count

[Command]

This function moves point forward *count* lines, to the beginning of the line following that. If *count* is negative, it moves point $-count$ lines backward, to the beginning of a line preceding that. If *count* is zero, it moves point to the beginning of the current line. If *count* is `nil`, that means `1`.

If `forward-line` encounters the beginning or end of the buffer (or of the accessible portion) before finding that many lines, it sets point there. No error is signaled.

`forward-line` returns the difference between *count* and the number of lines actually moved. If you attempt to move down five lines from the beginning of a buffer that has only three lines, point stops at the end of the last line, and the value will be `2`. As an

explicit exception, if the last accessible line is non-empty, but has no newline (e.g., if the buffer ends without a newline), the function sets point to the end of that line, and the value returned by the function counts that line as one line successfully moved.

In an interactive call, *count* is the numeric prefix argument.

count-lines start end &optional ignore-invisible-lines [Function]

This function returns the number of lines between the positions *start* and *end* in the current buffer. If *start* and *end* are equal, then it returns 0. Otherwise it returns at least 1, even if *start* and *end* are on the same line. This is because the text between them, considered in isolation, must contain at least one line unless it is empty.

If the optional *ignore-invisible-lines* is non-*nil*, invisible lines will not be included in the count.

count-words start end [Command]

This function returns the number of words between the positions *start* and *end* in the current buffer.

This function can also be called interactively. In that case, it prints a message reporting the number of lines, words, and characters in the buffer, or in the region if the region is active.

line-number-at-pos &optional pos absolute [Function]

This function returns the line number in the current buffer corresponding to the buffer position *pos*. If *pos* is *nil* or omitted, the current buffer position is used. If *absolute* is *nil*, the default, counting starts at (*point-min*), so the value refers to the contents of the accessible portion of the (potentially narrowed) buffer. If *absolute* is non-*nil*, ignore any narrowing and return the absolute line number.

Also see the functions **bolp** and **eolp** in Section 33.1 [Near Point], page 878. These functions do not move point, but test whether it is already at the beginning or end of a line.

31.2.5 Motion by Screen Lines

The line functions in the previous section count text lines, delimited only by newline characters. By contrast, these functions count screen lines, which are defined by the way the text appears on the screen. A text line is a single screen line if it is short enough to fit the width of the selected window, but otherwise it may occupy several screen lines.

In some cases, text lines are truncated on the screen rather than continued onto additional screen lines. In these cases, **vertical-motion** moves point much like **forward-line**. See Section 41.3 [Truncation], page 1130.

Because the width of a given string depends on the flags that control the appearance of certain characters, **vertical-motion** behaves differently, for a given piece of text, depending on the buffer it is in, and even on the selected window (because the width, the truncation flag, and display table may vary between windows). See Section 41.23.1 [Usual Display], page 1242.

These functions scan text to determine where screen lines break, and thus take time proportional to the distance scanned.

vertical-motion count &optional window cur-col [Function]

This function moves point to the start of the screen line *count* screen lines down from the screen line containing point. If *count* is negative, it moves up instead. If *count* is zero, point moves to the visual start of the current screen line.

The *count* argument can be a cons cell, (*cols . lines*), instead of an integer. Then the function moves by *lines* screen lines, as described for *count* above, and puts point *cols* columns from the visual start of that screen line. The value of *cols* can be a float, and is interpreted in units of the frame's canonical character width (see Section 30.3.2 [Frame Font], page 797); this allows specifying accurate horizontal position of point when the target screen line uses variable fonts. Note that *cols* are counted from the *visual* start of the line; if the window is scrolled horizontally (see Section 29.23 [Horizontal Scrolling], page 767), the column where point will end is in addition to the number of columns by which the text is scrolled, and if the target line is a continuation line, its leftmost column is considered column zero (unlike column-oriented functions, see Section 33.16 [Columns], page 909).

The return value is the number of screen lines over which point was moved. The value may be less in absolute value than *count* if the beginning or end of the buffer was reached.

The window *window* is used for obtaining parameters such as the width, the horizontal scrolling, and the display table. But **vertical-motion** always operates on the current buffer, even if *window* currently displays some other buffer.

The optional argument *cur-col* specifies the current column when the function is called. This is the window-relative horizontal coordinate of point, measured in units of font width of the frame's default face. Providing it speeds up the function, especially in very long lines, because the function doesn't have to go back in the buffer in order to determine the current column. Note that *cur-col* is also counted from the visual start of the line.

count-screen-lines &optional beg end count-final-newline window [Function]

This function returns the number of screen lines in the text from *beg* to *end*. The number of screen lines may be different from the number of actual lines, due to line continuation, the display table, etc. If *beg* and *end* are `nil` or omitted, they default to the beginning and end of the accessible portion of the buffer.

If the region ends with a newline, that is ignored unless the optional third argument *count-final-newline* is non-`nil`.

The optional fourth argument *window* specifies the window for obtaining parameters such as width, horizontal scrolling, and so on. The default is to use the selected window's parameters.

Like **vertical-motion**, **count-screen-lines** always uses the current buffer, regardless of which buffer is displayed in *window*. This makes possible to use **count-screen-lines** in any buffer, whether or not it is currently displayed in some window.

move-to-window-line count [Command]

This function moves point with respect to the text currently displayed in the selected window. It moves point to the beginning of the screen line *count* screen lines from the top of the window; zero means the topmost line. If *count* is negative, that specifies a

position *–count* lines from the bottom (or the last line of the buffer, if the buffer ends above the specified screen position); thus, *count* of *–1* specifies the last fully visible screen line of the window.

If *count* is **nil**, then point moves to the beginning of the line in the middle of the window. If the absolute value of *count* is greater than the size of the window, then point moves to the place that would appear on that screen line if the window were tall enough. This will probably cause the next redisplay to scroll to bring that location onto the screen.

In an interactive call, *count* is the numeric prefix argument.

The value returned is the screen line number point has moved to, relative to the top line of the window.

move-to-window-group-line count [Function]

This function is like **move-to-window-line**, except that when the selected window is a part of a group of windows (see [Window Group], page 698), **move-to-window-group-line** will move to a position with respect to the entire group, not just the single window. This condition holds when the buffer local variable **move-to-window-group-line-function** is set to a function. In this case, **move-to-window-group-line** calls the function with the argument *count*, then returns its result.

compute-motion from frompos to topos width offsets window [Function]

This function scans the current buffer, calculating screen positions. It scans the buffer forward from position *from*, assuming that is at screen coordinates *frompos*, to position *to* or coordinates *topos*, whichever comes first. It returns the ending buffer position and screen coordinates.

The coordinate arguments *frompos* and *topos* are cons cells of the form (*hpos . vpos*).

The argument *width* is the number of columns available to display text; this affects handling of continuation lines. **nil** means the actual number of usable text columns in the window, which is equivalent to the value returned by (**window-width window**).

The argument *offsets* is either **nil** or a cons cell of the form (*hscroll . tab-offset*). Here *hscroll* is the number of columns not being displayed at the left margin; most callers get this by calling **window-hscroll**. Meanwhile, *tab-offset* is the offset between column numbers on the screen and column numbers in the buffer. This can be nonzero in a continuation line, when the previous screen lines' widths do not add up to a multiple of **tab-width**. It is always zero in a non-continuation line.

The window *window* serves only to specify which display table to use. **compute-motion** always operates on the current buffer, regardless of what buffer is displayed in *window*.

The return value is a list of five elements:

(*pos hpos vpos prevhpos contin*)

Here *pos* is the buffer position where the scan stopped, *vpos* is the vertical screen position, and *hpos* is the horizontal screen position.

The result *prevhpos* is the horizontal position one character back from *pos*. The result *contin* is **t** if the last line was continued after (or within) the previous character.

For example, to find the buffer position of column *col* of screen line *line* of a certain window, pass the window’s display start location as *from* and the window’s upper-left coordinates as *frompos*. Pass the buffer’s (*point-max*) as *to*, to limit the scan to the end of the accessible portion of the buffer, and pass *line* and *col* as *topos*. Here’s a function that does this:

```
(defun coordinates-of-position (col line)
  (car (compute-motion (window-start)
    '(0 . 0)
    (point-max)
    (cons col line)
    (window-width)
    (cons (window-hscroll) 0)
    (selected-window))))
```

When you use `compute-motion` for the minibuffer, you need to use `minibuffer-prompt-width` to get the horizontal position of the beginning of the first screen line. See Section 21.12 [Minibuffer Contents], page 419.

31.2.6 Moving over Balanced Expressions

Here are several functions concerned with balanced-parenthesis expressions (also called *sexps* in connection with moving across them in Emacs). The syntax table controls how these functions interpret various characters; see Chapter 36 [Syntax Tables], page 1022. See Section 36.6 [Parsing Expressions], page 1030, for lower-level primitives for scanning sexps or parts of sexps. For user-level commands, see Section “Commands for Editing with Parentheses” in *The GNU Emacs Manual*.

forward-list &optional arg [Command]

This function moves forward across *arg* (default 1) balanced groups of parentheses. (Other syntactic entities such as words or paired string quotes are ignored.)

backward-list &optional arg [Command]

This function moves backward across *arg* (default 1) balanced groups of parentheses. (Other syntactic entities such as words or paired string quotes are ignored.)

up-list &optional arg escape-strings no-syntax-crossing [Command]

This function moves forward out of *arg* (default 1) levels of parentheses. A negative argument means move backward but still to a less deep spot. If *escape-strings* is non-*nil* (as it is interactively), move out of enclosing strings as well. If *no-syntax-crossing* is non-*nil* (as it is interactively), prefer to break out of any enclosing string instead of moving to the start of a list broken across multiple strings. On error, location of point is unspecified.

backward-up-list &optional arg escape-strings no-syntax-crossing [Command]

This function is just like `up-list`, but with a negated argument.

down-list &optional arg [Command]

This function moves forward into *arg* (default 1) levels of parentheses. A negative argument means move backward but still go deeper in parentheses ($-arg$ levels).

forward-sexp &optional arg [Command]

This function moves forward across *arg* (default 1) balanced expressions. Balanced expressions include both those delimited by parentheses and other kinds, such as words and string constants. See Section 36.6 [Parsing Expressions], page 1030. For example,

```
----- Buffer: foo -----
(concat* "foo " (car x) y z)
----- Buffer: foo -----  
  

(forward-sexp 3)
⇒ nil  
  

----- Buffer: foo -----
(concat "foo " (car x) y* z)
----- Buffer: foo -----
```

backward-sexp &optional arg [Command]

This function moves backward across *arg* (default 1) balanced expressions.

beginning-of-defun &optional arg [Command]

This function moves back to the *arg*th beginning of a defun. If *arg* is negative, this actually moves forward, but it still moves to the beginning of a defun, not to the end of one. *arg* defaults to 1.

end-of-defun &optional arg [Command]

This function moves forward to the *arg*th end of a defun. If *arg* is negative, this actually moves backward, but it still moves to the end of a defun, not to the beginning of one. *arg* defaults to 1.

defun-prompt-regexp [User Option]

If non-*nil*, this buffer-local variable holds a regular expression that specifies what text can appear before the open-parenthesis that starts a defun. That is to say, a defun begins on a line that starts with a match for this regular expression, followed by a character with open-parenthesis syntax.

open-paren-in-column-0-is-defun-start [User Option]

If this variable's value is non-*nil*, an open parenthesis in column 0 is considered to be the start of a defun. If it is *nil*, an open parenthesis in column 0 has no special meaning. The default is *t*. If a string literal happens to have a parenthesis in column 0, escape it with a backslash to avoid a false positive.

beginning-of-defun-function [Variable]

If non-*nil*, this variable holds a function for finding the beginning of a defun. The function `beginning-of-defun` calls this function instead of using its normal method, passing it its optional argument. If the argument is non-*nil*, the function should move back by that many functions, like `beginning-of-defun` does.

end-of-defun-function [Variable]

If non-*nil*, this variable holds a function for finding the end of a defun. The function `end-of-defun` calls this function instead of using its normal method.

If Emacs is compiled with tree-sitter, it can use the tree-sitter parser information to move across syntax constructs. Since what exactly is considered a defun varies between languages, a major mode should set `treesit-defun-type-regexp` to determine that. Then the mode can get navigation-by-defun functionality for free, by using `treesit-beginning-of-defun` and `treesit-end-of-defun`.

treesit-defun-type-regexp [Variable]

This variable determines which nodes are considered defuns by Emacs. It can be a regexp that matches the type of defun nodes. (For “node” and “node type”, see Chapter 37 [Parsing Program Source], page 1039.)

For example, `python-mode` sets this variable to a regexp that matches either ‘`function_definition`’ or ‘`class_definition`’.

Sometimes not all nodes matched by the regexp are valid defuns. Therefore, this variable can also be a cons cell of the form (`regexp . pred`), where `pred` should be a function that takes a node as its argument, and returns `non-nil` if the node is a valid defun, or `nil` if it is not valid.

treesit-defun-tactic [Variable]

This variable determines how Emacs treats nested defuns. If the value is `top-level`, navigation functions only move across top-level defuns. If the value is `nested`, navigation functions recognize nested defuns.

31.2.7 Skipping Characters

The following two functions move point over a specified set of characters. For example, they are often used to skip whitespace. For related functions, see Section 36.5 [Motion and Syntax], page 1030.

These functions convert the set string to multibyte if the buffer is multibyte, and they convert it to unibyte if the buffer is unibyte, as the search functions do (see Chapter 35 [Searching and Matching], page 993).

skip-chars-forward character-set &optional limit [Function]

This function moves point in the current buffer forward, skipping over a given set of characters. It examines the character following point, then advances point if the character matches `character-set`. This continues until it reaches a character that does not match. The function returns the number of characters moved over.

The argument `character-set` is a string, like the inside of a ‘`[...]`’ in a regular expression except that ‘`]`’ does not terminate it, and ‘`\`’ quotes ‘`^`’, ‘`-`’ or ‘`\`’. Thus, “`a-zA-Z`” skips over all letters, stopping before the first nonletter, and “`^a-zA-Z`” skips nonletters stopping before the first letter (see Section 35.3 [Regular Expressions], page 995). Character classes can also be used, e.g., “`[:alnum:]`” (see Section 35.3.1.2 [Char Classes], page 1000).

If `limit` is supplied (it must be a number or a marker), it specifies the maximum position in the buffer that point can be skipped to. Point will stop at or before `limit`.

In the following example, point is initially located directly before the ‘`T`’. After the form is evaluated, point is located at the end of that line (between the ‘`t`’ of ‘`hat`’ and the newline). The function skips all letters and spaces, but not newlines.

```
----- Buffer: foo -----
I read "★The cat in the hat
comes back" twice.
----- Buffer: foo -----  

(skip-chars-forward "a-zA-Z ")
⇒ 18  

----- Buffer: foo -----
I read "The cat in the hat★
comes back" twice.
----- Buffer: foo -----
```

skip-chars-backward *character-set &optional limit* [Function]

This function moves point backward, skipping characters that match *character-set*, until *limit*. It is just like **skip-chars-forward** except for the direction of motion.

The return value indicates the distance traveled. It is an integer that is zero or less.

31.3 Excursions

It is often useful to move point temporarily within a localized portion of the program. This is called an *excursion*, and it is done with the **save-excursion** special form. This construct remembers the initial identity of the current buffer, and its value of point, and restores them after the excursion completes. It is the standard way to move point within one part of a program and avoid affecting the rest of the program, and is used thousands of times in the Lisp sources of Emacs.

If you only need to save and restore the identity of the current buffer, use **save-current-buffer** or **with-current-buffer** instead (see Section 28.2 [Current Buffer], page 671). If you need to save or restore window configurations, see the forms described in Section 29.26 [Window Configurations], page 774, and in Section 30.13 [Frame Configurations], page 831.

save-excursion *body...* [Special Form]

This special form saves the identity of the current buffer and the value of point in it, evaluates *body*, and finally restores the buffer and its saved value of point. Both saved values are restored even in case of an abnormal exit via **throw** or error (see Section 11.7 [Nonlocal Exits], page 177).

The value returned by **save-excursion** is the result of the last form in *body*, or **nil** if no body forms were given.

Because **save-excursion** only saves point for the buffer that was current at the start of the excursion, any changes made to point in other buffers, during the excursion, will remain in effect afterward. This frequently leads to unintended consequences, so the byte compiler warns if you call **set-buffer** during an excursion:

Warning: Use ‘**with-current-buffer**’ rather than
save-excursion+set-buffer

To avoid such problems, you should call **save-excursion** only after setting the desired current buffer, as in the following example:

```
(defun append-string-to-buffer (string buffer)
  "Append STRING to the end of BUFFER."
  (with-current-buffer buffer
    (save-excursion
      (goto-char (point-max))
      (insert string)))
```

Likewise, `save-excursion` does not restore window-buffer correspondences altered by functions such as `switch-to-buffer`.

Warning: Ordinary insertion of text adjacent to the saved point value relocates the saved value, just as it relocates all markers. More precisely, the saved value is a marker with insertion type `nil`. See Section 32.5 [Marker Insertion Types], page 872. Therefore, when the saved point value is restored, it normally comes before the inserted text.

`save-mark-and-excursion body...` [Macro]

This macro is like `save-excursion`, but also saves and restores the mark location and `mark-active`. This macro does what `save-excursion` did before Emacs 25.1.

31.4 Narrowing

Narrowing means limiting the text addressable by Emacs editing commands to a limited range of characters in a buffer. The text that remains addressable is called the *accessible portion* of the buffer.

Narrowing is specified with two buffer positions, which become the beginning and end of the accessible portion. For most editing commands and primitives, these positions replace the values of the beginning and end of the buffer. While narrowing is in effect, no text outside the accessible portion is displayed, and point cannot move outside the accessible portion. Note that narrowing does not alter actual buffer positions (see Section 31.1 [Point], page 853); it only determines which positions are considered the accessible portion of the buffer. Most functions refuse to operate on text that is outside the accessible portion.

Commands for saving buffers are unaffected by narrowing; they save the entire buffer regardless of any narrowing.

If you need to display in a single buffer several very different types of text, consider using an alternative facility described in Section 28.12 [Swapping Text], page 688.

`narrow-to-region start end` [Command]

This function sets the accessible portion of the current buffer to start at `start` and end at `end`. Both arguments should be character positions.

In an interactive call, `start` and `end` are set to the bounds of the current region (point and the mark, with the smallest first).

However, when the narrowing has been set by `with-restriction` with a label argument (see below), `narrow-to-region` can be used only within the limits of that narrowing. If `start` or `end` are outside these limits, the corresponding limit set by `with-restriction` is used instead. To gain access to other portions of the buffer, use `without-restriction` with the same label.

narrow-to-page &**optional** move-count

[Command]

This function sets the accessible portion of the current buffer to include just the current page. An optional first argument *move-count* non-**nil** means to move forward or backward by *move-count* pages and then narrow to one page. The variable **page-delimiter** specifies where pages start and end (see Section 35.8 [Standard Regexp], page 1020).

In an interactive call, *move-count* is set to the numeric prefix argument.

widen

[Command]

This function cancels any narrowing in the current buffer, so that the entire contents are accessible. This is called *widening*. It is equivalent to the following expression:

```
(narrow-to-region 1 (1+ (buffer-size)))
```

However, when a narrowing has been set by **with-restriction** with a label argument (see below), the limits set by **with-restriction** are restored, instead of canceling the narrowing. To gain access to other portions of the buffer, use **without-restriction** with the same label.

buffer-narrowed-p

[Function]

This function returns **non-nil** if the buffer is narrowed, and **nil** otherwise.

save-restriction body...

[Special Form]

This special form saves the current bounds of the accessible portion, evaluates the *body* forms, and finally restores the saved bounds, thus restoring the same state of narrowing (or absence thereof) formerly in effect. The state of narrowing is restored even in the event of an abnormal exit via **throw** or **error** (see Section 11.7 [Nonlocal Exits], page 177). Therefore, this construct is a clean way to narrow a buffer temporarily.

This construct also saves and restores the narrowings that were set by **with-restriction** with a label argument (see below).

The value returned by **save-restriction** is that returned by the last form in *body*, or **nil** if no body forms were given.

Caution: it is easy to make a mistake when using the **save-restriction** construct. Read the entire description here before you try it.

If *body* changes the current buffer, **save-restriction** still restores the restrictions on the original buffer (the buffer whose restrictions it saved from), but it does not restore the identity of the current buffer.

save-restriction does *not* restore point; use **save-excursion** for that. If you use both **save-restriction** and **save-excursion** together, **save-excursion** should come first (on the outside). Otherwise, the old point value would be restored with temporary narrowing still in effect. If the old point value were outside the limits of the temporary narrowing, this would fail to restore it accurately.

Here is a simple example of correct use of **save-restriction**:

```
----- Buffer: foo -----
This is the contents of foo
This is the contents of foo
This is the contents of foo*
----- Buffer: foo -----
```

```
(save-excursion
  (save-restriction
    (goto-char 1)
    (forward-line 2)
    (narrow-to-region 1 (point))
    (goto-char (point-min))
    (replace-string "foo" "bar")))

----- Buffer: foo -----
This is the contents of bar
This is the contents of bar
This is the contents of foo*
----- Buffer: foo -----
```

with-restriction *start end* [[:*label label*] *body*] [Special Form]

This special form saves the current bounds of the accessible portion of the buffer, sets the accessible portion to start at *start* and end at *end*, evaluates the *body* forms, and restores the saved bounds. In that case it is equivalent to

```
(save-restriction
  (narrow-to-region start end)
  body)
```

When the optional argument *label*, which is evaluated to get the label to use and must yield a non-`nil` value, is present, the narrowing is *labeled*. A labeled narrowing differs from a non-labeled one in several ways:

- During the evaluation of the *body* form, `narrow-to-region` and `widen` can be used only within the *start* and *end* limits.
- To lift the restriction introduced by `with-restriction` and gain access to other portions of the buffer, use `without-restriction` with the same *label* argument. (Another way to gain access to other portions of the buffer is to use an indirect buffer (see Section 28.11 [Indirect Buffers], page 687).)
- Labeled narrowings can be nested.
- Labeled narrowings can only be used in Lisp programs: they are never visible on display, and never interfere with narrowings set by the user.

If you use `with-restriction` with the optional *label* argument, we recommend documenting the *label* in the doc strings of the functions which use it, so that other Lisp programs your code calls could lift the labeled narrowing if and when it needs.

without-restriction [[:*label label*] *body*] [Special Form]

This special form saves the current bounds of the accessible portion of the buffer, widens the buffer, evaluates the *body* forms, and restores the saved bounds. In that case it is equivalent to

```
(save-restriction
  (widen)
  body)
```

When the optional argument *label* is present, the narrowing set by `with-restriction` with the same *label* argument is lifted.

32 Markers

A *marker* is a Lisp object used to specify a position in a buffer relative to the surrounding text. A marker changes its offset from the beginning of the buffer automatically whenever text is inserted or deleted, so that it stays with the two characters on either side of it.

32.1 Overview of Markers

A marker specifies a buffer and a position in that buffer. A marker can be used to represent a position in functions that require one, just as an integer could be used. In that case, the marker’s buffer is normally ignored. Of course, a marker used in this way usually points to a position in the buffer that the function operates on, but that is entirely the programmer’s responsibility. See Chapter 31 [Positions], page 853, for a complete description of positions.

A marker has three attributes: the marker position, the marker buffer, and the insertion type. The marker position is an integer that is equivalent (at a given time) to the marker as a position in that buffer. But the marker’s position value can change during the life of the marker, and often does. Insertion and deletion of text in the buffer relocate the marker. The idea is that a marker positioned between two characters remains between those two characters despite insertion and deletion elsewhere in the buffer. Relocation changes the integer equivalent of the marker.

Deleting text around a marker’s position leaves the marker between the characters immediately before and after the deleted text. Inserting text at the position of a marker normally leaves the marker either in front of or after the new text, depending on the marker’s *insertion type* (see Section 32.5 [Marker Insertion Types], page 872)—unless the insertion is done with `insert-before-markers` (see Section 33.4 [Insertion], page 882).

Insertion and deletion in a buffer must check all the markers and relocate them if necessary. This slows processing in a buffer with a large number of markers. For this reason, it is a good idea to make a marker point nowhere if you are sure you don’t need it any more. Markers that can no longer be accessed are eventually removed (see Section E.3 [Garbage Collection], page 1350).

Because it is common to perform arithmetic operations on a marker position, most of these operations (including `+` and `-`) accept markers as arguments. In such cases, the marker stands for its current position.

Here are examples of creating markers, setting markers, and moving point to markers:

```
; ; Make a new marker that initially does not point anywhere:  
(setq m1 (make-marker))  
⇒ #<marker in no buffer>  
  
; ; Set m1 to point between the 99th and 100th characters  
; ;   in the current buffer:  
(set-marker m1 100)  
⇒ #<marker at 100 in markers.texi>
```

```

;; Now insert one character at the beginning of the buffer:
(goto-char (point-min))
  ⇒ 1
(insert "Q")
  ⇒ nil

;; m1 is updated appropriately.
m1
  ⇒ #<marker at 101 in markers.texi>

;; Two markers that point to the same position
;; are not eq, but they are equal.
(setq m2 (copy-marker m1))
  ⇒ #<marker at 101 in markers.texi>
(eq m1 m2)
  ⇒ nil
(equal m1 m2)
  ⇒ t

;; When you are finished using a marker, make it point nowhere.
(set-marker m1 nil)
  ⇒ #<marker in no buffer>
```

32.2 Predicates on Markers

You can test an object to see whether it is a marker, or whether it is either an integer or a marker. The latter test is useful in connection with the arithmetic functions that work with both markers and integers.

markerp *object* [Function]
 This function returns **t** if *object* is a marker, **nil** otherwise. Note that integers are not markers, even though many functions will accept either a marker or an integer.

integer-or-marker-p *object* [Function]
 This function returns **t** if *object* is an integer or a marker, **nil** otherwise.

number-or-marker-p *object* [Function]
 This function returns **t** if *object* is a number (either integer or floating point) or a marker, **nil** otherwise.

32.3 Functions that Create Markers

When you create a new marker, you can make it point nowhere, or point to the present position of point, or to the beginning or end of the accessible portion of the buffer, or to the same place as another given marker.

The next four functions all return markers with insertion type **nil**. See Section 32.5 [Marker Insertion Types], page 872.

make-marker [Function]

This function returns a newly created marker that does not point anywhere.

```
(make-marker)
⇒ #<marker in no buffer>
```

point-marker [Function]

This function returns a new marker that points to the present position of point in the current buffer. See Section 31.1 [Point], page 853. For an example, see `copy-marker`, below.

point-min-marker [Function]

This function returns a new marker that points to the beginning of the accessible portion of the buffer. This will be the beginning of the buffer unless narrowing is in effect. See Section 31.4 [Narrowing], page 865.

point-max-marker [Function]

This function returns a new marker that points to the end of the accessible portion of the buffer. This will be the end of the buffer unless narrowing is in effect. See Section 31.4 [Narrowing], page 865.

Here are examples of this function and `point-min-marker`, shown in a buffer containing a version of the source file for the text of this chapter.

```
(point-min-marker)
⇒ #<marker at 1 in markers.texi>
(point-max-marker)
⇒ #<marker at 24080 in markers.texi>

(narrow-to-region 100 200)
⇒ nil
(point-min-marker)
⇒ #<marker at 100 in markers.texi>
(point-max-marker)
⇒ #<marker at 200 in markers.texi>
```

copy-marker &optional marker-or-integer insertion-type [Function]

If passed a marker as its argument, `copy-marker` returns a new marker that points to the same place and the same buffer as does `marker-or-integer`. If passed an integer as its argument, `copy-marker` returns a new marker that points to position `marker-or-integer` in the current buffer.

The new marker's insertion type is specified by the argument `insertion-type`. See Section 32.5 [Marker Insertion Types], page 872.

```
(copy-marker 0)
⇒ #<marker at 1 in markers.texi>

(copy-marker 90000)
⇒ #<marker at 24080 in markers.texi>
```

An error is signaled if `marker` is neither a marker nor an integer.

Two distinct markers are considered `equal` (even though not `eq`) to each other if they have the same position and buffer, or if they both point nowhere.

```
(setq p (point-marker))
⇒ #<marker at 2139 in markers.texi>

(setq q (copy-marker p))
⇒ #<marker at 2139 in markers.texi>

(eq p q)
⇒ nil

(equal p q)
⇒ t
```

32.4 Information from Markers

This section describes the functions for accessing the components of a marker object.

`marker-position marker` [Function]

This function returns the position that `marker` points to, or `nil` if it points nowhere.

`marker-buffer marker` [Function]

This function returns the buffer that `marker` points into, or `nil` if it points nowhere.

```
(setq m (make-marker))
⇒ #<marker in no buffer>
(marker-position m)
⇒ nil
(marker-buffer m)
⇒ nil

(set-marker m 3770 (current-buffer))
⇒ #<marker at 3770 in markers.texi>
(marker-buffer m)
⇒ #<buffer markers.texi>
(marker-position m)
⇒ 3770
```

32.5 Marker Insertion Types

When you insert text directly at the place where a marker points, there are two possible ways to relocate that marker: it can point before the inserted text, or point after it. You can specify which one a given marker should do by setting its *insertion type*. Note that use of `insert-before-markers` ignores markers' insertion types, always relocating a marker to point after the inserted text.

`set-marker-insertion-type marker type` [Function]

This function sets the insertion type of marker `marker` to `type`. If `type` is `t`, `marker` will advance when text is inserted at its position. If `type` is `nil`, `marker` does not advance when text is inserted there.

marker-insertion-type *marker* [Function]

This function reports the current insertion type of *marker*.

All functions that create markers without accepting an argument that specifies the insertion type, create them with insertion type **nil** (see Section 32.3 [Creating Markers], page 870). Also, the mark has, by default, insertion type **nil**.

32.6 Moving Marker Positions

This section describes how to change the position of an existing marker. When you do this, be sure you know whether the marker is used outside of your program, and, if so, what effects will result from moving it—otherwise, confusing things may happen in other parts of Emacs.

set-marker *marker position &optional buffer* [Function]

This function moves *marker* to *position* in *buffer*. If *buffer* is not provided, it defaults to the current buffer.

If *position* is **nil** or a marker that points nowhere, then *marker* is set to point nowhere.

The value returned is *marker*.

```
(setq m (point-marker))
     ⇒ #<marker at 4714 in markers.texi>
(set-marker m 55)
     ⇒ #<marker at 55 in markers.texi>
(setq b (get-buffer "foo"))
     ⇒ #<buffer foo>
(set-marker m 0 b)
     ⇒ #<marker at 1 in foo>
```

move-marker *marker position &optional buffer* [Function]

This is another name for **set-marker**.

32.7 The Mark

Each buffer has a special marker, which is designated *the mark*. When a buffer is newly created, this marker exists but does not point anywhere; this means that the mark doesn't exist in that buffer yet. Subsequent commands can set the mark.

The mark specifies a position to bound a range of text for many commands, such as **kill-region** and **indent-rigidly**. These commands typically act on the text between point and the mark, which is called the *region*. If you are writing a command that operates on the region, don't examine the mark directly; instead, use **interactive** with the '**r**' specification. This provides the values of point and the mark as arguments to the command in an interactive call, but permits other Lisp programs to specify arguments explicitly. See Section 22.2.2 [Interactive Codes], page 427.

Some commands set the mark as a side-effect. Commands should do this only if it has a potential use to the user, and never for their own internal purposes. For example, the **replace-regexp** command sets the mark to the value of point before doing any replacements, because this enables the user to move back there conveniently after the replace is finished.

Once the mark exists in a buffer, it normally never ceases to exist. However, it may become *inactive*, if Transient Mark mode is enabled. The buffer-local variable `mark-active`, if non-`nil`, means that the mark is active. A command can call the function `deactivate-mark` to deactivate the mark directly, or it can request deactivation of the mark upon return to the editor command loop by setting the variable `deactivate-mark` to a non-`nil` value.

If Transient Mark mode is enabled, certain editing commands that normally apply to text near point, apply instead to the region when the mark is active. This is the main motivation for using Transient Mark mode. (Another is that this enables highlighting of the region when the mark is active. See Chapter 41 [Display], page 1129.)

In addition to the mark, each buffer has a *mark ring* which is a list of markers containing previous values of the mark. When editing commands change the mark, they should normally save the old value of the mark on the mark ring. The variable `mark-ring-max` specifies the maximum number of entries in the mark ring; once the list becomes this long, adding a new element deletes the last element.

There is also a separate global mark ring, but that is used only in a few particular user-level commands, and is not relevant to Lisp programming. So we do not describe it here.

`mark &optional force` [Function]

This function returns the current buffer's mark position as an integer, or `nil` if no mark has ever been set in this buffer.

If Transient Mark mode is enabled, and `mark-even-if-inactive` is `nil`, `mark` signals an error if the mark is inactive. However, if `force` is non-`nil`, then `mark` disregards inactivity of the mark, and returns the mark position (or `nil`) anyway.

`mark-marker` [Function]

This function returns the marker that represents the current buffer's mark. It is not a copy, it is the marker used internally. Therefore, changing this marker's position will directly affect the buffer's mark. Don't do that unless that is the effect you want.

```
(setq m (mark-marker))
⇒ #<marker at 3420 in markers.texi>
(set-marker m 100)
⇒ #<marker at 100 in markers.texi>
(mark-marker)
⇒ #<marker at 100 in markers.texi>
```

Like any marker, this marker can be set to point at any buffer you like. If you make it point at any buffer other than the one of which it is the mark, it will yield perfectly consistent, but rather odd, results. We recommend that you not do it!

`set-mark position` [Function]

This function sets the mark to `position`, and activates the mark. The old value of the mark is *not* pushed onto the mark ring.

Please note: Use this function only if you want the user to see that the mark has moved, and you want the previous mark position to be lost. Normally, when a new mark is set, the old one should go on the `mark-ring`. For this reason, most applications should use `push-mark` and `pop-mark`, not `set-mark`.

Novice Emacs Lisp programmers often try to use the mark for the wrong purposes. The mark saves a location for the user's convenience. An editing command should not alter the mark unless altering the mark is part of the user-level functionality of the command. (And, in that case, this effect should be documented.) To remember a location for internal use in the Lisp program, store it in a Lisp variable. For example:

```
(let ((beg (point)))
  (forward-line 1)
  (delete-region beg (point))).
```

push-mark &optional position nomsg activate

[Function]

This function sets the current buffer's mark to *position*, and pushes a copy of the previous mark onto `mark-ring`. If *position* is `nil`, then the value of `point` is used.

The function `push-mark` normally *does not* activate the mark. To do that, specify `t` for the argument *activate*.

A ‘Mark set’ message is displayed unless *nomsg* is non-`nil`.

pop-mark

[Function]

This function pops off the top element of `mark-ring` and makes that mark become the buffer's actual mark. This does not move point in the buffer, and it does nothing if `mark-ring` is empty. It deactivates the mark.

transient-mark-mode

[User Option]

This variable, if non-`nil`, enables Transient Mark mode. In Transient Mark mode, every buffer-modifying primitive sets `deactivate-mark`. As a consequence, most commands that modify the buffer also deactivate the mark.

When Transient Mark mode is enabled and the mark is active, many commands that normally apply to the text near point instead apply to the region. Such commands should use the function `use-region-p` to test whether they should operate on the region. See Section 32.8 [The Region], page 877.

Lisp programs can set `transient-mark-mode` to non-`nil`, non-`t` values to enable Transient Mark mode temporarily. If the value is `lambda`, Transient Mark mode is automatically turned off after any action, such as buffer modification, that would normally deactivate the mark. If the value is `(only . oldval)`, then `transient-mark-mode` is set to the value *oldval* after any subsequent command that moves point and is not shift-translated (see Section 22.8.1 [Key Sequence Input], page 461), or after any other action that would normally deactivate the mark. (Marking a region with the mouse will temporarily enable `transient-mark-mode` in this way.)

mark-even-if-inactive

[User Option]

If this is non-`nil`, Lisp programs and the Emacs user can use the mark even when it is inactive. This option affects the behavior of Transient Mark mode. When the option is non-`nil`, deactivation of the mark turns off region highlighting, but commands that use the mark behave as if the mark were still active.

deactivate-mark

[Variable]

If an editor command sets this variable non-`nil`, then the editor command loop deactivates the mark after the command returns (if Transient Mark mode is enabled).

All the primitives that change the buffer set `deactivate-mark`, to deactivate the mark when the command is finished. Setting this variable makes it buffer-local.

To write Lisp code that modifies the buffer without causing deactivation of the mark at the end of the command, bind `deactivate-mark` to `nil` around the code that does the modification. For example:

```
(let (deactivate-mark)
      (insert " "))
```

deactivate-mark &optional force [Function]

If Transient Mark mode is enabled or *force* is non-`nil`, this function deactivates the mark and runs the normal hook `deactivate-mark-hook`. Otherwise, it does nothing.

mark-active [Variable]

The mark is active when this variable is non-`nil`. This variable is always buffer-local in each buffer. Do *not* use the value of this variable to decide whether a command that normally operates on text near point should operate on the region instead. Use the function `use-region-p` for that (see Section 32.8 [The Region], page 877).

activate-mark-hook [Variable]

deactivate-mark-hook [Variable]

These normal hooks are run, respectively, when the mark becomes active and when it becomes inactive. The hook `activate-mark-hook` is also run when the region is reactivated, for instance after using a command that switches back to a buffer that has an active mark.

handle-shift-selection [Function]

This function implements the shift-selection behavior of point-motion commands. See Section “Shift Selection” in *The GNU Emacs Manual*. It is called automatically by the Emacs command loop whenever a command with a ‘~’ character in its `interactive` spec is invoked, before the command itself is executed (see Section 22.2.2 [Interactive Codes], page 427).

If `shift-select-mode` is non-`nil` and the current command was invoked via shift translation (see Section 22.8.1 [Key Sequence Input], page 461), this function sets the mark and temporarily activates the region, unless the region was already temporarily activated in this way. Otherwise, if the region has been activated temporarily, it deactivates the mark and restores the variable `transient-mark-mode` to its earlier value.

mark-ring [Variable]

The value of this buffer-local variable is the list of saved former marks of the current buffer, most recent first.

```
mark-ring
⇒ (#<marker at 11050 in markers.texi>
    #<marker at 10832 in markers.texi>
    ...)
```

mark-ring-max

[User Option]

The value of this variable is the maximum size of `mark-ring`. If more marks than this are pushed onto the `mark-ring`, `push-mark` discards an old mark when it adds a new one.

When Delete Selection mode (see Section “Using Region” in *The GNU Emacs Manual*) is enabled, commands that operate on the active region (a.k.a. “selection”) behave slightly differently. This works by adding the function `delete-selection-pre-hook` to the `pre-command-hook` (see Section 22.1 [Command Overview], page 423). That function calls `delete-selection-helper` to delete the selection as appropriate for the command. If you want to adapt a command to Delete Selection mode, put the `delete-selection` property on the function’s symbol (see Section 9.4.1 [Symbol Plists], page 138); commands that don’t have this property on their symbol won’t delete the selection. This property can have one of several values to tailor the behavior to what the command is supposed to do; see the doc strings of `delete-selection-pre-hook` and `delete-selection-helper` for the details.

32.8 The Region

The text between point and the mark is known as *the region*. Various functions operate on text delimited by point and the mark, but only those functions specifically related to the region itself are described here.

The next two functions signal an error if the mark does not point anywhere. If Transient Mark mode is enabled and `mark-even-if-inactive` is `nil`, they also signal an error if the mark is inactive.

region-beginning

[Function]

This function returns the position of the beginning of the region (as an integer). This is the position of either point or the mark, whichever is smaller.

region-end

[Function]

This function returns the position of the end of the region (as an integer). This is the position of either point or the mark, whichever is larger.

Instead of using `region-beginning` and `region-end`, a command designed to operate on a region should normally use `interactive` with the ‘r’ specification to find the beginning and end of the region. This lets other Lisp programs specify the bounds explicitly as arguments. See Section 22.2.2 [Interactive Codes], page 427.

use-region-p

[Function]

This function returns `t` if Transient Mark mode is enabled, the mark is active, and there is a valid region in the buffer. This function is intended to be used by commands that operate on the region, instead of on text near point, when the mark is active.

A region is valid if it has a non-zero size, or if the user option `use-empty-active-region` is non-`nil` (by default, it is `nil`). The function `region-active-p` is similar to `use-region-p`, but considers all regions as valid. In most cases, you should not use `region-active-p`, since if the region is empty it is often more appropriate to operate on point.

33 Text

This chapter describes the functions that deal with the text in a buffer. Most examine, insert, or delete text in the current buffer, often operating at point or on text adjacent to point. Many are interactive. All the functions that change the text provide for undoing the changes (see Section 33.9 [Undo], page 895).

Many text-related functions operate on a region of text defined by two buffer positions passed in arguments named *start* and *end*. These arguments should be either markers (see Chapter 32 [Markers], page 869) or numeric character positions (see Chapter 31 [Positions], page 853). The order of these arguments does not matter; it is all right for *start* to be the end of the region and *end* the beginning. For example, (`(delete-region 1 10)`) and (`(delete-region 10 1)`) are equivalent. An `args-out-of-range` error is signaled if either *start* or *end* is outside the accessible portion of the buffer. In an interactive call, point and the mark are used for these arguments.

Throughout this chapter, “text” refers to the characters in the buffer, together with their properties (when relevant). Keep in mind that point is always between two characters, and the cursor appears on the character after point.

33.1 Examining Text Near Point

Many functions are provided to look at the characters around point. Several simple functions are described here. See also `looking-at` in Section 35.4 [Regexp Search], page 1008.

In the following four functions, “beginning” or “end” of buffer refers to the beginning or end of the accessible portion.

`char-after` &*optional position*

[Function]

This function returns the character in the current buffer at (i.e., immediately after) position *position*. If *position* is out of range for this purpose, either before the beginning of the buffer, or at or beyond the end, then the value is `nil`. The default for *position* is point.

In the following example, assume that the first character in the buffer is ‘@’:

```
(string (char-after 1))
⇒ "@"
```

`char-before` &*optional position*

[Function]

This function returns the character in the current buffer immediately before position *position*. If *position* is out of range for this purpose, either at or before the beginning of the buffer, or beyond the end, then the value is `nil`. The default for *position* is point.

`following-char`

[Function]

This function returns the character following point in the current buffer. This is similar to (`(char-after (point))`). However, if point is at the end of the buffer, then `following-char` returns 0.

Remember that point is always between characters, and the cursor normally appears over the character following point. Therefore, the character returned by `following-char` is the character the cursor is over.

In this example, point is between the ‘a’ and the ‘c’.

```
----- Buffer: foo -----
Gentlemen may cry ``Pea*c*ce! Peace!','
but there is no peace.
----- Buffer: foo -----
```

```
(string (preceding-char))
⇒ "a"
(string (following-char))
⇒ "c"
```

preceding-char [Function]

This function returns the character preceding point in the current buffer. See above, under **following-char**, for an example. If point is at the beginning of the buffer, **preceding-char** returns 0.

bobp [Function]

This function returns **t** if point is at the beginning of the buffer. If narrowing is in effect, this means the beginning of the accessible portion of the text. See also **point-min** in Section 31.1 [Point], page 853.

eobp [Function]

This function returns **t** if point is at the end of the buffer. If narrowing is in effect, this means the end of accessible portion of the text. See also **point-max** in See Section 31.1 [Point], page 853.

bolp [Function]

This function returns **t** if point is at the beginning of a line. See Section 31.2.4 [Text Lines], page 856. The beginning of the buffer (or of its accessible portion) always counts as the beginning of a line.

eolp [Function]

This function returns **t** if point is at the end of a line. The end of the buffer (or of its accessible portion) is always considered the end of a line.

33.2 Examining Buffer Contents

This section describes functions that allow a Lisp program to convert any portion of the text in the buffer into a string.

buffer-substring start end [Function]

This function returns a string containing a copy of the text of the region defined by positions *start* and *end* in the current buffer. If the arguments are not positions in the accessible portion of the buffer, **buffer-substring** signals an **args-out-of-range** error.

Here’s an example which assumes Font-Lock mode is not enabled:

```
----- Buffer: foo -----
This is the contents of buffer foo
```

```
----- Buffer: foo -----
```

```
(buffer-substring 1 10)
  ⇒ "This is t"
(buffer-substring (point-max) 10)
  ⇒ "he contents of buffer foo\n"
```

If the text being copied has any text properties, these are copied into the string along with the characters they belong to. See Section 33.19 [Text Properties], page 917. However, overlays (see Section 41.9 [Overlays], page 1150) in the buffer and their properties are ignored, not copied.

For example, if Font-Lock mode is enabled, you might get results like these:

```
(buffer-substring 1 10)
  ⇒ #("This is t" 0 1 (fontified t) 1 9 (fontified t))
```

buffer-substring-no-properties start end [Function]

This is like `buffer-substring`, except that it does not copy text properties, just the characters themselves. See Section 33.19 [Text Properties], page 917.

buffer-string [Function]

This function returns the contents of the entire accessible portion of the current buffer, as a string. If the text being copied has any text properties, these are copied into the string along with the characters they belong to.

If you need to make sure the resulting string, when copied to a different location, will not change its visual appearance due to reordering of bidirectional text, use the `buffer-substring-with-bidi-context` function (see Section 41.27 [Bidirectional Display], page 1250).

filter-buffer-substring start end &optional delete [Function]

This function filters the buffer text between `start` and `end` using a function specified by the variable `filter-buffer-substring-function`, and returns the result.

The default filter function consults the obsolete wrapper hook `filter-buffer-substring-functions` (see the documentation string of the macro `with-wrapper-hook` for the details about this obsolete facility). If it is `nil`, it returns the unaltered text from the buffer, i.e., what `buffer-substring` would return.

If `delete` is non-`nil`, the function deletes the text between `start` and `end` after copying it, like `delete-and-extract-region`.

Lisp code should use this function instead of `buffer-substring`, `buffer-substring-no-properties`, or `delete-and-extract-region` when copying into user-accessible data structures such as the kill-ring, X clipboard, and registers. Major and minor modes can modify `filter-buffer-substring-function` to alter such text as it is copied out of the buffer.

filter-buffer-substring-function [Variable]

The value of this variable is a function that `filter-buffer-substring` will call to do the actual work. The function receives three arguments, the same as those of `filter-buffer-substring`, which it should treat as per the documentation of that function. It should return the filtered text (and optionally delete the source text).

The following two variables are obsoleted by `filter-buffer-substring-function`, but are still supported for backward compatibility.

filter-buffer-substring-functions [Variable]

This obsolete variable is a wrapper hook, whose members should be functions that accept four arguments: `fun`, `start`, `end`, and `delete`. `fun` is a function that takes three arguments (`start`, `end`, and `delete`), and returns a string. In both cases, the `start`, `end`, and `delete` arguments are the same as those of `filter-buffer-substring`.

The first hook function is passed a `fun` that is equivalent to the default operation of `filter-buffer-substring`, i.e., it returns the buffer-substring between `start` and `end` and optionally deletes the original text from the buffer. In most cases, the hook function will call `fun` once, and then do its own processing of the result. The next hook function receives a `fun` equivalent to this, and so on. The actual return value is the result of all the hook functions acting in sequence.

current-word &optional strict really-word [Function]

This function returns the symbol (or word) at or near point, as a string. The return value includes no text properties.

If the optional argument `really-word` is non-`nil`, it finds a word; otherwise, it finds a symbol (which includes both word characters and symbol constituent characters).

If the optional argument `strict` is non-`nil`, then point must be in or next to the symbol or word—if no symbol or word is there, the function returns `nil`. Otherwise, a nearby symbol or word on the same line is acceptable.

thing-at-point thing &optional no-properties [Function]

Return the `thing` around or next to point, as a string.

The argument `thing` is a symbol which specifies a kind of syntactic entity. Possibilities include `symbol`, `list`, `sexp`, `defun`, `filename`, `existing-filename`, `url`, `word`, `sentence`, `whitespace`, `line`, `page`, `string`, and others.

When the optional argument `no-properties` is non-`nil`, this function strips text properties from the return value.

```
----- Buffer: foo -----
Gentlemen may cry ``Peace! Peace!','
but there is no peace.
----- Buffer: foo -----
```

```
(thing-at-point 'word)
⇒ "Peace"
(thing-at-point 'line)
⇒ "Gentlemen may cry ``Peace! Peace!', '\n"
(thing-at-point 'whitespace)
⇒ nil
```

thing-at-point-provider-alist [Variable]

This variable allows users and modes to tweak how `thing-at-point` works. It's an association list of `things` and functions (called with zero parameters) to

return that thing. Entries for *thing* will be evaluated in turn until a non-*nil* result is returned.

For instance, a major mode could say:

```
(setq-local thing-at-point-provider-alist
            (append thing-at-point-provider-alist
                    '((url . my-mode--url-at-point))))
```

If no providers have a non-*nil* return, the *thing* will be computed the standard way.

33.3 Comparing Text

This function lets you compare portions of the text in a buffer, without copying them into strings first.

compare-buffer-substrings *buffer1 start1 end1 buffer2 start2 end2* [Function]

This function lets you compare two substrings of the same buffer or two different buffers. The first three arguments specify one substring, giving a buffer (or a buffer name) and two positions within the buffer. The last three arguments specify the other substring in the same way. You can use *nil* for *buffer1*, *buffer2*, or both to stand for the current buffer.

The value is negative if the first substring is less, positive if the first is greater, and zero if they are equal. The absolute value of the result is one plus the index of the first differing characters within the substrings.

This function ignores case when comparing characters if **case-fold-search** is non-*nil*. It always ignores text properties.

Suppose you have the text ‘foobarbar haha!rara!’ in the current buffer; then in this example the two substrings are ‘rbar’ and ‘rara!’. The value is 2 because the first substring is greater at the second character.

```
(compare-buffer-substrings nil 6 11 nil 16 21)
⇒ 2
```

33.4 Inserting Text

Insertion means adding new text to a buffer. The inserted text goes at point—between the character before point and the character after point. Some insertion functions leave point before the inserted text, while other functions leave it after. We call the former insertion *after point* and the latter insertion *before point*.

Insertion moves markers located at positions after the insertion point, so that they stay with the surrounding text (see Chapter 32 [Markers], page 869). When a marker points at the place of insertion, insertion may or may not relocate the marker, depending on the marker’s insertion type (see Section 32.5 [Marker Insertion Types], page 872). Certain special functions such as **insert-before-markers** relocate all such markers to point after the inserted text, regardless of the markers’ insertion type.

Insertion functions signal an error if the current buffer is read-only (see Section 28.7 [Read Only Buffers], page 680) or if they insert within read-only text (see Section 33.19.4 [Special Properties], page 924).

These functions copy text characters from strings and buffers along with their properties. The inserted characters have exactly the same properties as the characters they were copied from. By contrast, characters specified as separate arguments, not part of a string or buffer, inherit their text properties from the neighboring text.

The insertion functions convert text from unibyte to multibyte in order to insert in a multibyte buffer, and vice versa—if the text comes from a string or from a buffer. However, they do not convert unibyte character codes 128 through 255 to multibyte characters, not even if the current buffer is a multibyte buffer. See Section 34.3 [Converting Representations], page 965.

insert &rest args [Function]

This function inserts the strings and/or characters *args* into the current buffer, at point, moving point forward. In other words, it inserts the text before point. An error is signaled unless all *args* are either strings or characters. The value is `nil`.

insert-before-markers &rest args [Function]

This function inserts the strings and/or characters *args* into the current buffer, at point, moving point forward. An error is signaled unless all *args* are either strings or characters. The value is `nil`.

This function is unlike the other insertion functions in that it relocates markers initially pointing at the insertion point, to point after the inserted text. If an overlay begins at the insertion point, the inserted text falls outside the overlay; if a nonempty overlay ends at the insertion point, the inserted text falls inside that overlay.

insert-char character &optional count inherit [Command]

This command inserts *count* instances of *character* into the current buffer before point. The argument *count* must be an integer, and *character* must be a character.

If called interactively, this command prompts for *character* using its Unicode name or its code point. See Section “Inserting Text” in *The GNU Emacs Manual*.

This function does not convert unibyte character codes 128 through 255 to multibyte characters, not even if the current buffer is a multibyte buffer. See Section 34.3 [Converting Representations], page 965.

If *inherit* is non-`nil`, the inserted characters inherit sticky text properties from the two characters before and after the insertion point. See Section 33.19.6 [Sticky Properties], page 932.

insert-buffer-substring from-buffer-or-name &optional start end [Function]

This function inserts a portion of buffer *from-buffer-or-name* into the current buffer before point. The text inserted is the region between *start* (inclusive) and *end* (exclusive). (These arguments default to the beginning and end of the accessible portion of that buffer.) This function returns `nil`.

In this example, the form is executed with buffer ‘bar’ as the current buffer. We assume that buffer ‘bar’ is initially empty.

```
----- Buffer: foo -----
We hold these truths to be self-evident, that all
----- Buffer: foo -----
```

```
(insert-buffer-substring "foo" 1 20)
⇒ nil
```

```
----- Buffer: bar -----
We hold these truths*
----- Buffer: bar -----
```

insert-buffer-substring-no-properties *from-buffer-or-name* [Function]
&optional *start end*

This is like **insert-buffer-substring** except that it does not copy any text properties.

insert-into-buffer *to-buffer &optional start end* [Function]

This is like **insert-buffer-substring**, but works in the opposite direction: The text is copied from the current buffer into *to-buffer*. The block of text is copied to the current point in *to-buffer*, and point (in that buffer) is advanced to after the end of the copied text. If *start/end* is **nil**, the entire text in the current buffer is copied over.

See Section 33.19.6 [Sticky Properties], page 932, for other insertion functions that inherit text properties from the nearby text in addition to inserting it. Whitespace inserted by indentation functions also inherits text properties.

33.5 User-Level Insertion Commands

This section describes higher-level commands for inserting text, commands intended primarily for the user but useful also in Lisp programs.

insert-buffer *from-buffer-or-name* [Command]

This command inserts the entire accessible contents of *from-buffer-or-name* (which must exist) into the current buffer after point. It leaves the mark after the inserted text. The value is **nil**.

self-insert-command *count &optional char* [Command]

This command inserts the character *char* (the last character typed); it does so *count* times, before point, and returns **nil**. Most printing characters are bound to this command. In routine use, **self-insert-command** is the most frequently called function in Emacs, but programs rarely use it except to install it on a keymap.

In an interactive call, *count* is the numeric prefix argument.

Self-insertion translates the input character through **translation-table-for-input**. See Section 34.9 [Translation of Characters], page 975.

This command calls **auto-fill-function** whenever that is non-**nil** and the character inserted is in the table **auto-fill-chars** (see Section 33.14 [Auto Filling], page 905).

This command performs abbrev expansion if Abbrev mode is enabled and the inserted character does not have word-constituent syntax. (See Chapter 38 [Abbrevs], page 1066, and Section 36.2.1 [Syntax Class Table], page 1023.) It is also responsible for calling **blink-paren-function** when the inserted character has close parenthesis syntax (see Section 41.22 [Blinking], page 1241).

The final thing this command does is to run the hook `post-self-insert-hook`. You could use this to automatically reindent text as it is typed, for example. The functions on this hook can use `last-command-event` (see Section 22.5 [Command Loop Info], page 436) to access the character just inserted.

If any function on this hook needs to act on the region (see Section 32.8 [The Region], page 877), it should make sure Delete Selection mode (see Section “Using Region” in *The GNU Emacs Manual*) doesn’t delete the region before `post-self-insert-hook` functions are invoked. The way to do so is to add a function that returns `nil` to `self-insert-uses-region-functions`, a special hook that tells Delete Selection mode it should not delete the region.

Do not try substituting your own definition of `self-insert-command` for the standard one. The editor command loop handles this function specially.

newline &optional *number-of-newlines* interactive [Command]

This command inserts newlines into the current buffer before point. If *number-of-newlines* is supplied, that many newline characters are inserted. In an interactive call, *number-of-newlines* is the numeric prefix argument.

This command calls `self-insert-command` to insert newlines, which may subsequently break the preceding line by calling `auto-fill-function` (see Section 33.14 [Auto Filling], page 905). Typically what `auto-fill-function` does is insert a newline; thus, the overall result in this case is to insert two newlines at different places: one at point, and another earlier in the line. `newline` does not auto-fill if *number-of-newlines* is non-`nil`.

This command does not run the hook `post-self-insert-hook` unless called interactively or *interactive* is non-`nil`.

This command indents to the left margin if that is not zero. See Section 33.12 [Margins], page 902.

The value returned is `nil`.

ensure-empty-lines &optional *number-of-empty-lines* [Command]

This command can be used to ensure that you have a specific number of empty lines before point. (An “empty line” is here defined as a line with no characters on it—a line with space characters isn’t an empty line.) It defaults to ensuring that there’s a single empty line before point.

If point isn’t at the beginning of a line, a newline character is inserted first. If there’s more empty lines before point than specified, the number of empty lines is reduced. Otherwise it’s increased to the specified number.

overwrite-mode [Variable]

This variable controls whether overwrite mode is in effect. The value should be `overwrite-mode-textual`, `overwrite-mode-binary`, or `nil`. `overwrite-mode-textual` specifies textual overwrite mode (treats newlines and tabs specially), and `overwrite-mode-binary` specifies binary overwrite mode (treats newlines and tabs like any other characters).

33.6 Deleting Text

Deletion means removing part of the text in a buffer, without saving it in the kill ring (see Section 33.8 [The Kill Ring], page 889). Deleted text can't be yanked, but can be reinserted using the undo mechanism (see Section 33.9 [Undo], page 895). Some deletion functions do save text in the kill ring in some special cases.

All of the deletion functions operate on the current buffer.

`erase-buffer`

[Command]

This function deletes the entire text of the current buffer (*not* just the accessible portion), leaving it empty. If the buffer is read-only, it signals a `buffer-read-only` error; if some of the text in it is read-only, it signals a `text-read-only` error. Otherwise, it deletes the text without asking for any confirmation. It returns `nil`.

Normally, deleting a large amount of text from a buffer inhibits further auto-saving of that buffer because it has shrunk. However, `erase-buffer` does not do this, the idea being that the future text is not really related to the former text, and its size should not be compared with that of the former text.

`delete-region start end`

[Command]

This command deletes the text between positions *start* and *end* in the current buffer, and returns `nil`. If point was inside the deleted region, its value afterward is *start*. Otherwise, point relocates with the surrounding text, as markers do.

`delete-and-extract-region start end`

[Function]

This function deletes the text between positions *start* and *end* in the current buffer, and returns a string containing the text just deleted.

If point was inside the deleted region, its value afterward is *start*. Otherwise, point relocates with the surrounding text, as markers do.

`delete-char count &optional killp`

[Command]

This command deletes *count* characters directly after point, or before point if *count* is negative. If *killp* is non-`nil`, then it saves the deleted characters in the kill ring.

In an interactive call, *count* is the numeric prefix argument, and *killp* is the unprocessed prefix argument. Therefore, if a prefix argument is supplied, the text is saved in the kill ring. If no prefix argument is supplied, then one character is deleted, but not saved in the kill ring.

The value returned is always `nil`.

`delete-backward-char count &optional killp`

[Command]

This command deletes *count* characters directly before point, or after point if *count* is negative. If *killp* is non-`nil`, then it saves the deleted characters in the kill ring.

In an interactive call, *count* is the numeric prefix argument, and *killp* is the unprocessed prefix argument. Therefore, if a prefix argument is supplied, the text is saved in the kill ring. If no prefix argument is supplied, then one character is deleted, but not saved in the kill ring.

The value returned is always `nil`.

backward-delete-char-untabify count &optional killp [Command]

This command deletes *count* characters backward, changing tabs into spaces. When the next character to be deleted is a tab, it is first replaced with the proper number of spaces to preserve alignment and then one of those spaces is deleted instead of the tab. If *killp* is non-*nil*, then the command saves the deleted characters in the kill ring.

Conversion of tabs to spaces happens only if *count* is positive. If it is negative, exactly $-|count|$ characters after point are deleted.

In an interactive call, *count* is the numeric prefix argument, and *killp* is the unprocessed prefix argument. Therefore, if a prefix argument is supplied, the text is saved in the kill ring. If no prefix argument is supplied, then one character is deleted, but not saved in the kill ring.

The value returned is always *nil*.

backward-delete-char-untabify-method [User Option]

This option specifies how `backward-delete-char-untabify` should deal with whitespace. Possible values include `untabify`, the default, meaning convert a tab to many spaces and delete one; `hungry`, meaning delete all tabs and spaces before point with one command; `all` meaning delete all tabs, spaces and newlines before point, and `nil`, meaning do nothing special for whitespace characters.

33.7 User-Level Deletion Commands

This section describes higher-level commands for deleting text, commands intended primarily for the user but useful also in Lisp programs.

delete-horizontal-space &optional backward-only [Command]

This function deletes all spaces and tabs around point. It returns *nil*.

If *backward-only* is non-*nil*, the function deletes spaces and tabs before point, but not after point.

In the following examples, we call `delete-horizontal-space` four times, once on each line, with point between the second and third characters on the line each time.

```
----- Buffer: foo -----
I *thought
I *      thought
We* thought
Yo*u thought
----- Buffer: foo -----
```

```
(delete-horizontal-space)    ; Four times.
⇒ nil
```

```
----- Buffer: foo -----
Ithought
Ithought
Wethought
You thought
----- Buffer: foo -----
```

delete-indentation &optional join-following-p beg end [Command]

This function joins the line point is on to the previous line, deleting any whitespace at the join and in some cases replacing it with one space. If *join-following-p* is non-*nil*, **delete-indentation** joins this line to the following line instead. Otherwise, if *beg* and *end* are non-*nil*, this function joins all lines in the region they define.

In an interactive call, *join-following-p* is the prefix argument, and *beg* and *end* are, respectively, the start and end of the region if it is active, else *nil*. The function returns *nil*.

If there is a fill prefix, and the second of the lines being joined starts with the prefix, then **delete-indentation** deletes the fill prefix before joining the lines. See Section 33.12 [Margins], page 902.

In the example below, point is located on the line starting ‘events’, and it makes no difference if there are trailing spaces in the preceding line.

```
----- Buffer: foo -----
When in the course of human
*   events, it becomes necessary
----- Buffer: foo -----  
  

(delete-indentation)
⇒ nil  
  

----- Buffer: foo -----
When in the course of human* events, it becomes necessary
----- Buffer: foo -----
```

After the lines are joined, the function **fixup-whitespace** is responsible for deciding whether to leave a space at the junction.

fixup-whitespace [Command]

This function replaces all the horizontal whitespace surrounding point with either one space or no space, according to the context. It returns *nil*.

At the beginning or end of a line, the appropriate amount of space is none. Before a character with close parenthesis syntax, or after a character with open parenthesis or expression-prefix syntax, no space is also appropriate. Otherwise, one space is appropriate. See Section 36.2.1 [Syntax Class Table], page 1023.

In the example below, **fixup-whitespace** is called the first time with point before the word ‘spaces’ in the first line. For the second invocation, point is directly after the ‘(’.

```
----- Buffer: foo -----
This has too many      *spaces
This has too many spaces at the start of (*  this list)
----- Buffer: foo -----  
  

(fixup-whitespace)
⇒ nil
(fixup-whitespace)
⇒ nil  
  

----- Buffer: foo -----
This has too many spaces
This has too many spaces at the start of (this list)
----- Buffer: foo -----
```

just-one-space &optional n [Command]

This command replaces any spaces and tabs around point with a single space, or *n* spaces if *n* is specified. It returns `nil`.

delete-blank-lines [Command]

This function deletes blank lines surrounding point. If point is on a blank line with one or more blank lines before or after it, then all but one of them are deleted. If point is on an isolated blank line, then it is deleted. If point is on a nonblank line, the command deletes all blank lines immediately following it.

A blank line is defined as a line containing only tabs and spaces.

`delete-blank-lines` returns `nil`.

delete-trailing-whitespace &optional start end [Command]

Delete trailing whitespace in the region defined by *start* and *end*.

This command deletes whitespace characters after the last non-whitespace character in each line in the region.

If this command acts on the entire buffer (i.e., if called interactively with the mark inactive, or called from Lisp with *end nil*), it also deletes all trailing lines at the end of the buffer if the variable `delete-trailing-lines` is non-`nil`.

33.8 The Kill Ring

Kill functions delete text like the deletion functions, but save it so that the user can reinsert it by *yanking*. Most of these functions have ‘kill-’ in their name. By contrast, the functions whose names start with ‘`delete-`’ normally do not save text for yanking (though they can still be undone); these are deletion functions.

Most of the kill commands are primarily for interactive use, and are not described here. What we do describe are the functions provided for use in writing such commands. You can use these functions to write commands for killing text. When you need to delete text for internal purposes within a Lisp function, you should normally use deletion functions, so as not to disturb the kill ring contents. See Section 33.6 [Deletion], page 886.

Killed text is saved for later yanking in the *kill ring*. This is a list that holds a number of recent kills, not just the last text kill. We call this a “ring” because yanking treats it as having elements in a cyclic order. The list is kept in the variable `kill-ring`, and can be operated on with the usual functions for lists; there are also specialized functions, described in this section, that treat it as a ring.

Some people think this use of the word “kill” is unfortunate, since it refers to operations that specifically *do not* destroy the entities killed. This is in sharp contrast to ordinary life, in which death is permanent and killed entities do not come back to life. Therefore, other metaphors have been proposed. For example, the term “cut ring” makes sense to people who, in pre-computer days, used scissors and paste to cut up and rearrange manuscripts. However, it would be difficult to change the terminology now.

33.8.1 Kill Ring Concepts

The kill ring records killed text as strings in a list, most recent first. A short kill ring, for example, might look like this:

```
("some text" "a different piece of text" "even older text")
```

When the list reaches `kill-ring-max` entries in length, adding a new entry automatically deletes the last entry.

When kill commands are interwoven with other commands, each kill command makes a new entry in the kill ring. Multiple kill commands in succession build up a single kill ring entry, which would be yanked as a unit; the second and subsequent consecutive kill commands add text to the entry made by the first one.

For yanking, one entry in the kill ring is designated the front of the ring. Some yank commands rotate the ring by designating a different element as the front. But this virtual rotation doesn't change the list itself—the most recent entry always comes first in the list.

33.8.2 Functions for Killing

`kill-region` is the usual subroutine for killing text. Any command that calls this function is a kill command (and should probably have ‘kill’ in its name). `kill-region` puts the newly killed text in a new element at the beginning of the kill ring or adds it to the most recent element. It determines automatically (using `last-command`) whether the previous command was a kill command, and if so appends the killed text to the most recent entry.

The commands described below can filter the killed text before they save it in the kill ring. They call `filter-buffer-substring` (see Section 33.2 [Buffer Contents], page 879) to perform the filtering. By default, there's no filtering, but major and minor modes and hook functions can set up filtering, so that text saved in the kill ring is different from what was in the buffer.

`kill-region start end &optional region`

[Command]

This function kills the stretch of text between `start` and `end`; but if the optional argument `region` is non-`nil`, it ignores `start` and `end`, and kills the text in the current region instead. The text is deleted but saved in the kill ring, along with its text properties. The value is always `nil`.

In an interactive call, `start` and `end` are point and the mark, and `region` is always non-`nil`, so the command always kills the text in the current region.

If the buffer or text is read-only, `kill-region` modifies the kill ring just the same, then signals an error without modifying the buffer. This is convenient because it lets the user use a series of kill commands to copy text from a read-only buffer into the kill ring.

`kill-read-only-ok`

[User Option]

If this option is non-`nil`, `kill-region` does not signal an error if the buffer or text is read-only. Instead, it simply returns, updating the kill ring but not changing the buffer.

`copy-region-as-kill start end &optional region`

[Command]

This function saves the stretch of text between `start` and `end` on the kill ring (including text properties), but does not delete the text from the buffer. However, if the optional argument `region` is non-`nil`, the function ignores `start` and `end`, and saves the current region instead. It always returns `nil`.

In an interactive call, `start` and `end` are point and the mark, and `region` is always non-`nil`, so the command always saves the text in the current region.

The command does not set `this-command` to `kill-region`, so a subsequent kill command does not append to the same kill ring entry.

33.8.3 Yanking

Yanking means inserting text from the kill ring, but it does not insert the text blindly. The `yank` command, and related commands, use `insert-for-yank` to perform special processing on the text before it is inserted.

`insert-for-yank` *string*

[Function]

This function works like `insert`, except that it processes the text in *string* according to the `yank-handler` text property, as well as the variables `yank-handled-properties` and `yank-excluded-properties` (see below), before inserting the result into the current buffer.

string will be run through `yank-transform-functions` (see below) before inserting.

`insert-buffer-substring-as-yank` *buf &optional start end*

[Function]

This function resembles `insert-buffer-substring`, except that it processes the text according to `yank-handled-properties` and `yank-excluded-properties`. (It does not handle the `yank-handler` property, which does not normally occur in buffer text anyway.)

If you put a `yank-handler` text property on all or part of a string, that alters how `insert-for-yank` inserts the string. If different parts of the string have different `yank-handler` values (comparison being done with `eq`), each substring is handled separately. The property value must be a list of one to four elements, with the following format (where elements after the first may be omitted):

`(function param noexclude undo)`

Here is what the elements do:

`function` When *function* is non-`nil`, it is called instead of `insert` to insert the string, with one argument—the string to insert.

`param` If *param* is present and non-`nil`, it replaces *string* (or the substring of *string* being processed) as the object passed to *function* (or `insert`). For example, if *function* is `yank-rectangle`, *param* should be a list of strings to insert as a rectangle.

`noexclude` If *noexclude* is present and non-`nil`, that disables the normal action of `yank-handled-properties` and `yank-excluded-properties` on the inserted string.

`undo` If *undo* is present and non-`nil`, it is a function that will be called by `yank-pop` to undo the insertion of the current object. It is called with two arguments, the start and end of the current region. *function* can set `yank-undo-function` to override the *undo* value.

`yank-handled-properties`

[User Option]

This variable specifies special text property handling conditions for yanked text. It takes effect after the text has been inserted (either normally, or via the `yank-handler` property), and prior to `yank-excluded-properties` taking effect.

The value should be an alist of elements (*prop . fun*). Each alist element is handled in order. The inserted text is scanned for stretches of text having text properties `eq` to *prop*; for each such stretch, *fun* is called with three arguments: the value of the property, and the start and end positions of the text.

yank-excluded-properties

[User Option]

The value of this variable is the list of properties to remove from inserted text. Its default value contains properties that might lead to annoying results, such as causing the text to respond to the mouse or specifying key bindings. It takes effect after `yank-handled-properties`.

yank-transform-functions

[Variable]

This variable is a list of functions. Each function is called (in order) with the string to be yanked as the argument, and should return a (possibly transformed) string. This variable can be set globally, but can also be used to create new commands that are variations on `yank`. For instance, to create a command that works like `yank`, but cleans up whitespace before inserting, you could say something like:

```
(defun yank-with-clean-whitespace ()
  (interactive)
  (let ((yank-transform-functions
        '(string-clean-whitespace)))
    (call-interactively #'yank)))
```

33.8.4 Functions for Yanking

This section describes higher-level commands for yanking, which are intended primarily for the user but useful also in Lisp programs. Both `yank` and `yank-pop` honor the `yank-excluded-properties` variable and `yank-handler` text property (see Section 33.8.3 [Yanking], page 891).

yank &optional arg

[Command]

This command inserts before point the text at the front of the kill ring. It sets the mark at the beginning of that text, using `push-mark` (see Section 32.7 [The Mark], page 873), and puts point at the end.

If *arg* is a non-`nil` list (which occurs interactively when the user types `C-u` with no digits), then `yank` inserts the text as described above, but puts point before the yanked text and sets the mark after it.

If *arg* is a number, then `yank` inserts the *arg*th most recently killed text—the *arg*th element of the kill ring list, counted cyclically from the front, which is considered the first element for this purpose.

`yank` does not alter the contents of the kill ring, unless it used text provided by another program, in which case it pushes that text onto the kill ring. However if *arg* is an integer different from one, it rotates the kill ring to place the yanked string at the front.

`yank` returns `nil`.

yank-pop &optional arg

[Command]

When invoked immediately after a `yank` or another `yank-pop`, this command replaces the just-yanked entry from the kill ring with a different entry from the kill ring. When

this command is invoked like that, the region contains text that was just inserted by another yank command. `yank-pop` deletes that text and inserts in its place a different piece of killed text. It does not add the deleted text to the kill ring, since it is already in the kill ring somewhere. It does however rotate the kill ring to place the newly yanked string at the front.

If `arg` is `nil`, then the replacement text is the previous element of the kill ring. If `arg` is numeric, the replacement is the `arg`th previous kill. If `arg` is negative, a more recent kill is the replacement.

The sequence of kills in the kill ring wraps around, so if `yank-pop` is invoked repeatedly and reaches the oldest kill, the one that comes after it is the newest one, and the one before the newest one is the oldest one.

This command can also be invoked after a command that is not a yank command. In that case, it prompts in the minibuffer for a kill-ring entry, with completion, and uses the kill ring elements as the minibuffer history (see Section 21.4 [Minibuffer History], page 392). This allows the user to interactively select one of the previous kills recorded in the kill ring.

The return value is always `nil`.

`yank-undo-function`

[Variable]

If this variable is non-`nil`, the function `yank-pop` uses its value instead of `delete-region` to delete the text inserted by the previous `yank` or `yank-pop` command. The value must be a function of two arguments, the start and end of the current region.

The function `insert-for-yank` automatically sets this variable according to the `undo` element of the `yank-handler` text property, if there is one.

33.8.5 Low-Level Kill Ring

These functions and variables provide access to the kill ring at a lower level, but are still convenient for use in Lisp programs, because they take care of interaction with window system selections (see Section 30.20 [Window System Selections], page 840).

`current-kill n &optional do-not-move`

[Function]

The function `current-kill` rotates the yanking pointer, which designates the front of the kill ring, by `n` places (from newer kills to older ones), and returns the text at that place in the ring.

If the optional second argument `do-not-move` is non-`nil`, then `current-kill` doesn't alter the yanking pointer; it just returns the `n`th kill, counting from the current yanking pointer.

If `n` is zero, indicating a request for the latest kill, `current-kill` calls the value of `interprogram-paste-function` (documented below) before consulting the kill ring. If that value is a function and calling it returns a string or a list of several strings, `current-kill` pushes the strings onto the kill ring and returns the first string. It also sets the yanking pointer to point to the kill-ring entry of the first string returned by `interprogram-paste-function`, regardless of the value of `do-not-move`. Otherwise, `current-kill` does not treat a zero value for `n` specially: it returns the entry pointed at by the yanking pointer and does not move the yanking pointer.

kill-new *string* &**optional** *replace* [Function]

This function pushes the text *string* onto the kill ring and makes the yanking pointer point to it. It discards the oldest entry if appropriate. It also invokes the values of **interprogram-paste-function** (subject to the user option **save-interprogram-paste-before-kill**) and **interprogram-cut-function** (see below).

If *replace* is non-*nil*, then **kill-new** replaces the first element of the kill ring with *string*, rather than pushing *string* onto the kill ring.

kill-append *string* *before-p* [Function]

This function appends the text *string* to the first entry in the kill ring and makes the yanking pointer point to the combined entry. Normally *string* goes at the end of the entry, but if *before-p* is non-*nil*, it goes at the beginning. This function calls **kill-new** as a subroutine, thus causing the values of **interprogram-cut-function** and possibly **interprogram-paste-function** (see below) to be invoked by extension.

interprogram-paste-function [Variable]

This variable provides a way of transferring killed text from other programs, when you are using a window system. Its value should be *nil* or a function of no arguments.

If the value is a function, **current-kill** calls it to get the most recent kill. If the function returns a non-*nil* value, then that value is used as the most recent kill. If it returns *nil*, then the front of the kill ring is used.

To facilitate support for window systems that support multiple selections, this function may also return a list of strings. In that case, the first string is used as the most recent kill, and all the other strings are pushed onto the kill ring, for easy access by **yank-pop**.

The normal use of this function is to get the window system's clipboard as the most recent kill, even if the selection belongs to another application. See Section 30.20 [Window System Selections], page 840. However, if the clipboard contents come from the current Emacs session, this function should return *nil*.

interprogram-cut-function [Variable]

This variable provides a way of communicating killed text to other programs, when you are using a window system. Its value should be *nil* or a function of one required argument.

If the value is a function, **kill-new** and **kill-append** call it with the new first element of the kill ring as the argument.

The normal use of this function is to put newly killed text in the window system's clipboard. See Section 30.20 [Window System Selections], page 840.

33.8.6 Internals of the Kill Ring

The variable **kill-ring** holds the kill ring contents, in the form of a list of strings. The most recent kill is always at the front of the list.

The **kill-ring-yank-pointer** variable points to a link in the kill ring list, whose CAR is the text to yank next. We say it identifies the front of the ring. Moving **kill-ring-yank-pointer** to a different link is called *rotating the kill ring*. We call the kill ring a “ring” because the functions that move the yank pointer wrap around from the end of the list to

the beginning, or vice-versa. Rotation of the kill ring is virtual; it does not change the value of `kill-ring`.

Both `kill-ring` and `kill-ring-yank-pointer` are Lisp variables whose values are normally lists. The word “pointer” in the name of the `kill-ring-yank-pointer` indicates that the variable’s purpose is to identify one element of the list for use by the next yank command.

The value of `kill-ring-yank-pointer` is always `eq` to one of the links in the kill ring list. The element it identifies is the CAR of that link. Kill commands, which change the kill ring, also set this variable to the value of `kill-ring`. The effect is to rotate the ring so that the newly killed text is at the front.

Here is a diagram that shows the variable `kill-ring-yank-pointer` pointing to the second entry in the kill ring ("some text" "a different piece of text" "yet older text").

This state of affairs might occur after *C-y* (*yank*) immediately followed by *M-y* (*yank-pop*).

kill-ring [Variable]
This variable holds the list of killed text sequences, most recently killed first.

kill-ring-yank-pointer [Variable]
This variable's value indicates which element of the kill ring is at the front of the ring for yanking. More precisely, the value is a tail of the value of `kill-ring`, and its CAR is the kill string that `C-y` should yank.

kill-ring-max [User Option]
The value of this variable is the maximum length to which the kill ring can grow, before elements are thrown away at the end. The default value for `kill-ring-max` is 120.

33.9 Undo

Most buffers have an *undo list*, which records all changes made to the buffer's text so that they can be undone. (The buffers that don't have one are usually special-purpose buffers for which Emacs assumes that undoing is not useful. In particular, any buffer whose name begins with a space has its undo recording off by default; see Section 28.3 [Buffer Names], page 674.) All the primitives that modify the text in the buffer automatically add elements to the front of the undo list, which is in the variable `buffer-undo-list`.

buffer-undo-list

[Variable]

This buffer-local variable's value is the undo list of the current buffer. A value of `t` disables the recording of undo information.

Here are the kinds of elements an undo list can have:

position This kind of element records a previous value of point; undoing this element moves point to *position*. Ordinary cursor motion does not make any sort of undo record, but deletion operations use these entries to record where point was before the command.

(beg . end)

This kind of element indicates how to delete text that was inserted. Upon insertion, the text occupied the range *beg*–*end* in the buffer.

(text . position)

This kind of element indicates how to reinsert text that was deleted. The deleted text itself is the string *text*. The place to reinsert it is `(abs position)`. If *position* is positive, point was at the beginning of the deleted text, otherwise it was at the end. Zero or more `(marker . adjustment)` elements follow immediately after this element.

(t . time-flag)

This kind of element indicates that an unmodified buffer became modified. A *time-flag* that is a non-integer Lisp timestamp represents the visited file's modification time as of when it was previously visited or saved, using the same format as `current-time`; see Section 42.5 [Time of Day], page 1270. A *time-flag* of 0 means the buffer does not correspond to any file; –1 means the visited file previously did not exist. `primitive-undo` uses these values to determine whether to mark the buffer as unmodified once again; it does so only if the file's status matches that of *time-flag*.

(nil property value beg . end)

This kind of element records a change in a text property. Here's how you might undo the change:

`(put-text-property beg end property value)`

(marker . adjustment)

This kind of element records the fact that the marker *marker* was relocated due to deletion of surrounding text, and that it moved *adjustment* character positions. If the marker's location is consistent with the `(text . position)` element preceding it in the undo list, then undoing this element moves *marker* – *adjustment* characters.

(apply funname . args)

This is an extensible undo item, which is undone by calling *funname* with arguments *args*.

(apply delta beg end funname . args)

This is an extensible undo item, which records a change limited to the range *beg* to *end*, which increased the size of the buffer by *delta* characters. It is undone by calling *funname* with arguments *args*.

This kind of element enables undo limited to a region to determine whether the element pertains to that region.

nil This element is a boundary. The elements between two boundaries are called a *change group*; normally, each change group corresponds to one keyboard command, and undo commands normally undo an entire group as a unit.

undo-boundary [Function]

This function places a boundary element in the undo list. The undo command stops at such a boundary, and successive undo commands undo to earlier and earlier boundaries. This function returns **nil**.

Calling this function explicitly is useful for splitting the effects of a command into more than one unit. For example, `query-replace` calls `undo-boundary` after each replacement, so that the user can undo individual replacements one by one.

Mostly, however, this function is called automatically at an appropriate time.

undo-auto-amalgamate [Function]

The editor command loop automatically calls `undo-boundary` just before executing each key sequence, so that each undo normally undoes the effects of one command. A few exceptional commands are *amalgamating*: these commands generally cause small changes to buffers, so with these a boundary is inserted only every 20th command, allowing the changes to be undone as a group. By default, the commands `self-insert-command`, which produces self-inserting input characters (see Section 33.5 [Commands for Insertion], page 884), and `delete-char`, which deletes characters (see Section 33.6 [Deletion], page 886), are amalgamating. Where a command affects the contents of several buffers, as may happen, for example, when a function on the `post-command-hook` affects a buffer other than the `current-buffer`, then `undo-boundary` will be called in each of the affected buffers.

This function can be called before an amalgamating command. It removes the previous `undo-boundary` if a series of such calls have been made.

The maximum number of changes that can be amalgamated is controlled by the `amalgamating-undo-limit` variable. If this variable is 1, no changes are amalgamated.

A Lisp program can amalgamate a series of changes into a single change group by calling `undo-amalgamate-change-group` (see Section 33.33 [Atomic Changes], page 959). Note that `amalgamating-undo-limit` has no effect on the groups produced by that function.

undo-auto-current-boundary-timer [Variable]

Some buffers, such as process buffers, can change even when no commands are executing. In these cases, `undo-boundary` is normally called periodically by the timer in this variable. Setting this variable to `non-nil` prevents this behavior.

undo-in-progress [Variable]

This variable is normally `nil`, but the undo commands bind it to `t`. This is so that various kinds of change hooks can tell when they're being called for the sake of undoing.

primitive-undo count list [Function]

This is the basic function for undoing elements of an undo list. It undoes the first `count` elements of `list`, returning the rest of `list`.

`primitive-undo` adds elements to the buffer's undo list when it changes the buffer. Undo commands avoid confusion by saving the undo list value at the beginning of a sequence of undo operations. Then the undo operations use and update the saved value. The new elements added by undoing are not part of this saved value, so they don't interfere with continuing to undo.

This function does not bind `undo-in-progress`.

`with-undo-amalgamate body...` [Macro]

This macro removes all the undo boundaries inserted during the execution of `body` so that it can be undone as a single step.

Some commands leave the region active after execution in such a way that it interferes with selective undo of that command. To make `undo` ignore the active region when invoked immediately after such a command, set the property `undo-inhibit-region` of the command's function symbol to a non-`nil` value. See Section 9.4.2 [Standard Properties], page 139.

33.10 Maintaining Undo Lists

This section describes how to enable and disable undo information for a given buffer. It also explains how the undo list is truncated automatically so it doesn't get too big.

Recording of undo information in a newly created buffer is normally enabled to start with; but if the buffer name starts with a space, the undo recording is initially disabled. You can explicitly enable or disable undo recording with the following two functions, or by setting `buffer-undo-list` yourself.

`buffer-enable-undo &optional buffer-or-name` [Command]

This command enables recording undo information for buffer `buffer-or-name`, so that subsequent changes can be undone. If no argument is supplied, then the current buffer is used. This function does nothing if undo recording is already enabled in the buffer. It returns `nil`.

In an interactive call, `buffer-or-name` is the current buffer. You cannot specify any other buffer.

`buffer-disable-undo &optional buffer-or-name` [Command]

This function discards the undo list of `buffer-or-name`, and disables further recording of undo information. As a result, it is no longer possible to undo either previous changes or any subsequent changes. If the undo list of `buffer-or-name` is already disabled, this function has no effect.

In an interactive call, `BUFFER-OR-NAME` is the current buffer. You cannot specify any other buffer. This function returns `nil`.

As editing continues, undo lists get longer and longer. To prevent them from using up all available memory space, garbage collection trims them back to size limits you can set. (For this purpose, the size of an undo list measures the cons cells that make up the list, plus the strings of deleted text.) Three variables control the range of acceptable sizes: `undo-limit`, `undo-strong-limit` and `undo-outer-limit`. In these variables, size is counted as the number of bytes occupied, which includes both saved text and other data.

undo-limit

[User Option]

This is the soft limit for the acceptable size of an undo list. The change group at which this size is exceeded is the last one kept.

undo-strong-limit

[User Option]

This is the upper limit for the acceptable size of an undo list. The change group at which this size is exceeded is discarded itself (along with all older change groups). There is one exception: the very latest change group is only discarded if it exceeds `undo-outer-limit`.

undo-outer-limit

[User Option]

If at garbage collection time the undo info for the current command exceeds this limit, Emacs discards the info and displays a warning. This is a last ditch limit to prevent memory overflow.

undo-ask-before-discard

[User Option]

If this variable is non-`nil`, when the undo info exceeds `undo-outer-limit`, Emacs asks in the echo area whether to discard the info. The default value is `nil`, which means to discard it automatically.

This option is mainly intended for debugging. Garbage collection is inhibited while the question is asked, which means that Emacs might leak memory if the user waits too long before answering the question.

33.11 Filling

Filling means adjusting the lengths of lines (by moving the line breaks) so that they are nearly (but no greater than) a specified maximum width. Additionally, lines can be *justified*, which means inserting spaces to make the left and/or right margins line up precisely. The width is controlled by the variable `fill-column`. For ease of reading, lines should be no longer than 70 or so columns.

You can use Auto Fill mode (see Section 33.14 [Auto Filling], page 905) to fill text automatically as you insert it, but changes to existing text may leave it improperly filled. Then you must fill the text explicitly.

Most of the commands in this section return values that are not meaningful. All the functions that do filling take note of the current left margin, current right margin, and current justification style (see Section 33.12 [Margins], page 902). If the current justification style is `none`, the filling functions don't actually do anything.

Several of the filling functions have an argument `justify`. If it is non-`nil`, that requests some kind of justification. It can be `left`, `right`, `full`, or `center`, to request a specific style of justification. If it is `t`, that means to use the current justification style for this part of the text (see `current-justification`, below). Any other value is treated as `full`.

When you call the filling functions interactively, using a prefix argument implies the value `full` for `justify`.

fill-paragraph &optional `justify` region

[Command]

This command fills the paragraph at or after point. If `justify` is non-`nil`, each line is justified as well. It uses the ordinary paragraph motion commands to find paragraph boundaries. See Section “Paragraphs” in *The GNU Emacs Manual*.

When `region` is non-`nil`, then if Transient Mark mode is enabled and the mark is active, this command calls `fill-region` to fill all the paragraphs in the region, instead of filling only the current paragraph. When this command is called interactively, `region` is `t`.

fill-region `start end &optional justify nosqueeze to-eop` [Command]

This command fills each of the paragraphs in the region from `start` to `end`. It justifies as well if `justify` is non-`nil`.

If `nosqueeze` is non-`nil`, that means to leave whitespace other than line breaks untouched. If `to-eop` is non-`nil`, that means to keep filling to the end of the paragraph—or the next hard newline, if `use-hard-newlines` is enabled (see below).

The variable `paragraph-separate` controls how to distinguish paragraphs. See Section 35.8 [Standard Regexp], page 1020.

pixel-fill-region `start end pixel-width` [Function]

Most Emacs buffers use monospaced text, so all the filling functions (like `fill-region`) work based on the number of characters and `char-width`. However, Emacs can render other types of things, like text that contains images and using proportional fonts, and the `pixel-fill-region` exists to handle that. It fills the region of text between `start` and `end` at pixel granularity, so text using variable-pitch fonts or several different fonts looks filled regardless of different character sizes. The argument `pixel-width` specifies the maximum pixel width a line is allowed to have after filling; it is the pixel-resolution equivalent of the `fill-column` in `fill-region`. For instance, this Lisp snippet will insert text using a proportional font, and then fill this to be no wider than 300 pixels:

```
(insert (propertize
  "This is a sentence that's ends here."
  'face 'variable-pitch))
(pixel-fill-region (point) (point-max) 300)
```

If `start` isn't at the start of a line, the horizontal position of `start`, converted to pixel units, will be used as the indentation prefix on subsequent lines.

The `pixel-fill-width` helper function can be used to compute the pixel width to use. If given no arguments, it'll return a value slightly less than the width of the current window. The first optional value, `columns`, specifies the number of columns using the standard, monospaced fonts, e.g. `fill-column`. The second optional value is the window to use. You'd typically use it like this:

```
(pixel-fill-region
  start end (pixel-fill-width fill-column))
```

fill-individual-paragraphs `start end &optional justify citation-regexp` [Command]

This command fills each paragraph in the region according to its individual fill prefix. Thus, if the lines of a paragraph were indented with spaces, the filled paragraph will remain indented in the same fashion.

The first two arguments, `start` and `end`, are the beginning and end of the region to be filled. The third and fourth arguments, `justify` and `citation-regexp`, are optional. If `justify` is non-`nil`, the paragraphs are justified as well as filled. If `citation-regexp` is

`non-nil`, it means the function is operating on a mail message and therefore should not fill the header lines. If `citation-regexp` is a string, it is used as a regular expression; if it matches the beginning of a line, that line is treated as a citation marker.

Ordinarily, `fill-individual-paragraphs` regards each change in indentation as starting a new paragraph. If `fill-individual-varying-indent` is `non-nil`, then only separator lines separate paragraphs. That mode can handle indented paragraphs with additional indentation on the first line.

`fill-individual-varying-indent` [User Option]

This variable alters the action of `fill-individual-paragraphs` as described above.

`fill-region-as-paragraph start end &optional justify nosqueeze squeeze-after` [Command]

This command considers a region of text as a single paragraph and fills it. If the region was made up of many paragraphs, the blank lines between paragraphs are removed. This function justifies as well as filling when `justify` is `non-nil`.

If `nosqueeze` is `non-nil`, that means to leave whitespace other than line breaks untouched. If `squeeze-after` is `non-nil`, it specifies a position in the region, and means that whitespace other than line breaks should be left untouched before that position. In Adaptive Fill mode, this command calls `fill-context-prefix` to choose a fill prefix by default. See Section 33.13 [Adaptive Fill], page 904.

`justify-current-line &optional how eop nosqueeze` [Command]

This command inserts spaces between the words of the current line so that the line ends exactly at `fill-column`. It returns `nil`.

The argument `how`, if `non-nil` specifies explicitly the style of justification. It can be `left`, `right`, `full`, `center`, or `none`. If it is `t`, that means to follow specified justification style (see `current-justification`, below). `nil` means to do full justification.

If `eop` is `non-nil`, that means do only left-justification if `current-justification` specifies full justification. This is used for the last line of a paragraph; even if the paragraph as a whole is fully justified, the last line should not be.

If `nosqueeze` is `non-nil`, that means do not change interior whitespace.

`default-justification` [User Option]

This variable's value specifies the style of justification to use for text that doesn't specify a style with a text property. The possible values are `left`, `right`, `full`, `center`, or `none`. The default value is `left`.

`current-justification` [Function]

This function returns the proper justification style to use for filling the text around point.

This returns the value of the `justification` text property at point, or the variable `default-justification` if there is no such text property. However, it returns `nil` rather than `none` to mean "don't justify".

`sentence-end-double-space` [User Option]

If this variable is `non-nil`, a period followed by just one space does not count as the end of a sentence, and the filling functions avoid breaking the line at such a place.

sentence-end-without-period [User Option]

If this variable is non-nil, a sentence can end without a period. This is used for languages like Thai, where sentences end with a double space but without a period.

sentence-end-without-space [User Option]

If this variable is non-nil, it should be a string of characters that can end a sentence without following spaces.

fill-separate-heterogeneous-words-with-space [User Option]

If this variable is non-nil, two words of different kind (e.g., English and CJK) will be separated with a space when concatenating one that is in the end of a line and the other that is in the beginning of the next line for filling.

fill-paragraph-function [Variable]

This variable provides a way to override the filling of paragraphs. If its value is non-nil, `fill-paragraph` calls this function to do the work. If the function returns a non-nil value, `fill-paragraph` assumes the job is done, and immediately returns that value.

The usual use of this feature is to fill comments in programming language modes. If the function needs to fill a paragraph in the usual way, it can do so as follows:

```
(let ((fill-paragraph-function nil))
  (fill-paragraph arg))
```

fill-forward-paragraph-function [Variable]

This variable provides a way to override how the filling functions, such as `fill-region` and `fill-paragraph`, move forward to the next paragraph. Its value should be a function, which is called with a single argument *n*, the number of paragraphs to move, and should return the difference between *n* and the number of paragraphs actually moved. The default value of this variable is `forward-paragraph`. See Section “Paragraphs” in *The GNU Emacs Manual*.

use-hard-newlines [Variable]

If this variable is non-nil, the filling functions do not delete newlines that have the `hard` text property. These hard newlines act as paragraph separators. See Section “Hard and Soft Newlines” in *The GNU Emacs Manual*.

33.12 Margins for Filling

fill-prefix [User Option]

This buffer-local variable, if non-nil, specifies a string of text that appears at the beginning of normal text lines and should be disregarded when filling them. Any line that fails to start with the fill prefix is considered the start of a paragraph; so is any line that starts with the fill prefix followed by additional whitespace. Lines that start with the fill prefix but no additional whitespace are ordinary text lines that can be filled together. The resulting filled lines also start with the fill prefix.

The fill prefix follows the left margin whitespace, if any.

fill-column

[User Option]

This buffer-local variable specifies the maximum width of filled lines. Its value should be an integer, which is a number of columns. All the filling, justification, and centering commands are affected by this variable, including Auto Fill mode (see Section 33.14 [Auto Filling], page 905).

As a practical matter, if you are writing text for other people to read, you should set **fill-column** to no more than 70. Otherwise the line will be too long for people to read comfortably, and this can make the text seem clumsy.

The default value for **fill-column** is 70. To disable Auto Fill mode in a specific mode, you could say something like:

```
(add-hook 'foo-mode-hook (lambda () (auto-fill-mode -1)))
```

set-left-margin from to margin

[Command]

This sets the **left-margin** property on the text from *from* to *to* to the value *margin*. If Auto Fill mode is enabled, this command also refills the region to fit the new margin.

set-right-margin from to margin

[Command]

This sets the **right-margin** property on the text from *from* to *to* to the value *margin*. If Auto Fill mode is enabled, this command also refills the region to fit the new margin.

current-left-margin

[Function]

This function returns the proper left margin value to use for filling the text around point. The value is the sum of the **left-margin** property of the character at the start of the current line (or zero if none), and the value of the variable **left-margin**.

current-fill-column

[Function]

This function returns the proper fill column value to use for filling the text around point. The value is the value of the **fill-column** variable, minus the value of the **right-margin** property of the character after point.

move-to-left-margin &optional n force

[Command]

This function moves point to the left margin of the current line. The column moved to is determined by calling the function **current-left-margin**. If the argument *n* is non-nil, **move-to-left-margin** moves forward *n*-1 lines first.

If *force* is non-nil, that says to fix the line's indentation if that doesn't match the left margin value.

delete-to-left-margin &optional from to

[Function]

This function removes left margin indentation from the text between *from* and *to*. The amount of indentation to delete is determined by calling **current-left-margin**. In no case does this function delete non-whitespace. If *from* and *to* are omitted, they default to the whole buffer.

indent-to-left-margin

[Function]

This function adjusts the indentation at the beginning of the current line to the value specified by the variable **left-margin**. (That may involve either inserting or deleting whitespace.) This function is value of **indent-line-function** in Paragraph-Indent Text mode.

left-margin

[User Option]

This variable specifies the base left margin column. In Fundamental mode, RET indents to this column. This variable automatically becomes buffer-local when set in any fashion.

fill-nobreak-predicate

[User Option]

This variable gives major modes a way to specify not to break a line at certain places. Its value should be a list of functions. Whenever filling considers breaking the line at a certain place in the buffer, it calls each of these functions with no arguments and with point located at that place. If any of the functions returns non-nil, then the line won't be broken there.

33.13 Adaptive Fill Mode

When *Adaptive Fill Mode* is enabled, Emacs determines the fill prefix automatically from the text in each paragraph being filled rather than using a predetermined value. During filling, this fill prefix gets inserted at the start of the second and subsequent lines of the paragraph as described in Section 33.11 [Filling], page 899, and in Section 33.14 [Auto Filling], page 905.

adaptive-fill-mode

[User Option]

Adaptive Fill mode is enabled when this variable is non-nil. It is t by default.

fill-context-prefix from to

[Function]

This function implements the heart of Adaptive Fill mode; it chooses a fill prefix based on the text between *from* and *to*, typically the start and end of a paragraph. It does this by looking at the first two lines of the paragraph, based on the variables described below.

Usually, this function returns the fill prefix, a string. However, before doing this, the function makes a final check (not specially mentioned in the following) that a line starting with this prefix wouldn't look like the start of a paragraph. Should this happen, the function signals the anomaly by returning nil instead.

In detail, *fill-context-prefix* does this:

1. It takes a candidate for the fill prefix from the first line—it tries first the function in *adaptive-fill-function* (if any), then the regular expression *adaptive-fill-regexp* (see below). The first non-nil result of these, or the empty string if they're both nil, becomes the first line's candidate.
2. If the paragraph has as yet only one line, the function tests the validity of the prefix candidate just found. The function then returns the candidate if it's valid, or a string of spaces otherwise. (see the description of *adaptive-fill-first-line-regexp* below).
3. When the paragraph already has two lines, the function next looks for a prefix candidate on the second line, in just the same way it did for the first line. If it doesn't find one, it returns nil.
4. The function now compares the two candidate prefixes heuristically: if the non-whitespace characters in the line 2 candidate occur in the same order in the line 1 candidate, the function returns the line 2 candidate. Otherwise, it returns the

largest initial substring which is common to both candidates (which might be the empty string).

adaptive-fill-regexp

[User Option]

Adaptive Fill mode matches this regular expression against the text starting after the left margin whitespace (if any) on a line; the characters it matches are that line's candidate for the fill prefix.

The default value matches whitespace with certain punctuation characters intermingled.

adaptive-fill-first-line-regexp

[User Option]

Used only in one-line paragraphs, this regular expression acts as an additional check of the validity of the one available candidate fill prefix: the candidate must match this regular expression, or match `comment-start-skip`. If it doesn't, `fill-context-prefix` replaces the candidate with a string of spaces of the same width as it.

The default value of this variable is "`\^\s*\t*\^\s*`", which matches only a string of whitespace. The effect of this default is to force the fill prefixes found in one-line paragraphs always to be pure whitespace.

adaptive-fill-function

[User Option]

You can specify more complex ways of choosing a fill prefix automatically by setting this variable to a function. The function is called with point after the left margin (if any) of a line, and it must preserve point. It should return either that line's fill prefix or `nil`, meaning it has failed to determine a prefix.

33.14 Auto Filling

Auto Fill mode is a minor mode that fills lines automatically as text is inserted. See Section “Auto Fill” in *The GNU Emacs Manual*. This section describes some variables used by Auto Fill mode. For a description of functions that you can call explicitly to fill and justify existing text, see Section 33.11 [Filling], page 899.

Auto Fill mode also enables the functions that change the margins and justification style to refill portions of the text. See Section 33.12 [Margins], page 902.

auto-fill-function

[Variable]

The value of this buffer-local variable should be a function (of no arguments) to be called after self-inserting a character from the table `auto-fill-chars`, see below. It may be `nil`, in which case nothing special is done in that case.

The value of `auto-fill-function` is `do-auto-fill` when Auto Fill mode is enabled. That is a function whose sole purpose is to implement the usual strategy for breaking a line.

normal-auto-fill-function

[Variable]

This variable specifies the function to use for `auto-fill-function`, if and when Auto Fill is turned on. Major modes can set buffer-local values for this variable to alter how Auto Fill works.

auto-fill-chars

[Variable]

A char table of characters which invoke `auto-fill-function` when self-inserted—space and newline in most language environments. They have an entry `t` in the table.

comment-auto-fill-only-comments

[User Option]

This variable, if non-`nil`, means to fill lines automatically within comments only. More precisely, this means that if a comment syntax was defined for the current buffer, then self-inserting a character outside of a comment will not call `auto-fill-function`.

33.15 Sorting Text

The sorting functions described in this section all rearrange text in a buffer. This is in contrast to the function `sort`, which rearranges the order of the elements of a list (see Section 5.6.3 [Rearrangement], page 90). The values returned by these functions are not meaningful.

sort-subr *reverse nextrecfun endrecfun &optional startkeyfun endkeyfun predicate* [Function]

This function is the general text-sorting routine that subdivides a buffer into records and then sorts them. Most of the commands in this section use this function.

To understand how `sort-subr` works, consider the whole accessible portion of the buffer as being divided into disjoint pieces called *sort records*. The records may or may not be contiguous, but they must not overlap. A portion of each sort record (perhaps all of it) is designated as the sort key. Sorting rearranges the records in order by their sort keys.

Usually, the records are rearranged in order of ascending sort key. If the first argument to the `sort-subr` function, `reverse`, is non-`nil`, the sort records are rearranged in order of descending sort key.

The next four arguments to `sort-subr` are functions that are called to move point across a sort record. They are called many times from within `sort-subr`.

1. *nextrecfun* is called with point at the end of a record. This function moves point to the start of the next record. The first record is assumed to start at the position of point when `sort-subr` is called. Therefore, you should usually move point to the beginning of the buffer before calling `sort-subr`.

This function can indicate there are no more sort records by leaving point at the end of the buffer.

2. *endrecfun* is called with point within a record. It moves point to the end of the record.
3. *startkeyfun* is called to move point from the start of a record to the start of the sort key. This argument is optional; if it is omitted, the whole record is the sort key. If supplied, the function should either return a non-`nil` value to be used as the sort key, or return `nil` to indicate that the sort key is in the buffer starting at point. In the latter case, *endkeyfun* is called to find the end of the sort key.
4. *endkeyfun* is called to move point from the start of the sort key to the end of the sort key. This argument is optional. If *startkeyfun* returns `nil` and this argument is omitted (or `nil`), then the sort key extends to the end of the record. There is no need for *endkeyfun* if *startkeyfun* returns a non-`nil` value.

The argument *predicate* is the function to use to compare keys. It is called with two arguments, the keys to compare, and should return non-`nil` if the first key should

come before the second in the sorting order. What exactly are the key arguments depends on what *startkeyfun* and *endkeyfun* return. If *predicate* is omitted or *nil*, it defaults to `<` if the keys are numbers, to `compare-buffer-substrings` if the keys are cons cells (whose `car` and `cdr` are start and end buffer positions of the key), and to `string<` otherwise (with keys assumed to be strings).

As an example of `sort-subr`, here is the complete function definition for `sort-lines`:

```
;; Note that the first two lines of doc string
;; are effectively one line when viewed by a user.
(defun sort-lines (reverse beg end)
  "Sort lines in region alphabetically; \
argument means descending order.
Called from a program, there are three arguments:
REVERSE (non-nil means reverse order), \
BEG and END (region to sort).
The variable `sort-fold-case' determines \
whether alphabetic case affects
the sort order."
  (interactive "P\nr")
  (save-excursion
    (save-restriction
      (narrow-to-region beg end)
      (goto-char (point-min))
      (let ((inhibit-field-text-motion t))
        (sort-subr reverse 'forward-line 'end-of-line)))))
```

Here `forward-line` moves point to the start of the next record, and `end-of-line` moves point to the end of record. We do not pass the arguments *startkeyfun* and *endkeyfun*, because the entire record is used as the sort key.

The `sort-parapraphs` function is very much the same, except that its `sort-subr` call looks like this:

```
(sort-subr reverse
  (lambda ()
    (while (and (not (eobp))
                (looking-at paragraph-separate))
      (forward-line 1)))
  'forward-paragraph)
```

Markers pointing into any sort records are left with no useful position after `sort-subr` returns.

sort-fold-case [User Option]
 If this variable is non-*nil*, `sort-subr` and the other buffer sorting functions ignore case when comparing strings.

sort-regexp-fields *reverse record-regexp key-regexp start end* [Command]
 This command sorts the region between *start* and *end* alphabetically as specified by *record-regexp* and *key-regexp*. If *reverse* is a negative integer, then sorting is in reverse order.

Alphabetical sorting means that two sort keys are compared by comparing the first characters of each, the second characters of each, and so on. If a mismatch is found, it means that the sort keys are unequal; the sort key whose character is less at the point of first mismatch is the lesser sort key. The individual characters are compared according to their numerical character codes in the Emacs character set.

The value of the *record-regexp* argument specifies how to divide the buffer into sort records. At the end of each record, a search is done for this regular expression, and the text that matches it is taken as the next record. For example, the regular expression ‘`^ .+ $`’, which matches lines with at least one character besides a newline, would make each such line into a sort record. See Section 35.3 [Regular Expressions], page 995, for a description of the syntax and meaning of regular expressions.

The value of the *key-regexp* argument specifies what part of each record is the sort key. The *key-regexp* could match the whole record, or only a part. In the latter case, the rest of the record has no effect on the sorted order of records, but it is carried along when the record moves to its new position.

The *key-regexp* argument can refer to the text matched by a subexpression of *record-regexp*, or it can be a regular expression on its own.

If *key-regexp* is:

‘`\digit`’ then the text matched by the *digit*th ‘`\(...\)`’ parenthesis grouping in *record-regexp* is the sort key.

‘`\&`’ then the whole record is the sort key.

a regular expression

then **sort-regexp-fields** searches for a match for the regular expression within the record. If such a match is found, it is the sort key. If there is no match for *key-regexp* within a record then that record is ignored, which means its position in the buffer is not changed. (The other records may move around it.)

For example, if you plan to sort all the lines in the region by the first word on each line starting with the letter ‘f’, you should set *record-regexp* to ‘`^ .* $`’ and set *key-regexp* to ‘`\<f\w*\>`’. The resulting expression looks like this:

```
(sort-regexp-fields nil "^.*$" "\<f\w*\>"  
                    (region-beginning)  
                    (region-end))
```

If you call **sort-regexp-fields** interactively, it prompts for *record-regexp* and *key-regexp* in the minibuffer.

sort-lines *reverse start end*

[Command]

This command alphabetically sorts lines in the region between *start* and *end*. If *reverse* is non-nil, the sort is in reverse order.

sort-paragraphs *reverse start end*

[Command]

This command alphabetically sorts paragraphs in the region between *start* and *end*. If *reverse* is non-nil, the sort is in reverse order.

sort-pages *reverse start end* [Command]

This command alphabetically sorts pages in the region between *start* and *end*. If *reverse* is non-nil, the sort is in reverse order.

sort-fields *field start end* [Command]

This command sorts lines in the region between *start* and *end*, comparing them alphabetically by the *field*th field of each line. Fields are separated by whitespace and numbered starting from 1. If *field* is negative, sorting is by the *-field*th field from the end of the line. This command is useful for sorting tables.

sort-numeric-fields *field start end* [Command]

This command sorts lines in the region between *start* and *end*, comparing them numerically by the *field*th field of each line. Fields are separated by whitespace and numbered starting from 1. The specified field must contain a number in each line of the region. Numbers starting with 0 are treated as octal, and numbers starting with ‘0x’ are treated as hexadecimal.

If *field* is negative, sorting is by the *-field*th field from the end of the line. This command is useful for sorting tables.

sort-numeric-base [User Option]

This variable specifies the default radix for **sort-numeric-fields** to parse numbers.

sort-columns *reverse &optional beg end* [Command]

This command sorts the lines in the region between *beg* and *end*, comparing them alphabetically by a certain range of columns. The column positions of *beg* and *end* bound the range of columns to sort on.

If *reverse* is non-nil, the sort is in reverse order.

One unusual thing about this command is that the entire line containing position *beg*, and the entire line containing position *end*, are included in the region sorted.

Note that **sort-columns** rejects text that contains tabs, because tabs could be split across the specified columns. Use *M-x untabify* to convert tabs to spaces before sorting.

When possible, this command actually works by calling the **sort** utility program.

33.16 Counting Columns

The column functions convert between a character position (counting characters from the beginning of the buffer) and a column position (counting screen characters from the beginning of a line).

These functions count each character according to the number of columns it occupies on the screen. This means control characters count as occupying 2 or 4 columns, depending upon the value of **ctl-arrow**, and tabs count as occupying a number of columns that depends on the value of **tab-width** and on the column where the tab begins. See Section 41.23.1 [Usual Display], page 1242.

Column number computations ignore the width of the window and the amount of horizontal scrolling. Consequently, a column value can be arbitrarily high. The first (or leftmost) column is numbered 0. They also ignore overlays and text properties, aside from

invisibility. Invisible text is considered as having zero width, unless `buffer-invisibility-spec` specifies that invisible text should be displayed as ellipsis (see Section 41.6 [Invisible Text], page 1142).

current-column

[Function]

This function returns the horizontal position of point, measured in columns, counting from 0 at the left margin. The column position is the sum of the widths of all the displayed representations of the characters between the start of the current line and point.

move-to-column *column* &**optional** *force*

[Command]

This function moves point to *column* in the current line. The calculation of *column* takes into account the widths of the displayed representations of the characters between the start of the line and point.

When called interactively, *column* is the value of prefix numeric argument. If *column* is not an integer, an error is signaled.

If it is impossible to move to column *column* because that is in the middle of a multicolumn character such as a tab, point moves to the end of that character. However, if *force* is non-`nil`, and *column* is in the middle of a tab, then `move-to-column` either converts the tab into spaces (when `indent-tabs-mode` is `nil`), or inserts enough spaces before it (otherwise), so that point can move precisely to column *column*. Other multicolumn characters can cause anomalies despite *force*, since there is no way to split them.

The argument *force* also has an effect if the line isn't long enough to reach column *column*; if it is `t`, that means to add whitespace at the end of the line to reach that column.

The return value is the column number actually moved to.

33.17 Indentation

The indentation functions are used to examine, move to, and change whitespace that is at the beginning of a line. Some of the functions can also change whitespace elsewhere on a line. Columns and indentation count from zero at the left margin.

33.17.1 Indentation Primitives

This section describes the primitive functions used to count and insert indentation. The functions in the following sections use these primitives. See Section 41.10 [Size of Displayed Text], page 1157, for related functions.

current-indentation

[Function]

This function returns the indentation of the current line, which is the horizontal position of the first nonblank character. If the contents are entirely blank, then this is the horizontal position of the end of the line.

This function considers invisible text as having zero width, unless `buffer-invisibility-spec` specifies that invisible text should be displayed as ellipsis. See Section 41.6 [Invisible Text], page 1142.

indent-to *column* &**optional** *minimum*

[Command]

This function indents from point with tabs and spaces until *column* is reached. If *minimum* is specified and non-*nil*, then at least that many spaces are inserted even if this requires going beyond *column*. Otherwise the function does nothing if point is already beyond *column*. The value is the column at which the inserted indentation ends.

The inserted whitespace characters inherit text properties from the surrounding text (usually, from the preceding text only). See Section 33.19.6 [Sticky Properties], page 932.

indent-tabs-mode

[User Option]

If this variable is non-*nil*, indentation functions can insert tabs as well as spaces. Otherwise, they insert only spaces. Setting this variable automatically makes it buffer-local in the current buffer.

33.17.2 Indentation Controlled by Major Mode

An important function of each major mode is to customize the TAB key to indent properly for the language being edited. This section describes the mechanism of the TAB key and how to control it. The functions in this section return unpredictable values.

indent-for-tab-command &**optional** *rigid*

[Command]

This is the command bound to TAB in most editing modes. Its usual action is to indent the current line, but it can alternatively insert a tab character or indent a region.

Here is what it does:

- First, it checks whether Transient Mark mode is enabled and the region is active. If so, it calls **indent-region** to indent all the text in the region (see Section 33.17.3 [Region Indent], page 913).
- Otherwise, if the indentation function in **indent-line-function** is **indent-to-left-margin** (a trivial command that inserts a tab character), or if the variable **tab-always-indent** specifies that a tab character ought to be inserted (see below), then it inserts a tab character.
- Otherwise, it indents the current line; this is done by calling the function **indent-line-function**. If the line is already indented, and the value of **tab-always-indent** is **complete** (see below), it tries completing the text at point.

If *rigid* is non-*nil* (interactively, with a prefix argument), then after this command indents a line or inserts a tab, it also rigidly indents the entire balanced expression which starts at the beginning of the current line, in order to reflect the new indentation. This argument is ignored if the command indents the region.

indent-line-function

[Variable]

This variable's value is the function to be used by **indent-for-tab-command**, and various other indentation commands, to indent the current line. It is usually assigned by the major mode; for instance, Lisp mode sets it to **lisp-indent-line**, C mode sets it to **c-indent-line**, and so on. The default value is **indent-relative**. See Section 24.7 [Auto-Indentation], page 581.

indent-according-to-mode [Command]

This command calls the function in `indent-line-function` to indent the current line in a way appropriate for the current major mode.

newline-and-indent [Command]

This function inserts a newline, then indents the new line (the one following the newline just inserted) according to the major mode. It does indentation by calling `indent-according-to-mode`.

reindent-then-newline-and-indent [Command]

This command reindents the current line, inserts a newline at point, and then indents the new line (the one following the newline just inserted). It does indentation on both lines by calling `indent-according-to-mode`.

tab-always-indent [User Option]

This variable can be used to customize the behavior of the TAB (`indent-for-tab-command`) command. If the value is `t` (the default), the command normally just indents the current line. If the value is `nil`, the command indents the current line only if point is at the left margin or in the line's indentation; otherwise, it inserts a tab character. If the value is `complete`, the command first tries to indent the current line, and if the line was already indented, it calls `completion-at-point` to complete the text at point (see Section 21.6.8 [Completion in Buffers], page 411).

tab-first-completion [User Option]

If `tab-always-indent` is `complete`, whether to expand or indent can be further customized via the `tab-first-completion` variable. The following values can be used:

`eol` Only complete if point is at the end of a line.

`word` Complete unless the next character has word syntax.

word-or-paren

Complete unless the next character has word syntax or is a parenthesis.

word-or-paren-or-punct

Complete unless the next character has word syntax, or is a parenthesis, or is punctuation.

In any case, typing TAB a second time always results in completion.

Some major modes need to support embedded regions of text whose syntax belongs to a different major mode. Examples include *literate programming* source files that combine documentation and snippets of source code, Yacc/Bison programs that include snippets of Python or JS code, etc. To correctly indent the embedded chunks, the primary mode needs to delegate the indentation to another mode's indentation engine (e.g., call `js-indent-line` for JS code or `python-indent-line` for Python), while providing it with some context to guide the indentation. Major modes, for their part, should avoid calling `widen` in their indentation code and obey `prog-first-column`.

prog-indentation-context

[Variable]

This variable, when non-*nil*, holds the indentation context for the sub-mode's indentation engine provided by the superior major mode. The value should be a list of the form (*first-column* . *rest*). The members of the list have the following meaning:

first-column

The column to be used for top-level constructs. This replaces the default value of the top-level column used by the sub-mode, usually zero.

rest

This value is currently unused.

The following convenience function should be used by major mode's indentation engine in support of invocations as sub-modes of another major mode.

prog-first-column

[Function]

Call this function instead of using a literal value (usually, zero) of the column number for indenting top-level program constructs. The function's value is the column number to use for top-level constructs. When no superior mode is in effect, this function returns zero.

33.17.3 Indenting an Entire Region

This section describes commands that indent all the lines in the region. They return unpredictable values.

indent-region start end &optional to-column

[Command]

This command indents each nonblank line starting between *start* (inclusive) and *end* (exclusive). If *to-column* is *nil*, **indent-region** indents each nonblank line by calling the current mode's indentation function, the value of **indent-line-function**.

If *to-column* is non-*nil*, it should be an integer specifying the number of columns of indentation; then this function gives each line exactly that much indentation, by either adding or deleting whitespace.

If there is a fill prefix, **indent-region** indents each line by making it start with the fill prefix.

indent-region-function

[Variable]

The value of this variable is a function that can be used by **indent-region** as a short cut. It should take two arguments, the start and end of the region. You should design the function so that it will produce the same results as indenting the lines of the region one by one, but presumably faster.

If the value is *nil*, there is no short cut, and **indent-region** actually works line by line.

A short-cut function is useful in modes such as C mode and Lisp mode, where the **indent-line-function** must scan from the beginning of the function definition: applying it to each line would be quadratic in time. The short cut can update the scan information as it moves through the lines indenting them; this takes linear time. In a mode where indenting a line individually is fast, there is no need for a short cut.

indent-region with a non-*nil* argument *to-column* has a different meaning and does not use this variable.

indent-rigidly start end count [Command]

This function indents all lines starting between *start* (inclusive) and *end* (exclusive) sideways by *count* columns. This preserves the shape of the affected region, moving it as a rigid unit.

This is useful not only for indenting regions of unindented text, but also for indenting regions of formatted code. For example, if *count* is 3, this command adds 3 columns of indentation to every line that begins in the specified region.

If called interactively with no prefix argument, this command invokes a transient mode for adjusting indentation rigidly. See Section “Indentation Commands” in *The GNU Emacs Manual*.

**indent-code-rigidly start end columns &optional
nochange-regexp** [Command]

This is like `indent-rigidly`, except that it doesn’t alter lines that start within strings or comments.

In addition, it doesn’t alter a line if *nochange-regexp* matches at the beginning of the line (if *nochange-regexp* is non-*nil*).

33.17.4 Indentation Relative to Previous Lines

This section describes two commands that indent the current line based on the contents of previous lines.

indent-relative &optional first-only unindented-ok [Command]

This command inserts whitespace at point, extending to the same column as the next *indent point* of the previous nonblank line. An indent point is a non-whitespace character following whitespace. The next indent point is the first one at a column greater than the current column of point. For example, if point is underneath and to the left of the first non-blank character of a line of text, it moves to that column by inserting whitespace.

If the previous nonblank line has no next indent point (i.e., none at a great enough column position), `indent-relative` either does nothing (if *unindented-ok* is non-*nil*) or calls `tab-to-tab-stop`. Thus, if point is underneath and to the right of the last column of a short line of text, this command ordinarily moves point to the next tab stop by inserting whitespace.

If *first-only* is non-*nil*, only the first indent point is considered.

The return value of `indent-relative` is unpredictable.

In the following example, point is at the beginning of the second line:

This line is indented twelve spaces.

★The quick brown fox jumped.

Evaluation of the expression (`indent-relative nil`) produces the following:

This line is indented twelve spaces.

★The quick brown fox jumped.

In this next example, point is between the ‘m’ and ‘p’ of ‘jumped’:

This line is indented twelve spaces.

The quick brown fox jum★ped.

Evaluation of the expression (`indent-relative nil`) produces the following:

```
This line is indented twelve spaces.  
The quick brown fox jum *ped.
```

indent-relative-first-indent-point [Command]

This command indents the current line like the previous nonblank line, by calling `indent-relative` with `t` as the *first-only* argument. The return value is unpredictable.

If the previous nonblank line has no indent points beyond the current column, this command does nothing.

33.17.5 Adjustable Tab Stops

This section explains the mechanism for user-specified tab stops and the mechanisms that use and set them. The name “tab stops” is used because the feature is similar to that of the tab stops on a typewriter. The feature works by inserting an appropriate number of spaces and tab characters to reach the next tab stop column; it does not affect the display of tab characters in the buffer (see Section 41.23.1 [Usual Display], page 1242). Note that the TAB character as input uses this tab stop feature only in a few major modes, such as Text mode. See Section “Tab Stops” in *The GNU Emacs Manual*.

tab-to-tab-stop [Command]

This command inserts spaces or tabs before point, up to the next tab stop column defined by `tab-stop-list`.

tab-stop-list [User Option]

This variable defines the tab stop columns used by `tab-to-tab-stop`. It should be either `nil`, or a list of increasing integers, which need not be evenly spaced. The list is implicitly extended to infinity through repetition of the interval between the last and penultimate elements (or `tab-width` if the list has fewer than two elements). A value of `nil` means a tab stop every `tab-width` columns.

Use `M-x edit-tab-stops` to edit the location of tab stops interactively.

33.17.6 Indentation-Based Motion Commands

These commands, primarily for interactive use, act based on the indentation in the text.

back-to-indentation [Command]

This command moves point to the first non-whitespace character in the current line (which is the line in which point is located).

backward-to-indentation &optional arg [Command]

This command moves point backward `arg` lines and then to the first nonblank character on that line. If `arg` is omitted or `nil`, it defaults to 1.

forward-to-indentation &optional arg [Command]

This command moves point forward `arg` lines and then to the first nonblank character on that line. If `arg` is omitted or `nil`, it defaults to 1.

33.18 Case Changes

The case change commands described here work on text in the current buffer. See Section 4.9 [Case Conversion], page 72, for case conversion functions that work on strings and characters. See Section 4.10 [Case Tables], page 74, for how to customize which characters are upper or lower case and how to convert them.

capitalize-region *start end*

[Command]

This function capitalizes all words in the region defined by *start* and *end*. To capitalize means to convert each word's first character to upper case and convert the rest of each word to lower case. The function returns **nil**.

If one end of the region is in the middle of a word, the part of the word within the region is treated as an entire word.

When **capitalize-region** is called interactively, *start* and *end* are point and the mark, with the smallest first.

```
----- Buffer: foo -----
This is the contents of the 5th foo.
----- Buffer: foo -----  
  

(capitalize-region 1 37)
⇒ nil  
  

----- Buffer: foo -----
This Is The Contents Of The 5th Foo.
----- Buffer: foo -----
```

downcase-region *start end*

[Command]

This function converts all of the letters in the region defined by *start* and *end* to lower case. The function returns **nil**.

When **downcase-region** is called interactively, *start* and *end* are point and the mark, with the smallest first.

upcase-region *start end*

[Command]

This function converts all of the letters in the region defined by *start* and *end* to upper case. The function returns **nil**.

When **upcase-region** is called interactively, *start* and *end* are point and the mark, with the smallest first.

capitalize-word *count*

[Command]

This function capitalizes *count* words after point, moving point over as it does. To capitalize means to convert each word's first character to upper case and convert the rest of each word to lower case. If *count* is negative, the function capitalizes the *-count* previous words but does not move point. The value is **nil**.

If point is in the middle of a word, the part of the word before point is ignored when moving forward. The rest is treated as an entire word.

When **capitalize-word** is called interactively, *count* is set to the numeric prefix argument.

downcase-word count

[Command]

This function converts the *count* words after point to all lower case, moving point over as it does. If *count* is negative, it converts the $-count$ previous words but does not move point. The value is `nil`.

When `downcase-word` is called interactively, *count* is set to the numeric prefix argument.

upcase-word count

[Command]

This function converts the *count* words after point to all upper case, moving point over as it does. If *count* is negative, it converts the $-count$ previous words but does not move point. The value is `nil`.

When `upcase-word` is called interactively, *count* is set to the numeric prefix argument.

33.19 Text Properties

Each character position in a buffer or a string can have a *text property list*, much like the property list of a symbol (see Section 5.9 [Property Lists], page 99). The properties belong to a particular character at a particular place, such as, the letter ‘T’ at the beginning of this sentence or the first ‘o’ in ‘foo’—if the same character occurs in two different places, the two occurrences in general have different properties.

Each property has a name and a value. Both of these can be any Lisp object, but the name is normally a symbol. Typically each property name symbol is used for a particular purpose; for instance, the text property `face` specifies the faces for displaying the character (see Section 33.19.4 [Special Properties], page 924). The usual way to access the property list is to specify a name and ask what value corresponds to it.

If a character has a `category` property, we call it the *property category* of the character. It should be a symbol. The properties of the symbol serve as defaults for the properties of the character.

Copying text between strings and buffers preserves the properties along with the characters; this includes such diverse functions as `substring`, `insert`, and `buffer-substring`. Killing and then yanking text (see Section 33.8 [The Kill Ring], page 889) also preserves the properties, except that some properties are handled specially and might be removed when text is yanked; see Section 33.8.3 [Yanking], page 891.

33.19.1 Examining Text Properties

The simplest way to examine text properties is to ask for the value of a particular property of a particular character. For that, use `get-text-property`. Use `text-properties-at` to get the entire property list of a character. See Section 33.19.3 [Property Search], page 921, for functions to examine the properties of a number of characters at once.

These functions handle both strings and buffers. Keep in mind that positions in a string start from 0, whereas positions in a buffer start from 1. Passing a buffer other than the current buffer may be slow.

get-text-property pos prop &optional object

[Function]

This function returns the value of the *prop* property of the character after position *pos* in *object* (a buffer or string). The argument *object* is optional and defaults to the current buffer.

If *position* is at the end of *object*, the value is `nil`, but note that buffer narrowing does not affect the value. That is, if *object* is a buffer or `nil`, and the buffer is narrowed and *position* is at the end of the narrowed buffer, the result may be non-`nil`.

If there is no *prop* property strictly speaking, but the character has a property category that is a symbol, then `get-text-property` returns the *prop* property of that symbol.

get-char-property *position prop &optional object* [Function]

This function is like `get-text-property`, except that it checks overlays first and then text properties. See Section 41.9 [Overlays], page 1150.

The argument *object* may be a string, a buffer, or a window. If it is a window, then the buffer displayed in that window is used for text properties and overlays, but only the overlays active for that window are considered. If *object* is a buffer, then overlays in that buffer are considered first, in order of decreasing priority, followed by the text properties. If *object* is a string, only text properties are considered, since strings never have overlays.

get-pos-property *position prop &optional object* [Function]

This function is like `get-char-property`, except that it pays attention to properties' stickiness and overlays' advancement settings instead of the property of the character at (i.e., right after) *position*.

get-char-property-and-overlay *position prop &optional object* [Function]

This is like `get-char-property`, but gives extra information about the overlay in which the property value comes from.

Its value is a cons cell whose CAR is the property value, the same value `get-char-property` would return with the same arguments. Its CDR is the overlay in which the property was found, or `nil`, if it was found as a text property or not found at all.

If *position* is at the end of *object*, both the CAR and the CDR of the value are `nil`.

char-property-alist [Variable]

This variable holds an alist which maps property names to a list of alternative property names. If a character does not specify a direct value for a property, the alternative property names are consulted in order; the first non-`nil` value is used. This variable takes precedence over `default-text-properties`, and category properties take precedence over this variable.

text-properties-at *position &optional object* [Function]

This function returns the entire property list of the character at *position* in the string or buffer *object*. If *object* is `nil`, it defaults to the current buffer.

If *position* is at the end of *object*, the value is `nil`, but note that buffer narrowing does not affect the value. That is, if *object* is a buffer or `nil`, and the buffer is narrowed and *position* is at the end of the narrowed buffer, the result may be non-`nil`.

default-text-properties [Variable]

This variable holds a property list giving default values for text properties. Whenever a character does not specify a value for a property, neither directly, through a category

symbol, or through `char-property-alias-alist`, the value stored in this list is used instead. Here is an example:

```
(setq default-text-properties '(foo 69)
      char-property-alias-alist nil)
;; Make sure character 1 has no properties of its own.
(set-text-properties 1 2 nil)
;; What we get, when we ask, is the default value.
(get-text-property 1 'foo)
⇒ 69
```

object-intervals *OBJECT* [Function]

This function returns a copy of the intervals (i.e., text properties) in *object* as a list of intervals. *object* must be a string or a buffer. Altering the structure of this list does not change the intervals in the object.

```
(object-intervals (propertize "foo" 'face 'bold))
⇒ ((0 3 (face bold)))
```

Each element in the returned list represents one interval. Each interval has three parts: The first is the start, the second is the end, and the third part is the text property itself.

33.19.2 Changing Text Properties

The primitives for changing properties apply to a specified range of text in a buffer or string. The function `set-text-properties` (see end of section) sets the entire property list of the text in that range; more often, it is useful to add, change, or delete just certain properties specified by name.

Since text properties are considered part of the contents of the buffer (or string), and can affect how a buffer looks on the screen, any change in buffer text properties marks the buffer as modified. Buffer text property changes are undoable also (see Section 33.9 [Undo], page 895). Positions in a string start from 0, whereas positions in a buffer start from 1.

put-text-property *start end prop value &optional object* [Function]

This function sets the *prop* property to *value* for the text between *start* and *end* in the string or buffer *object*. If *object* is `nil`, it defaults to the current buffer.

add-text-properties *start end props &optional object* [Function]

This function adds or overrides text properties for the text between *start* and *end* in the string or buffer *object*. If *object* is `nil`, it defaults to the current buffer.

The argument *props* specifies which properties to add. It should have the form of a property list (see Section 5.9 [Property Lists], page 99): a list whose elements include the property names followed alternately by the corresponding values.

The return value is `t` if the function actually changed some property's value; `nil` otherwise (if *props* is `nil` or its values agree with those in the text).

For example, here is how to set the `comment` and `face` properties of a range of text:

```
(add-text-properties start end
                     '(comment t face highlight))
```

remove-text-properties *start end props &optional object* [Function]

This function deletes specified text properties from the text between *start* and *end* in the string or buffer *object*. If *object* is `nil`, it defaults to the current buffer.

The argument *props* specifies which properties to delete. It should have the form of a property list (see Section 5.9 [Property Lists], page 99): a list whose elements are property names alternating with corresponding values. But only the names matter—the values that accompany them are ignored. For example, here's how to remove the `face` property.

```
(remove-text-properties start end '(face nil))
```

The return value is `t` if the function actually changed some property's value; `nil` otherwise (if *props* is `nil` or if no character in the specified text had any of those properties).

To remove all text properties from certain text, use `set-text-properties` and specify `nil` for the new property list.

remove-list-of-text-properties *start end list-of-properties &optional object* [Function]

Like `remove-text-properties` except that *list-of-properties* is a list of property names only, not an alternating list of property names and values.

set-text-properties *start end props &optional object* [Function]

This function completely replaces the text property list for the text between *start* and *end* in the string or buffer *object*. If *object* is `nil`, it defaults to the current buffer.

The argument *props* is the new property list. It should be a list whose elements are property names alternating with corresponding values.

After `set-text-properties` returns, all the characters in the specified range have identical properties.

If *props* is `nil`, the effect is to get rid of all properties from the specified range of text. Here's an example:

```
(set-text-properties start end nil)
```

Do not rely on the return value of this function.

add-face-text-property *start end face &optional appendp object* [Function]

This function acts on the text between *start* and *end*, adding the face *face* to the `face` text property. *face* should be a valid value for the `face` property (see Section 33.19.4 [Special Properties], page 924), such as a face name or an anonymous face (see Section 41.12 [Faces], page 1164).

If any text in the region already has a non-`nil` `face` property, those face(s) are retained. This function sets the `face` property to a list of faces, with *face* as the first element (by default) and the pre-existing faces as the remaining elements. If the optional argument *appendp* is non-`nil`, *face* is appended to the end of the list instead. Note that in a face list, the first occurring value for each attribute takes precedence.

For example, the following code would assign an italicized green face to the text between *start* and *end*:

```
(add-face-text-property start end 'italic)
```

```
(add-face-text-property start end '(:foreground "red"))
  (add-face-text-property start end '(:foreground "green"))
```

The optional argument *object*, if non-`nil`, specifies a buffer or string to act on, rather than the current buffer. If *object* is a string, then *start* and *end* are zero-based indices into the string.

The easiest way to make a string with text properties is with `propertize`:

`propertize string &rest properties` [Function]

This function returns a copy of *string* with the text properties *properties* added. These properties apply to all the characters in the string that is returned. Here is an example that constructs a string with a `face` property and a `mouse-face` property:

```
(propertize "foo" 'face 'italic
           'mouse-face 'bold-italic)
⇒ #("foo" 0 3 (mouse-face bold-italic face italic))
```

To put different properties on various parts of a string, you can construct each part with `propertize` and then combine them with `concat`:

```
(concat
  (propertize "foo" 'face 'italic
              'mouse-face 'bold-italic)
  " and "
  (propertize "bar" 'face 'italic
              'mouse-face 'bold-italic))
⇒ #("foo and bar"
     0 3 (face italic mouse-face bold-italic)
     3 8 nil
     8 11 (face italic mouse-face bold-italic))
```

See Section 33.2 [Buffer Contents], page 879, for the function `buffer-substring-no-properties`, which copies text from the buffer but does not copy its properties.

If you wish to add text properties to a buffer or remove them without marking the buffer as modified, you can wrap the calls above in the `with-silent-modifications` macro. See Section 28.5 [Buffer Modification], page 677.

33.19.3 Text Property Search Functions

In typical use of text properties, most of the time several or many consecutive characters have the same value for a property. Rather than writing your programs to examine characters one by one, it is much faster to process chunks of text that have the same property value.

Here are functions you can use to do this. They use `eq` for comparing property values. In all cases, *object* defaults to the current buffer.

For good performance, it's very important to use the *limit* argument to these functions, especially the ones that search for a single property—otherwise, they may spend a long time scanning to the end of the buffer, if the property you are interested in does not change.

These functions do not move point; instead, they return a position (or `nil`). Remember that a position is always between two characters; the position returned by these functions is between two characters with different properties.

`next-property-change pos &optional object limit` [Function]

The function scans the text forward from position *pos* in the string or buffer *object* until it finds a change in some text property, then returns the position of the change. In

other words, it returns the position of the first character beyond *pos* whose properties are not identical to those of the character just after *pos*.

If *limit* is non-*nil*, then the scan ends at position *limit*. If there is no property change before that point, this function returns *limit*.

The value is *nil* if the properties remain unchanged all the way to the end of *object* and *limit* is *nil*. If the value is non-*nil*, it is a position greater than or equal to *pos*. The value equals *pos* only when *limit* equals *pos*.

Here is an example of how to scan the buffer by chunks of text within which all properties are constant:

```
(while (not (eobp))
  (let ((plist (text-properties-at (point)))
        (next-change
         (or (next-property-change (point) (current-buffer))
             (point-max))))
    Process text from point to next-change...
    (goto-char next-change)))
```

previous-property-change *pos* &**optional** *object limit* [Function]

This is like **next-property-change**, but scans back from *pos* instead of forward. If the value is non-*nil*, it is a position less than or equal to *pos*; it equals *pos* only if *limit* equals *pos*.

next-single-property-change *pos prop* &**optional** *object limit* [Function]

The function scans text for a change in the *prop* property, then returns the position of the change. The scan goes forward from position *pos* in the string or buffer *object*. In other words, this function returns the position of the first character beyond *pos* whose *prop* property differs from that of the character just after *pos*.

If *limit* is non-*nil*, then the scan ends at position *limit*. If there is no property change before that point, **next-single-property-change** returns *limit*.

The value is *nil* if the property remains unchanged all the way to the end of *object* and *limit* is *nil*. If the value is non-*nil*, it is a position greater than or equal to *pos*; it equals *pos* only if *limit* equals *pos*.

previous-single-property-change *pos prop* &**optional** *object limit* [Function]

This is like **next-single-property-change**, but scans back from *pos* instead of forward. If the value is non-*nil*, it is a position less than or equal to *pos*; it equals *pos* only if *limit* equals *pos*.

next-char-property-change *pos* &**optional** *limit* [Function]

This is like **next-property-change** except that it considers overlay properties as well as text properties, and if no change is found before the end of the buffer, it returns the maximum buffer position rather than *nil* (in this sense, it resembles the corresponding overlay function **next-overlay-change**, rather than **next-property-change**). There is no *object* operand because this function operates only on the current buffer. It returns the next address at which either kind of property changes.

previous-char-property-change *pos* &**optional** *limit* [Function]

This is like **next-char-property-change**, but scans back from *pos* instead of forward, and returns the minimum buffer position if no change is found.

next-single-char-property-change *pos prop &optional object limit* [Function]

This is like **next-single-property-change** except that it considers overlay properties as well as text properties, and if no change is found before the end of the *object*, it returns the maximum valid position in *object* rather than **nil**. Unlike **next-char-property-change**, this function *does* have an *object* operand; if *object* is not a buffer, only text-properties are considered.

previous-single-char-property-change *pos prop &optional object limit* [Function]

This is like **next-single-char-property-change**, but scans back from *pos* instead of forward, and returns the minimum valid position in *object* if no change is found.

text-property-any *start end prop value &optional object* [Function]

This function returns non-**nil** if at least one character between *start* and *end* has a property *prop* whose value is *value*. More precisely, it returns the position of the first such character. Otherwise, it returns **nil**.

The optional fifth argument, *object*, specifies the string or buffer to scan. Positions are relative to *object*. The default for *object* is the current buffer.

text-property-not-all *start end prop value &optional object* [Function]

This function returns non-**nil** if at least one character between *start* and *end* does not have a property *prop* with value *value*. More precisely, it returns the position of the first such character. Otherwise, it returns **nil**.

The optional fifth argument, *object*, specifies the string or buffer to scan. Positions are relative to *object*. The default for *object* is the current buffer.

text-property-search-forward *prop &optional value predicate not-current* [Function]

Search for the next region of text whose property *prop* is a match for *value* (which defaults to **nil**), according to *predicate*.

This function is modeled after **search-forward** (see Section 35.1 [String Search], page 993) and friends, in that it moves point, but it also returns a structure that describes the match instead of returning it in **match-beginning** and friends.

If the text property whose value is a match can't be found, the function returns **nil**. If it's found, point is placed at the end of the region that has this matching text property, and the function returns a **prop-match** structure with information about the match.

predicate can either be **t** (which is a synonym for **equal**), **nil** (which means "not equal"), or a predicate that will be called with two arguments: *value* and the value of the text property *prop* at the buffer position that is a candidate for a match. The function should return non-**nil** if there's a match, **nil** otherwise.

If *not-current* is non-**nil**, then if point is already in a region where we have a property match, skip past that region and find the next region instead.

The **prop-match** structure has the following accessor functions: **prop-match-beginning** (the start of the match), **prop-match-end** (the end of the match), and **prop-match-value** (the value of property at the start of the match).

In the examples below, we use a buffer whose contents is:

This is a **bold** and here's *bolditalic* and this is the end.

That is, the “bold” words are the **bold** face, and the “italic” word is in the *italic* face.

With point at the start:

```
(while (setq match (text-property-search-forward 'face 'bold t))
  (push (buffer-substring (prop-match-beginning match)
                           (prop-match-end match)))
        words))
```

This will pick out all the words that use the **bold** face.

```
(while (setq match (text-property-search-forward 'face nil t))
  (push (buffer-substring (prop-match-beginning match)
                           (prop-match-end match)))
        words))
```

This will pick out all the bits that have no face properties, which will result in the list ‘("This is a " "and here's " "and this is the end")’ (only in reverse order, since we used `push`, see Section 5.5 [List Variables], page 85).

```
(while (setq match (text-property-search-forward 'face nil nil))
  (push (buffer-substring (prop-match-beginning match)
                           (prop-match-end match)))
        words))
```

This will pick out all the regions where `face` is set to something, but this is split up into where the properties change, so the result here will be ‘("bold" "bold" "italic")’.

For a more realistic example where you might use this, consider that you have a buffer where certain sections represent URLs, and these are tagged with `shr-url`.

```
(while (setq match (text-property-search-forward 'shr-url nil nil))
  (push (prop-match-value match) urls))
```

This will give you a list of all those URLs.

`text-property-search-backward prop &optional value predicate` [Function]
`not-current`

This is just like `text-property-search-forward`, but searches backward instead, and if a match is found, point is placed at the beginning of the matched region instead of the end.

33.19.4 Properties with Special Meanings

Here is a table of text property names that have special built-in meanings. The following sections list a few additional special property names that control filling and property inheritance. All other names have no standard meaning, and you can use them as you like.

Note: the properties `composition`, `display`, `invisible` and `intangible` can also cause point to move to an acceptable place, after each Emacs command. See Section 22.6 [Adjusting Point], page 439.

category If a character has a `category` property, we call it the *property category* of the character. It should be a symbol. The properties of this symbol serve as defaults for the properties of the character.

face The **face** property controls the appearance of the character (see Section 41.12 [Faces], page 1164). The value of the property can be the following:

- A face name (a symbol or string).
- An anonymous face: a property list of the form (**keyword** **value** ...), where each **keyword** is a face attribute name and **value** is a value for that attribute.
- A list of faces. Each list element should be either a face name or an anonymous face. This specifies a face which is an aggregate of the attributes of each of the listed faces. Faces occurring earlier in the list have higher priority.
- A cons cell of the form (**foreground-color** . **color-name**) or (**background-color** . **color-name**). This specifies the foreground or background color, similar to (:foreground **color-name**) or (:background **color-name**). This form is supported for backward compatibility only, and should be avoided.
- A cons cell of the form (:filtered **filter** **face-spec**), that specifies the face given by **face-spec**, but only if **filter** matches when the face is used for display. The **face-spec** can use any of the forms mentioned above. The **filter** should be of the form (:window **param** **value**), which matches for windows whose parameter **param** is eq to **value**. If the variable **face-filters-always-match** is non-nil, all face filters are deemed to have matched.

Font Lock mode (see Section 24.6 [Font Lock Mode], page 563) works in most buffers by dynamically updating the **face** property of characters based on the context.

The **add-face-text-property** function provides a convenient way to set this text property. See Section 33.19.2 [Changing Properties], page 919.

font-lock-face

This property specifies a value for the **face** property that Font Lock mode should apply to the underlying text. It is one of the fontification methods used by Font Lock mode, and is useful for special modes that implement their own highlighting. See Section 24.6.6 [Precalculated Fontification], page 573. When Font Lock mode is disabled, **font-lock-face** has no effect.

mouse-face

This property is used instead of **face** when the mouse pointer hovers over the text which has this property. When this happens, the entire stretch of text that has the same **mouse-face** property value, not just the character under the mouse, is highlighted.

Emacs ignores all face attributes from the **mouse-face** property that alter the text size (e.g., :height, :weight, and :slant). Those attributes are always the same as for the unhighlighted text.

cursor-face

This property is similar to **mouse-face**, but it is used when point (not the mouse) is inside text that has this property. The highlighting happens only if the mode **cursor-face-highlight-mode** is enabled. When the variable

`cursor-face-highlight-nonselected-window` is non-`nil`, the text with this face is highlighted even if the window is not selected, similarly to what `highlight-nonselected-windows` does for the region (see Section “The Mark and the Region” in *The GNU Emacs Manual*).

fontified

This property says whether the text is ready for display. If `nil`, Emacs’s redisplay routine calls the functions in `fontification-functions` (see Section 41.12.7 [Auto Faces], page 1178) to prepare this part of the buffer before it is displayed. It is used internally by the just-in-time font locking code.

display

This property activates various features that change the way text is displayed. For example, it can make text appear taller or shorter, higher or lower, wider or narrow, or replaced with an image. See Section 41.16 [Display Property], page 1198.

help-echo

If text has a string as its `help-echo` property, then when you move the mouse onto that text, Emacs displays that string in the echo area, or in the tooltip window (see Section 41.26 [Tooltips], page 1249), after passing it through `substitute-command-keys`.

If the value of the `help-echo` property is a function, that function is called with three arguments, `window`, `object` and `pos` and should return a help string or `nil` for none. The first argument, `window` is the window in which the help was found. The second, `object`, is the buffer, overlay or string which had the `help-echo` property. The `pos` argument is as follows:

- If `object` is a buffer, `pos` is the position in the buffer.
- If `object` is an overlay, that overlay has a `help-echo` property, and `pos` is the position in the overlay’s buffer.
- If `object` is a string (an overlay string or a string displayed with the `display` property), `pos` is the position in that string.

If the value of the `help-echo` property is neither a function nor a string, it is evaluated to obtain a help string.

You can alter the way help text is displayed by setting the variable `show-help-function` (see [Help display], page 931).

This feature is used in the mode line and for other active text.

help-echo-inhibit-substitution

If the first character of a `help-echo` string has a non-`nil` `help-echo-inhibit-substitution` property, then it is displayed as-is by `show-help-function`, without being passed through `substitute-command-keys`.

keymap

The `keymap` property specifies an additional keymap for commands. When this keymap applies, it is used for key lookup before the minor mode keymaps and before the buffer’s local map. See Section 23.7 [Active Keymaps], page 489. If the property value is a symbol, the symbol’s function definition is used as the keymap.

The property's value for the character before point applies if it is non-nil and rear-sticky, and the property's value for the character after point applies if it is non-nil and front-sticky. (For mouse clicks, the position of the click is used instead of the position of point.)

local-map

This property works like **keymap** except that it specifies a keymap to use *instead of* the buffer's local map. For most purposes (perhaps all purposes), it is better to use the **keymap** property.

syntax-table

The **syntax-table** property overrides what the syntax table says about this particular character. See Section 36.4 [Syntax Properties], page 1029.

read-only

If a character has the property **read-only**, then modifying that character is not allowed. Any command that would do so gets an error, **text-read-only**. If the property value is a string, that string is used as the error message.

Insertion next to a read-only character is an error if inserting ordinary text there would inherit the **read-only** property due to stickiness. Thus, you can control permission to insert next to read-only text by controlling the stickiness. See Section 33.19.6 [Sticky Properties], page 932.

Since changing properties counts as modifying the buffer, it is not possible to remove a **read-only** property unless you know the special trick: bind **inhibit-read-only** to a non-nil value and then remove the property. See Section 28.7 [Read Only Buffers], page 680.

inhibit-read-only

Characters that have the property **inhibit-read-only** can be edited even in read-only buffers. See Section 28.7 [Read Only Buffers], page 680.

invisible

A non-nil **invisible** property can make a character invisible on the screen. See Section 41.6 [Invisible Text], page 1142, for details.

inhibit-isearch

A non-nil **inhibit-isearch** property will make isearch skip the text.

intangible

If a group of consecutive characters have equal and non-nil **intangible** properties, then you cannot place point between them. If you try to move point forward into the group, point actually moves to the end of the group. If you try to move point backward into the group, point actually moves to the start of the group.

If consecutive characters have unequal non-nil **intangible** properties, they belong to separate groups; each group is separately treated as described above. When the variable **inhibit-point-motion-hooks** is non-nil (as it is by default), the **intangible** property is ignored.

Beware: this property operates at a very low level, and affects a lot of code in unexpected ways. So use it with extreme caution. A common misuse is to

put an intangible property on invisible text, which is actually unnecessary since the command loop will move point outside of the invisible text at the end of each command anyway. See Section 22.6 [Adjusting Point], page 439. For these reasons, this property is obsolete; use the `cursor-intangible` property instead.

`cursor-intangible`

When the minor mode `cursor-intangible-mode` is turned on, point is moved away from any position that has a non-nil `cursor-intangible` property, just before redisplay happens. Note that “stickiness” of the property (see Section 33.19.6 [Sticky Properties], page 932) is taken into account when computing allowed cursor positions, so (for instance) to insert a stretch of five ‘x’ characters into which the cursor can’t enter, you should do something like:

```
(insert
  (propertize "xxxx" 'cursor-intangible t)
  (propertize "x" 'cursor-intangible t 'rear-nonsticky t))
```

When the variable `cursor-sensor-inhibit` is non-nil, the `cursor-intangible` property and the `cursor-sensor-functions` property (described below) are ignored.

`field`

Consecutive characters with the same `field` property constitute a *field*. Some motion functions including `forward-word` and `beginning-of-line` stop moving at a field boundary. See Section 33.19.9 [Fields], page 936.

`cursor`

Normally, the cursor is displayed at the beginning or the end of any overlay and text property strings that “hide” (i.e., are displayed instead of) the current buffer position. You can instead tell Emacs to place the cursor on any desired character of these strings by giving that character a non-nil `cursor` text property. In addition, if the value of the `cursor` property is an integer, it specifies the number of buffer’s character positions, starting with the position where the overlay or the `display` property begins, for which the cursor should be displayed on that character. Specifically, if the value of the `cursor` property of a character is the number *n*, the cursor will be displayed on this character for any buffer position in the range [*ovpos*..*ovpos+n*], where *ovpos* is the overlay’s starting position given by `overlay-start` (see Section 41.9.1 [Managing Overlays], page 1150), or the position where the `display` text property begins in the buffer.

In other words, the string character with the `cursor` property of any non-nil value is the character where to display the cursor when the overlay or display string make point not visible on display. The value of the property says for which buffer positions to display the cursor there. If the value is an integer *n*, the cursor is displayed there when point is anywhere between the beginning of the overlay or `display` property and *n* positions after that. If the value is anything else and non-nil, the cursor is displayed there only when point is at the buffer position that is the beginning of the `display` property, or at `overlay-start` if that position is not visible on display. Note that an integer value of the `cursor` property could mean that the cursor is displayed on that character even when point is visible on display.

One subtlety of this property is that it doesn’t work to put this property on a newline character that is part of a display or overlay string. That’s because the

newline doesn't have a graphic representation on the screen for Emacs to find when it looks for a character on display with that `cursor` property.

When the buffer has many overlay strings (e.g., see Section 41.9.2 [Overlay Properties], page 1153) that conceal some of the buffer text or `display` properties that are strings, it is a good idea to use the `cursor` property on these strings to cue the Emacs display about the places where to put the cursor while traversing these strings. This directly communicates to the display engine where the Lisp program wants to put the cursor, or where the user would expect the cursor, when point is located on some buffer position that is “covered” by the display or overlay string.

pointer This specifies a specific pointer shape when the mouse pointer is over this text or image. See Section 30.19 [Pointer Shape], page 839, for possible pointer shapes.

line-spacing

A newline can have a `line-spacing` text or overlay property that controls the height of the display line ending with that newline. The property value overrides the default frame line spacing and the buffer local `line-spacing` variable. See Section 41.11 [Line Height], page 1162.

line-height

A newline can have a `line-height` text or overlay property that controls the total height of the display line ending in that newline. See Section 41.11 [Line Height], page 1162.

wrap-prefix

If text has a `wrap-prefix` property, the prefix it defines will be added at display time to the beginning of every continuation line due to text wrapping (so if lines are truncated, the wrap-prefix is never used). It may be a string or an image (see Section 41.16.4 [Other Display Specs], page 1203), or a stretch of whitespace such as specified by the `:width` or `:align-to` display properties (see Section 41.16.2 [Specified Space], page 1200).

A wrap-prefix may also be specified for an entire buffer using the `wrap-prefix` buffer-local variable (however, a `wrap-prefix` text-property takes precedence over the value of the `wrap-prefix` variable). See Section 41.3 [Truncation], page 1130.

line-prefix

If text has a `line-prefix` property, the prefix it defines will be added at display time to the beginning of every non-continuation line. It may be a string or an image (see Section 41.16.4 [Other Display Specs], page 1203), or a stretch of whitespace such as specified by the `:width` or `:align-to` display properties (see Section 41.16.2 [Specified Space], page 1200).

A line-prefix may also be specified for an entire buffer using the `line-prefix` buffer-local variable (however, a `line-prefix` text-property takes precedence over the value of the `line-prefix` variable). See Section 41.3 [Truncation], page 1130.

modification-hooks

If a character has the property **modification-hooks**, then its value should be a list of functions; modifying that character calls all of those functions before the actual modification. Each function receives two arguments: the beginning and end of the part of the buffer being modified. Note that if a particular modification hook function appears on several characters being modified by a single primitive, you can't predict how many times the function will be called. Furthermore, insertion will not modify any existing character, so this hook will only be run when removing some characters, replacing them with others, or changing their text-properties.

Unlike with other similar hooks, when Emacs calls these functions, **inhibit-modification-hooks** does *not* get bound to **non-nil**. If the functions modify the buffer, you should consider binding this variable to **non-nil** to prevent any buffer changes running the change hooks. Otherwise, you must be prepared for recursive calls. See Section 33.34 [Change Hooks], page 961.

Overlays also support the **modification-hooks** property, but the details are somewhat different (see Section 41.9.2 [Overlay Properties], page 1153).

insert-in-front-hooks**insert-behind-hooks**

The operation of inserting text in a buffer also calls the functions listed in the **insert-in-front-hooks** property of the following character and in the **insert-behind-hooks** property of the preceding character. These functions receive two arguments, the beginning and end of the inserted text. The functions are called *after* the actual insertion takes place.

When these functions are called, **inhibit-modification-hooks** is bound to **non-nil**. If the functions modify the buffer, you might want to bind **inhibit-modification-hooks** to **nil**, so as to cause the change hooks to run for these modifications. However, doing this may call your own change hook recursively, so be sure to prepare for that.

See also Section 33.34 [Change Hooks], page 961, for other hooks that are called when you change text in a buffer.

point-entered**point-left**

The special properties **point-entered** and **point-left** record hook functions that report motion of point. Each time point moves, Emacs compares these two property values:

- the **point-left** property of the character after the old location, and
- the **point-entered** property of the character after the new location.

If these two values differ, each of them is called (if not **nil**) with two arguments: the old value of point, and the new one.

The same comparison is made for the characters before the old and new locations. The result may be to execute two **point-left** functions (which may be the same function) and/or two **point-entered** functions (which may be the same function). In any case, all the **point-left** functions are called first, followed by all the **point-entered** functions.

It is possible to use `char-after` to examine characters at various buffer positions without moving point to those positions. Only an actual change in the value of point runs these hook functions.

The variable `inhibit-point-motion-hooks` by default inhibits running the `point-left` and `point-entered` hooks, see [Inhibit point motion hooks], page 931.

These properties are obsolete; please use `cursor-sensor-functions` instead.

`cursor-sensor-functions`

This special property records a list of functions that react to cursor motion. Each function in the list is called, just before redisplay, with 3 arguments: the affected window, the previous known position of the cursor, and one of the symbols `entered` or `left`, depending on whether the cursor is entering the text that has this property or leaving it. The functions are called only when the minor mode `cursor-sensor-mode` is turned on.

When the variable `cursor-sensor-inhibit` is non-`nil`, the `cursor-sensor-functions` property is ignored.

`composition`

This text property is used to display a sequence of characters as a single glyph composed from components. But the value of the property itself is completely internal to Emacs and should not be manipulated directly by, for instance, `put-text-property`.

`minibuffer-message`

This text property tells where to display temporary messages in an active minibuffer. Specifically, the first character of the minibuffer text which has this property will have the temporary message displayed before it. The default is to display temporary messages at the end of the minibuffer text. This text property is used by the function that is the default value of `set-message-function` (see Section 41.4.1 [Displaying Messages], page 1131).

`inhibit-point-motion-hooks`

[Variable]

When this obsolete variable is non-`nil`, `point-left` and `point-entered` hooks are not run, and the `intangible` property has no effect. Do not set this variable globally; bind it with `let`. Since the affected properties are obsolete, this variable's default value is `t`, to effectively disable them.

`show-help-function`

[Variable]

If this variable is non-`nil`, it specifies a function called to display help strings. These may be `help-echo` properties, menu help strings (see Section 23.18.1.1 [Simple Menu Items], page 510, see Section 23.18.1.2 [Extended Menu Items], page 511), or tool bar help strings (see Section 23.18.6 [Tool Bar], page 517). The specified function is called with one argument, the help string to display, which is passed through `substitute-command-keys` before being given to the function, unless the help string has a non-`nil` `help-echo-inhibit-substitution` property on its first character; see Section 25.3 [Keys in Documentation], page 598. See the code of Tooltip mode (see Section “Tooltips” in *The GNU Emacs Manual*) for an example of a mode that uses `show-help-function`.

face-filters-always-match [Variable]

If this variable is non-nil, face filters that specify attributes applied only when certain conditions are met will be deemed to match always.

33.19.5 Formatted Text Properties

These text properties affect the behavior of the fill commands. They are used for representing formatted text. See Section 33.11 [Filling], page 899, and Section 33.12 [Margins], page 902.

hard If a newline character has this property, it is a “hard” newline. The fill commands do not alter hard newlines and do not move words across them. However, this property takes effect only if the `use-hard-newlines` minor mode is enabled. See Section “Hard and Soft Newlines” in *The GNU Emacs Manual*.

right-margin

This property specifies an extra right margin for filling this part of the text.

left-margin

This property specifies an extra left margin for filling this part of the text.

justification

This property specifies the style of justification for filling this part of the text.

33.19.6 Stickiness of Text Properties

Self-inserting characters, the ones that get inserted into a buffer when the user types them (see Section 33.5 [Commands for Insertion], page 884), normally take on the same properties as the preceding character. This is called *inheritance* of properties.

By contrast, a Lisp program can do insertion with inheritance or without, depending on the choice of insertion primitive. The ordinary text insertion functions, such as `insert`, do not inherit any properties. They insert text with precisely the properties of the string being inserted, and no others. This is correct for programs that copy text from one context to another—for example, into or out of the kill ring. To insert with inheritance, use the special primitives described in this section. Self-inserting characters inherit properties because they work using these primitives.

When you do insertion with inheritance, *which* properties are inherited, and from where, depends on which properties are *sticky*. Insertion after a character inherits those of its properties that are *rear-sticky*. Insertion before a character inherits those of its properties that are *front-sticky*. When both sides offer different sticky values for the same property, the previous character’s value takes precedence.

By default, a text property is rear-sticky but not front-sticky; thus, the default is to inherit all the properties of the preceding character, and nothing from the following character.

You can control the stickiness of various text properties with two specific text properties, `front-sticky` and `rear-nonsticky`, and with the variable `text-property-default-nonsticky`. You can use the variable to specify a different default for a given property. You can use those two text properties to make any specific properties sticky or nonsticky in any particular part of the text.

If a character’s `front-sticky` property is `t`, then all its properties are front-sticky. If the `front-sticky` property is a list, then the sticky properties of the character are those whose names are in the list. For example, if a character has a `front-sticky` property whose value

is `(face read-only)`, then insertion before the character can inherit its `face` property and its `read-only` property, but no others.

The `rear-nonsticky` property works the opposite way. Most properties are rear-sticky by default, so the `rear-nonsticky` property says which properties are *not* rear-sticky. If a character's `rear-nonsticky` property is `t`, then none of its properties are rear-sticky. If the `rear-nonsticky` property is a list, properties are rear-sticky *unless* their names are in the list.

`text-property-default-nonsticky`

[Variable]

This variable holds an alist which defines the default rear-stickiness of various text properties. Each element has the form `(property . nonstickiness)`, and it defines the stickiness of a particular text property, `property`.

If `nonstickiness` is `non-nil`, this means that the property `property` is rear-nonsticky by default. Since all properties are front-nonsticky by default, this makes `property` nonsticky in both directions by default.

The text properties `front-sticky` and `rear-nonsticky`, when used, take precedence over the default `nonstickiness` specified in `text-property-default-nonsticky`.

Here are the functions that insert text with inheritance of properties:

`insert-and-inherit &rest strings`

[Function]

Insert the strings `strings`, just like the function `insert`, but inherit any sticky properties from the adjoining text.

`insert-before-markers-and-inherit &rest strings`

[Function]

Insert the strings `strings`, just like the function `insert-before-markers`, but inherit any sticky properties from the adjoining text.

See Section 33.4 [Insertion], page 882, for the ordinary insertion functions which do not inherit.

33.19.7 Lazy Computation of Text Properties

Instead of computing text properties for all the text in the buffer, you can arrange to compute the text properties for parts of the text when and if something depends on them.

The primitive that extracts text from the buffer along with its properties is `buffer-substring`. Before examining the properties, this function runs the abnormal hook `buffer-access-fontify-functions`.

`buffer-access-fontify-functions`

[Variable]

This variable holds a list of functions for computing text properties. Before `buffer-substring` copies the text and text properties for a portion of the buffer, it calls all the functions in this list. Each of the functions receives two arguments that specify the range of the buffer being accessed. (The buffer itself is always the current buffer.)

The function `buffer-substring-no-properties` does not call these functions, since it ignores text properties anyway.

In order to prevent the hook functions from being called more than once for the same part of the buffer, you can use the variable `buffer-access-fontified-property`.

buffer-access-fontified-property [Variable]

If this variable's value is non-nil, it is a symbol which is used as a text property name. A non-nil value for that text property means the other text properties for this character have already been computed.

If all the characters in the range specified for **buffer-substring** have a non-nil value for this property, **buffer-substring** does not call the **buffer-access-fontify-functions** functions. It assumes these characters already have the right text properties, and just copies the properties they already have.

The normal way to use this feature is that the **buffer-access-fontify-functions** functions add this property, as well as others, to the characters they operate on. That way, they avoid being called over and over for the same text.

33.19.8 Defining Clickable Text

Clickable text is text that can be clicked, with either the mouse or via a keyboard command, to produce some result. Many major modes use clickable text to implement textual hyper-links, or *links* for short.

The easiest way to insert and manipulate links is to use the **button** package. See Section 41.20 [Buttons], page 1232. In this section, we will explain how to manually set up clickable text in a buffer, using text properties. For simplicity, we will refer to the clickable text as a *link*.

Implementing a link involves three separate steps: (1) indicating clickability when the mouse moves over the link; (2) making RET or **mouse-2** on that link do something; and (3) setting up a **follow-link** condition so that the link obeys **mouse-1-click-follows-link**.

To indicate clickability, add the **mouse-face** text property to the text of the link; then Emacs will highlight the link when the mouse moves over it. In addition, you should define a tooltip or echo area message, using the **help-echo** text property. See Section 33.19.4 [Special Properties], page 924. For instance, here is how **Dired** indicates that file names are clickable:

```
(if (dired-move-to-filename)
  (add-text-properties
   (point)
   (save-excursion
     (dired-move-to-end-of-filename)
     (point)))
  '(mouse-face highlight
    help-echo "mouse-2: visit this file in other window")))
```

To make the link clickable, bind RET and **mouse-2** to commands that perform the desired action. Each command should check to see whether it was called on a link, and act accordingly. For instance, **Dired**'s major mode keymap binds **mouse-2** to the following command:

```
(defun dired-mouse-find-file-other-window (event)
  "In Dired, visit the file or directory name you click on."
  (interactive "e")
  (let ((window (posn-window (event-end event)))
        (pos (posn-point (event-end event)))
        file)
    (if (not (windowp window))
        (error "No file chosen"))
    (with-current-buffer (window-buffer window)
```

```
(goto-char pos)
(setq file (dired-get-file-for-visit))
(if (file-directory-p file)
    (or (and (cdr dired-subdir-alist)
              (dired-goto-subdir file)))
        (progn
            (select-window window)
            (dired-other-window file)))
    (select-window window)
    (find-file-other-window (file-name-sans-versions file t)))))
```

This command uses the functions `posn-window` and `posn-point` to determine where the click occurred, and `dired-get-file-for-visit` to determine which file to visit.

Instead of binding the mouse command in a major mode keymap, you can bind it within the link text, using the `keymap` text property (see Section 33.19.4 [Special Properties], page 924). For instance:

```
(let ((map (make-sparse-keymap)))
  (define-key map [mouse-2] 'operate-this-button)
  (put-text-property link-start link-end 'keymap map))
```

With this method, you can easily define different commands for different links. Furthermore, the global definition of RET and `mouse-2` remain available for the rest of the text in the buffer.

The basic Emacs command for clicking on links is `mouse-2`. However, for compatibility with other graphical applications, Emacs also recognizes `mouse-1` clicks on links, provided the user clicks on the link quickly without moving the mouse. This behavior is controlled by the user option `mouse-1-click-follows-link`. See Section “Mouse References” in *The GNU Emacs Manual*.

To set up the link so that it obeys `mouse-1-click-follows-link`, you must either (1) apply a `follow-link` text or overlay property to the link text, or (2) bind the `follow-link` event to a keymap (which can be a major mode keymap or a local keymap specified via the `keymap` text property). The value of the `follow-link` property, or the binding for the `follow-link` event, acts as a condition for the link action. This condition tells Emacs two things: the circumstances under which a `mouse-1` click should be regarded as occurring inside the link, and how to compute an action code that says what to translate the `mouse-1` click into. The link action condition can be one of the following:

`mouse-face`

If the condition is the symbol `mouse-face`, a position is inside a link if there is a non-nil `mouse-face` property at that position. The action code is always `t`.

For example, here is how Info mode handles `mouse-1`:

```
(keymap-set Info-mode-map "<follow-link>" 'mouse-face)
```

a function If the condition is a function, `func`, then a position `pos` is inside a link if `(func pos)` evaluates to non-nil. The value returned by `func` serves as the action code.

For example, here is how pcvs enables `mouse-1` to follow links on file names only:

```
(keymap-set map "<follow-link>"
  (lambda (pos)
    (eq (get-char-property pos 'face) 'cvs-filename-face)))
```

anything else

If the condition value is anything else, then the position is inside a link and the condition itself is the action code. Clearly, you should specify this kind of condition only when applying the condition via a text or overlay property on the link text (so that it does not apply to the entire buffer).

The action code tells `mouse-1` how to follow the link:

a string or vector

If the action code is a string or vector, the `mouse-1` event is translated into the first element of the string or vector; i.e., the action of the `mouse-1` click is the local or global binding of that character or symbol. Thus, if the action code is "`foo`", `mouse-1` translates into `f`. If it is `[foo]`, `mouse-1` translates into `foo`.

anything else

For any other non-`nil` action code, the `mouse-1` event is translated into a `mouse-2` event at the same position.

To define `mouse-1` to activate a button defined with `define-button-type`, give the button a `:follow-link` property. The property value should be a link action condition, as described above. See Section 41.20 [Buttons], page 1232. For example, here is how Help mode handles `mouse-1`:

```
(define-button-type 'help-xref
  'follow-link t
  'action #'help-button-action)
```

To define `mouse-1` on a widget defined with `define-widget`, give the widget a `:follow-link` property. The property value should be a link action condition, as described above. For example, here is how the `link` widget specifies that a `mouse-1` click shall be translated to RET:

```
(define-widget 'link 'item
  "An embedded link."
  :button-prefix 'widget-link-prefix
  :button-suffix 'widget-link-suffix
  :follow-link "\C-m"
  :help-echo "Follow the link."
  :format "%[%t%]")
```

`mouse-on-link-p pos`

[Function]

This function returns non-`nil` if position `pos` in the current buffer is on a link. `pos` can also be a mouse event location, as returned by `event-start` (see Section 22.7.15 [Accessing Mouse], page 456).

33.19.9 Defining and Using Fields

A field is a range of consecutive characters in the buffer that are identified by having the same value (comparing with `eq`) of the `field` property (either a text-property or an overlay property). This section describes special functions that are available for operating on fields.

You specify a field with a buffer position, `pos`. We think of each field as containing a range of buffer positions, so the position you specify stands for the field containing that position.

When the characters before and after `pos` are part of the same field, there is no doubt which field contains `pos`: the one those characters both belong to. When `pos` is at a boundary

between fields, which field it belongs to depends on the stickiness of the `field` properties of the two surrounding characters (see Section 33.19.6 [Sticky Properties], page 932). The field whose property would be inherited by text inserted at `pos` is the field that contains `pos`.

There is an anomalous case where newly inserted text at `pos` would not inherit the `field` property from either side. This happens if the previous character's `field` property is not rear-sticky, and the following character's `field` property is not front-sticky. In this case, `pos` belongs to neither the preceding field nor the following field; the field functions treat it as belonging to an empty field whose beginning and end are both at `pos`.

In all of these functions, if `pos` is omitted or `nil`, the value of point is used by default. If narrowing is in effect, then `pos` should fall within the accessible portion. See Section 31.4 [Narrowing], page 865.

field-beginning &optional pos escape-from-edge limit [Function]

This function returns the beginning of the field specified by `pos`.

If `pos` is at the beginning of its field, and `escape-from-edge` is non-`nil`, then the return value is always the beginning of the preceding field that *ends* at `pos`, regardless of the stickiness of the `field` properties around `pos`.

If `limit` is non-`nil`, it is a buffer position; if the beginning of the field is before `limit`, then `limit` will be returned instead.

field-end &optional pos escape-from-edge limit [Function]

This function returns the end of the field specified by `pos`.

If `pos` is at the end of its field, and `escape-from-edge` is non-`nil`, then the return value is always the end of the following field that *begins* at `pos`, regardless of the stickiness of the `field` properties around `pos`.

If `limit` is non-`nil`, it is a buffer position; if the end of the field is after `limit`, then `limit` will be returned instead.

field-string &optional pos [Function]

This function returns the contents of the field specified by `pos`, as a string.

field-string-no-properties &optional pos [Function]

This function returns the contents of the field specified by `pos`, as a string, discarding text properties.

delete-field &optional pos [Function]

This function deletes the text of the field specified by `pos`.

**constrain-to-field new-pos old-pos &optional escape-from-edge
only-in-line inhibit-capture-property** [Function]

This function constrains `new-pos` to the field that `old-pos` belongs to—in other words, it returns the position closest to `new-pos` that is in the same field as `old-pos`.

If `new-pos` is `nil`, then `constrain-to-field` uses the value of point instead, and moves point to the resulting position in addition to returning that position.

If `old-pos` is at the boundary of two fields, then the acceptable final positions depend on the argument `escape-from-edge`. If `escape-from-edge` is `nil`, then `new-pos` must be in the field whose `field` property equals what new characters inserted at `old-pos`

would inherit. (This depends on the stickiness of the `field` property for the characters before and after `old-pos`.) If `escape-from-edge` is non-`nil`, `new-pos` can be anywhere in the two adjacent fields. Additionally, if two fields are separated by another field with the special value `boundary`, then any point within this special field is also considered to be on the boundary.

Commands like `C-a` with no argument, that normally move backward to a specific kind of location and stay there once there, probably should specify `nil` for `escape-from-edge`. Other motion commands that check fields should probably pass `t`.

If the optional argument `only-in-line` is non-`nil`, and constraining `new-pos` in the usual way would move it to a different line, `new-pos` is returned unconstrained. This is used in commands that move by line, such as `next-line` and `beginning-of-line`, so that they respect field boundaries only in the case where they can still move to the right line.

If the optional argument `inhibit-capture-property` is non-`nil`, and `old-pos` has a non-`nil` property of that name, then any field boundaries are ignored.

You can cause `constrain-to-field` to ignore all field boundaries (and so never constrain anything) by binding the variable `inhibit-field-text-motion` to a non-`nil` value.

33.19.10 Why Text Properties are not Intervals

Some editors that support adding attributes to text in the buffer do so by letting the user specify intervals within the text, and adding the properties to the intervals. Those editors permit the user or the programmer to determine where individual intervals start and end. We deliberately provided a different sort of interface in Emacs Lisp to avoid certain paradoxical behavior associated with text modification.

If the actual subdivision into intervals is meaningful, that means you can distinguish between a buffer that is just one interval with a certain property, and a buffer containing the same text subdivided into two intervals, both of which have that property.

Suppose you take the buffer with just one interval and kill part of the text. The text remaining in the buffer is one interval, and the copy in the kill ring (and the undo list) becomes a separate interval. Then if you yank back the killed text, you get two intervals with the same properties. Thus, editing does not preserve the distinction between one interval and two.

Suppose we attempt to fix this problem by coalescing the two intervals when the text is inserted. That works fine if the buffer originally was a single interval. But suppose instead that we have two adjacent intervals with the same properties, and we kill the text of one interval and yank it back. The same interval-coalescence feature that rescues the other case causes trouble in this one: after yanking, we have just one interval. Once again, editing does not preserve the distinction between one interval and two.

Insertion of text at the border between intervals also raises questions that have no satisfactory answer.

However, it is easy to arrange for editing to behave consistently for questions of the form, “What are the properties of text at this buffer or string position?” So we have decided these are the only questions that make sense; we have not implemented asking questions about where intervals start or end.

In practice, you can usually use the text property search functions in place of explicit interval boundaries. You can think of them as finding the boundaries of intervals, assuming that intervals are always coalesced whenever possible. See Section 33.19.3 [Property Search], page 921.

Emacs also provides explicit intervals as a presentation feature; see Section 41.9 [Overlays], page 1150.

33.20 Substituting for a Character Code

The following functions replace characters within a specified region based on their character codes.

subst-char-in-region *start end old-char new-char &optional noundo* [Function]

This function replaces all occurrences of the character *old-char* with the character *new-char* in the region of the current buffer defined by *start* and *end*. Both characters must have the same length of their multibyte form.

If *noundo* is non-nil, then **subst-char-in-region** does not record the change for undo and does not mark the buffer as modified. This was useful for controlling the old selective display feature (see Section 41.7 [Selective Display], page 1145).

subst-char-in-region does not move point and returns **nil**.

```
----- Buffer: foo -----
This is the contents of the buffer before.
----- Buffer: foo -----
```

```
(subst-char-in-region 1 20 ?i ?X)
⇒ nil
```

```
----- Buffer: foo -----
ThXs Xs the contents of the buffer before.
----- Buffer: foo -----
```

subst-char-in-string *fromchar tochar string &optional inplace* [Function]

This function replaces all occurrences of the character *fromchar* with *tochar* in *string*. By default, substitution occurs in a copy of *string*, but if the optional argument *inplace* is non-nil, the function modifies the *string* itself. In any case, the function returns the resulting string.

translate-region *start end table* [Command]

This function applies a translation table to the characters in the buffer between positions *start* and *end*.

The translation table *table* is a string or a char-table; (*aref table uchar*) gives the translated character corresponding to *uchar*. If *table* is a string, any characters with codes larger than the length of *table* are not altered by the translation.

The return value of **translate-region** is the number of characters that were actually changed by the translation. This does not count characters that were mapped into themselves in the translation table.

33.21 Registers

A register is a sort of variable used in Emacs editing that can hold a variety of different kinds of values. Each register is named by a single character. All ASCII characters and their meta variants (but with the exception of *C-g*) can be used to name registers. Thus, there are 255 possible registers. A register is designated in Emacs Lisp by the character that is its name.

register-alist [Variable]

This variable is an alist of elements of the form (*name* . *contents*). Normally, there is one element for each Emacs register that has been used.

The object *name* is a character (an integer) identifying the register.

The *contents* of a register can have several possible types:

- a number A number stands for itself. If `insert-register` finds a number in the register, it converts the number to decimal.
- a marker A marker represents a buffer position to jump to.
- a string A string is text saved in the register.
- a rectangle A rectangle is represented by a list of strings.

(window-configuration position)

This represents a window configuration to restore in one frame, and a position to jump to in the current buffer.

(frame-configuration position)

This represents a frame configuration to restore, and a position to jump to in the current buffer. Frame configurations are also known as framesets.

(file filename)

This represents a file to visit; jumping to this value visits file *filename*.

(file-query filename position)

This represents a file to visit and a position in it; jumping to this value visits file *filename* and goes to buffer position *position*. Restoring this type of position asks the user for confirmation first.

(buffer buffer-name)

This represents a buffer; jumping to this value switches to buffer *buffer-name*.

The functions in this section return unpredictable values unless otherwise stated.

get-register reg [Function]

This function returns the contents of the register *reg*, or `nil` if it has no contents.

set-register reg value [Function]

This function sets the contents of register *reg* to *value*. A register can be set to any value, but the other register functions expect only certain data types. The return value is *value*.

view-register *reg* [Command]

This command displays what is contained in register *reg*.

insert-register *reg &optional beforep* [Command]

This command inserts contents of register *reg* into the current buffer.

Normally, this command puts point before the inserted text, and the mark after it. However, if the optional second argument *beforep* is non-*nil*, it puts the mark before and point after.

When called interactively, the command defaults to putting point after text, and a prefix argument inverts this behavior.

If the register contains a rectangle, then the rectangle is inserted with its upper left corner at point. This means that text is inserted in the current line and underneath it on successive lines.

If the register contains something other than saved text (a string) or a rectangle (a list), currently useless things happen. This may be changed in the future.

register-read-with-preview *prompt* [Function]

This function reads and returns a register name, prompting with *prompt* and possibly showing a preview of the existing registers and their contents. The preview is shown in a temporary window, after the delay specified by the user option **register-preview-delay**, if its value and **register-alist** are both non-*nil*. The preview is also shown if the user requests help (e.g., by typing the help character). We recommend that all interactive commands which read register names use this function.

33.22 Transposition of Text

This function can be used to transpose stretches of text:

transpose-regions *start1 end1 start2 end2 &optional leave-markers* [Function]

This function exchanges two nonoverlapping portions of the buffer (if they overlap, the function signals an error). Arguments *start1* and *end1* specify the bounds of one portion and arguments *start2* and *end2* specify the bounds of the other portion.

Normally, **transpose-regions** relocates markers with the transposed text; a marker previously positioned within one of the two transposed portions moves along with that portion, thus remaining between the same two characters in their new position. However, if *leave-markers* is non-*nil*, **transpose-regions** does not do this—it leaves all markers unrelocated.

33.23 Replacing Buffer Text

You can use the following function to replace the text of one buffer with the text of another buffer:

replace-buffer-contents *source &optional max-secs max-costs* [Command]

This function replaces the accessible portion of the current buffer with the accessible portion of the buffer *source*. *source* may either be a buffer object or the name of a buffer. When **replace-buffer-contents** succeeds, the text of the accessible portion

of the current buffer will be equal to the text of the accessible portion of the *source* buffer.

This function attempts to keep point, markers, text properties, and overlays in the current buffer intact. One potential case where this behavior is useful is external code formatting programs: they typically write the reformatted text into a temporary buffer or file, and using `delete-region` and `insert-buffer-substring` would destroy these properties. However, the latter combination is typically faster (See Section 33.6 [Deletion], page 886, and Section 33.4 [Insertion], page 882).

For its working, `replace-buffer-contents` needs to compare the contents of the original buffer with that of *source* which is a costly operation if the buffers are huge and there is a high number of differences between them. In order to keep `replace-buffer-contents`'s runtime in bounds, it has two optional arguments.

max-secs defines a hard boundary in terms of seconds. If given and exceeded, it will fall back to `delete-region` and `insert-buffer-substring`.

max-costs defines the quality of the difference computation. If the actual costs exceed this limit, heuristics are used to provide a faster but suboptimal solution. The default value is 1000000.

`replace-buffer-contents` returns `t` if a non-destructive replacement could be performed. Otherwise, i.e., if *max-secs* was exceeded, it returns `nil`.

replace-region-contents *beg end replace-fn &optional max-secs max-costs* [Function]

This function replaces the region between *beg* and *end* using the given *replace-fn*. The function *replace-fn* is run in the current buffer narrowed to the specified region and it should return either a string or a buffer replacing the region.

The replacement is performed using `replace-buffer-contents` (see above) which also describes the *max-secs* and *max-costs* arguments and the return value.

Note: If the replacement is a string, it will be placed in a temporary buffer so that `replace-buffer-contents` can operate on it. Therefore, if you already have the replacement in a buffer, it makes no sense to convert it to a string using `buffer-substring` or similar.

33.24 Dealing With Compressed Data

When `auto-compression-mode` is enabled, Emacs automatically uncompresses compressed files when you visit them, and automatically recompresses them if you alter and save them. See Section “Compressed Files” in *The GNU Emacs Manual*.

The above feature works by calling an external executable (e.g., `gzip`). Emacs can also be compiled with support for built-in decompression using the zlib library, which is faster than calling an external program.

zlib-available-p [Function]

This function returns non-`nil` if built-in zlib decompression is available.

zlib-decompress-region *start end &optional allow-partial* [Function]

This function decompresses the region between *start* and *end*, using built-in zlib decompression. The region should contain data that were compressed with gzip or zlib.

On success, the function replaces the contents of the region with the decompressed data. If *allow-partial* is `nil` or omitted, then on failure, the function leaves the region unchanged and returns `nil`. Otherwise, it returns the number of bytes that were not decompressed and replaces the region text by whatever data was successfully decompressed. This function can be called only in unibyte buffers.

33.25 Base 64 Encoding

Base 64 code is used in email to encode a sequence of 8-bit bytes as a longer sequence of ASCII graphic characters. It is defined in Internet RFC¹2045 and also in RFC 4648. This section describes the functions for converting to and from this code.

base64-encode-region *beg end &optional no-line-break* [Command]

This function converts the region from *beg* to *end* into base 64 code. It returns the length of the encoded text. An error is signaled if a character in the region is multibyte, i.e., in a multibyte buffer the region must contain only ASCII characters or raw bytes.

Normally, this function inserts newline characters into the encoded text, to avoid overlong lines. However, if the optional argument *no-line-break* is non-`nil`, these newlines are not added, so the output is just one long line.

base64url-encode-region *beg end &optional no-pad* [Command]

This function is like **base64-encode-region**, but it implements the URL variant of base 64 encoding, per RFC 4648, and it doesn't insert newline characters into the encoded text, so the output is just one long line.

If the optional argument *no-pad* is non-`nil` then this function doesn't generate the padding (=).

base64-encode-string *string &optional no-line-break* [Function]

This function converts the string *string* into base 64 code. It returns a string containing the encoded text. As for **base64-encode-region**, an error is signaled if a character in the string is multibyte.

Normally, this function inserts newline characters into the encoded text, to avoid overlong lines. However, if the optional argument *no-line-break* is non-`nil`, these newlines are not added, so the result string is just one long line.

base64url-encode-string *string &optional no-pad* [Function]

Like **base64-encode-string**, but generates the URL variant of base 64, and doesn't insert newline characters into the encoded text, so the result is just one long line.

If the optional argument *no-pad* is non-`nil` then this function doesn't generate the padding.

base64-decode-region *beg end &optional base64url ignore-invalid* [Command]

This function converts the region from *beg* to *end* from base 64 code into the corresponding decoded text. It returns the length of the decoded text.

¹ An RFC, an acronym for *Request for Comments*, is a numbered Internet informational document describing a standard. RFCs are usually written by technical experts acting on their own initiative, and are traditionally written in a pragmatic, experience-driven manner.

The decoding functions ignore newline characters in the encoded text.

If optional argument `base64url` is non-`nil`, then padding is optional, and the URL variant of base 64 encoding is used. If optional argument `ignore-invalid` is non-`nil`, then any unrecognized characters are ignored.

base64-decode-string *string* &optional *base64url ignore-invalid* [Function]

This function converts the string *string* from base 64 code into the corresponding decoded text. It returns a unibyte string containing the decoded text.

The decoding functions ignore newline characters in the encoded text.

If optional argument `base64url` is non-`nil`, then padding is optional, and the URL variant of base 64 encoding is used. If optional argument `ignore-invalid` is non-`nil`, then any unrecognized characters are ignored.

33.26 Checksum/Hash

Emacs has built-in support for computing *cryptographic hashes*. A cryptographic hash, or *checksum*, is a digital fingerprint of a piece of data (e.g., a block of text) which can be used to check that you have an unaltered copy of that data.

Emacs supports several common cryptographic hash algorithms: MD5, SHA-1, SHA-2, SHA-224, SHA-256, SHA-384 and SHA-512. MD5 is the oldest of these algorithms, and is commonly used in *message digests* to check the integrity of messages transmitted over a network. MD5 and SHA-1 are not collision resistant (i.e., it is possible to deliberately design different pieces of data which have the same MD5 or SHA-1 hash), so you should not use them for anything security-related. For security-related applications you should use the other hash types, such as SHA-2 (e.g. `sha256` or `sha512`).

secure-hash-algorithms [Function]

This function returns a list of symbols representing algorithms that `secure-hash` can use.

secure-hash *algorithm object* &optional *start end binary* [Function]

This function returns a hash for *object*. The argument *algorithm* is a symbol stating which hash to compute: one of `md5`, `sha1`, `sha224`, `sha256`, `sha384` or `sha512`. The argument *object* should be a buffer or a string.

The optional arguments *start* and *end* are character positions specifying the portion of *object* to compute the message digest for. If they are `nil` or omitted, the hash is computed for the whole of *object*.

If the argument *binary* is omitted or `nil`, the function returns the *text form* of the hash, as an ordinary Lisp string. If *binary* is non-`nil`, it returns the hash in *binary form*, as a sequence of bytes stored in a unibyte string. The length of the returned string depends on *algorithm*:

- For `md5`: 32 characters (32 bytes if *binary* is non-`nil`).
- For `sha1`: 40 characters (40 bytes if *binary* is non-`nil`).
- For `sha224`: 56 characters (56 bytes if *binary* is non-`nil`).
- For `sha256`: 64 characters (64 bytes if *binary* is non-`nil`).
- For `sha384`: 96 characters (96 bytes if *binary* is non-`nil`).

- For `sha512`: 128 characters (128 bytes if `binary` is non-`nil`).

This function does not compute the hash directly from the internal representation of `object`'s text (see Section 34.1 [Text Representations], page 963). Instead, it encodes the text using a coding system (see Section 34.10 [Coding Systems], page 976), and computes the hash from that encoded text. If `object` is a buffer, the coding system used is the one which would be chosen by default for writing the text of that buffer into a file. If `object` is a string, the user's preferred coding system is used (see Section "Recognize Coding" in *GNU Emacs Manual*).

md5 `object &optional start end coding-system noerror` [Function]

This function returns an MD5 hash. It is semi-obsolete, since for most purposes it is equivalent to calling `secure-hash` with `md5` as the `algorithm` argument. The `object`, `start` and `end` arguments have the same meanings as in `secure-hash`. The function returns a 32-character string.

If `coding-system` is non-`nil`, it specifies a coding system to use to encode the text; if omitted or `nil`, the default coding system is used, like in `secure-hash`.

Normally, `md5` signals an error if the text can't be encoded using the specified or chosen coding system. However, if `noerror` is non-`nil`, it silently uses `raw-text` coding instead.

buffer-hash `&optional buffer-or-name` [Function]

Return a hash of `buffer-or-name`. If `nil`, this defaults to the current buffer. As opposed to `secure-hash`, this function computes the hash based on the internal representation of the buffer, disregarding any coding systems. It's therefore only useful when comparing two buffers running in the same Emacs, and is not guaranteed to return the same hash between different Emacs versions. It should be somewhat more efficient on larger buffers than `secure-hash` is, and should not allocate more memory.

sha1 `object &optional start end binary` [Function]

This function is equivalent to calling `secure-hash` like this:

```
(secure-hash 'sha1 object start end binary)
```

It returns a 40-character string if `binary` is `nil`, or a 40-byte unibyte string otherwise.

33.27 Suspicious Text

Emacs can display text from many external sources, like email and Web sites. Attackers may attempt to confuse the user reading this text by using obfuscated URLs or email addresses, and tricking the user into visiting a web page they didn't intend to visit, or sending an email to the wrong address.

This usually involves using characters from scripts that visually look like ASCII characters (i.e., are homoglyphs), but there are also other techniques used, like using bidirectional overrides, or having an HTML link text that says one thing, while the underlying URL points somewhere else.

To help identify these *suspicious text strings*, Emacs provides a library to do a number of checks on text. (See UTS #39: Unicode Security Mechanisms (<https://www.unicode.org/reports/tr39/>) for the rationale behind the checks that are available and more details

about them.) Packages that present data that might be suspicious should use this library to flag suspicious text on display.

textsec-suspicious-p *object type* [Function]

This function is the high-level interface function that packages should use. It respects the `textsec-check` user option, which allows the user to disable the checks.

This function checks *object* (whose data type depends on *type*) to see if it looks suspicious when interpreted as a thing of *type*. The available types and the corresponding *object* data types are:

domain Check whether a domain (e.g., ‘`www.gnu.org`’) looks suspicious. *object* should be a string, the domain name.

url Check whether an URL (e.g., ‘`http://gnu.org/foo/bar`’) looks suspicious. *object* should be a string, the URL to check.

link Check whether an HTML link (e.g., ‘`fsf.org`’) looks suspicious. In this case, *object* should be a `cons` cell where the `car` is the URL string, and the `cdr` is the link text. The link is deemed suspicious if the link text contains a domain name, and that domain name points to something other than the URL.

email-address

Check whether an email address (e.g., ‘`foo@example.org`’) looks suspicious. *object* should be a string.

local-address

Check whether the local part of an email address (the bit before the ‘@’ sign) looks suspicious. *object* should be a string.

name Check whether a name (used in an email address header) looks suspicious. *object* should be a string.

email-address-header

Check whether a full RFC2822 email address header (e.g., ‘=?utf-8?Q?=C3=81?= <`foo@example.com`>’) looks suspicious. *object* should be a string.

If *object* is suspicious, this function returns a string that explains why it is suspicious. If *object* is not suspicious, the function returns `nil`.

If the text is suspicious, the application should mark the suspicious text with the `textsec-suspicious` face, and make the explanation returned by `textsec-suspicious-p` available to the user in some way (for example, in a tooltip). The application might also prompt the user for confirmation before taking any action on a suspicious string (like sending an email to a suspicious email address).

33.28 GnuTLS Cryptography

If compiled with GnuTLS, Emacs offers built-in cryptographic support. Following the GnuTLS API terminology, the available tools are digests, MACs, symmetric ciphers, and AEAD ciphers.

The terms used herein, such as IV (Initialization Vector), require some familiarity with cryptography and will not be defined in detail. Please consult <https://www.gnutls.org/> for specific documentation which may help you understand the terminology and structure of the GnuTLS library.

33.28.1 Format of GnuTLS Cryptography Inputs

The inputs to GnuTLS cryptographic functions can be specified in several ways, both as primitive Emacs Lisp types or as lists.

The list form is currently similar to how `md5` and `secure-hash` operate.

- buffer** Simply passing a buffer as input means the whole buffer should be used.
- string** A string as input will be used directly. It may be modified by the function (unlike most other Emacs Lisp functions) to reduce the chance of exposing sensitive data after the function does its work.

(buffer-or-string start end coding-system noerror)

This specifies a buffer or a string as described above, but an optional range can be specified with `start` and `end`.

In addition an optional `coding-system` can be specified if needed.

The last optional item, `noerror`, overrides the normal error when the text can't be encoded using the specified or chosen coding system. When `noerror` is non-nil, this function silently uses `raw-text` coding instead.

(iv-auto length)

This generates a random IV (Initialization Vector) of the specified length and passes it to the function. This ensures that the IV is unpredictable and unlikely to be reused in the same session.

33.28.2 GnuTLS Cryptographic Functions

gnutls-digests

[Function]

This function returns the alist of the GnuTLS digest algorithms.

Each entry has a key which represents the algorithm, followed by a plist with internal details about the algorithm. The plist will have `:type gnutls-digest-algorithm` and also will have the key `:digest-algorithm-length 64` to indicate the size, in bytes, of the resulting digest.

There is a name parallel between GnuTLS MAC and digest algorithms but they are separate things internally and should not be mixed.

gnutls-hash-digest digest-method input

[Function]

The `digest-method` can be the whole plist from `gnutls-digests`, or just the symbol key, or a string with the name of that symbol.

The `input` can be specified as a buffer or string or in other ways (see Section 33.28.1 [Format of GnuTLS Cryptography Inputs], page 947).

This function returns `nil` on error, and signals a Lisp error if the `digest-method` or `input` are invalid. On success, it returns a list of a binary string (the output) and the IV used.

gnutls-macs

[Function]

This function returns the alist of the GnuTLS MAC algorithms.

Each entry has a key which represents the algorithm, followed by a plist with internal details about the algorithm. The plist will have `:type gnutls-mac-algorithm` and also will have the keys `:mac-algorithm-length` `:mac-algorithm-keysize` `:mac-algorithm-noncesize` to indicate the size, in bytes, of the resulting hash, the key, and the nonce respectively.

The nonce is currently unused and only some MACs support it.

There is a name parallel between GnuTLS MAC and digest algorithms but they are separate things internally and should not be mixed.

gnutls-hash-mac *hash-method* *key* *input*

[Function]

The *hash-method* can be the whole plist from `gnutls-macs`, or just the symbol `key`, or a string with the name of that symbol.

The *key* can be specified as a buffer or string or in other ways (see Section 33.28.1 [Format of GnuTLS Cryptography Inputs], page 947). The *key* will be wiped after use if it's a string.

The *input* can be specified as a buffer or string or in other ways (see Section 33.28.1 [Format of GnuTLS Cryptography Inputs], page 947).

This function returns `nil` on error, and signals a Lisp error if the *hash-method* or *key* or *input* are invalid.

On success, it returns a list of a binary string (the output) and the IV used.

gnutls-ciphers

[Function]

This function returns the alist of the GnuTLS ciphers.

Each entry has a key which represents the cipher, followed by a plist with internal details about the algorithm. The plist will have `:type gnutls-symmetric-cipher` and also will have the keys `:cipher-aead-capable` set to `nil` or `t` to indicate AEAD capability; and `:cipher-tagsize` `:cipher-blocksize` `:cipher-keysize` `:cipher-ivsize` to indicate the size, in bytes, of the tag, block size of the resulting data, the key, and the IV respectively.

gnutls-symmetric-encrypt *cipher* *key* *iv* *input* &**optional** *aead_auth*

[Function]

The *cipher* can be the whole plist from `gnutls-ciphers`, or just the symbol `key`, or a string with the name of that symbol.

The *key* can be specified as a buffer or string or in other ways (see Section 33.28.1 [Format of GnuTLS Cryptography Inputs], page 947). The *key* will be wiped after use if it's a string.

The *iv* and *input* and the optional *aead_auth* can be specified as a buffer or string or in other ways (see Section 33.28.1 [Format of GnuTLS Cryptography Inputs], page 947). *aead_auth* is only checked with AEAD ciphers, that is, ciphers whose plist has `:cipher-aead-capable t`. Otherwise it's ignored.

This function returns `nil` on error, and signals a Lisp error if the *cipher* or *key*, *iv*, or *input* are invalid, or if *aead_auth* was specified with an AEAD cipher and was invalid.

On success, it returns a list of a binary string (the output) and the IV used.

gnutls-symmetric-decrypt *cipher key iv input &optional aead-auth* [Function]

The *cipher* can be the whole plist from **gnutls-ciphers**, or just the symbol *key*, or a string with the name of that symbol.

The *key* can be specified as a buffer or string or in other ways (see Section 33.28.1 [Format of GnuTLS Cryptography Inputs], page 947). The *key* will be wiped after use if it's a string.

The *iv* and *input* and the optional *aead-auth* can be specified as a buffer or string or in other ways (see Section 33.28.1 [Format of GnuTLS Cryptography Inputs], page 947). *aead-auth* is only checked with AEAD ciphers, that is, ciphers whose plist has `:cipher-aead-capable t`. Otherwise it's ignored.

This function returns `nil` on decryption error, and signals a Lisp error if the *cipher* or *key*, *iv*, or *input* are invalid, or if *aead-auth* was specified with an AEAD cipher and was invalid.

On success, it returns a list of a binary string (the output) and the IV used.

33.29 Database

Emacs can be compiled with built-in support for accessing SQLite databases. This section describes the facilities available for accessing SQLite databases from Lisp programs.

sqlite-available-p [Function]

The function returns non-`nil` if built-in SQLite support is available in this Emacs session.

When SQLite support is available, the following functions can be used.

sqlite-open &optional file [Function]

This function opens *file* as an SQLite database file. If *file* doesn't exist, a new database will be created and stored in that file. If *file* is omitted or `nil`, a new in-memory database is created instead.

The return value is a *database object* that can be used as the argument to most of the subsequent functions described below.

sqlitetp object [Function]

This predicate returns non-`nil` if *object* is an SQLite database object. The database object returned by the **sqlite-open** function satisfies this predicate.

sqlite-close db [Function]

Close the database *db*. It's usually not necessary to call this function explicitly—the database will automatically be closed if Emacs shuts down or the database object is garbage collected.

sqlite-execute db statement &optional values [Function]

Execute the SQL *statement*. For instance:

```
(sqlite-execute db "insert into foo values ('bar', 2)")
```

If the optional *values* parameter is present, it should be either a list or a vector of values to bind while executing the statement. For instance:

```
(sqlite-execute db "insert into foo values (?, ?)" '("bar" 2))
```

This has exactly the same effect as the previous example, but is more efficient and safer (because it doesn't involve any string parsing or interpolation).

`sqlite-execute` usually returns the number of affected rows. For instance, an ‘`insert`’ statement will typically return ‘1’, whereas an ‘`update`’ statement may return zero or a higher number. However, when using SQL statements like ‘`insert into ... returning ...`’ and the like, the values specified by ‘`returning ...`’ will be returned instead.

Strings in SQLite are, by default, stored as `utf-8`, and selecting a text column will decode the string using that charset. Selecting a blob column will return the raw data without any decoding (i.e., it will return a unibyte string containing the bytes as stored in the database). Inserting binary data into blob columns, however, requires some care, as `sqlite-execute` will, by default, interpret all strings as `utf-8`.

So if you have, for instance, GIF data in a unibyte string called `gif`, you have to mark it specially to let `sqlite-execute` know this:

```
(put-text-property 0 1 'coding-system 'binary gif)
(sqlite-execute db "insert into foo values (?, ?)" (list gif 2))
```

sqlite-select *db query &optional values return-type* [Function]

Select some data from *db* and return them. For instance:

```
(sqlite-select db "select * from foo where key = 2")
⇒ (("bar" 2))
```

As with the `sqlite-execute`, you can optionally pass in a list or a vector of values that will be bound before executing the select:

```
(sqlite-select db "select * from foo where key = ?" [2])
⇒ (("bar" 2))
```

This is usually more efficient and safer than the method used by the previous example. By default, this function returns a list of matching rows, where each row is a list of column values. If *return-type* is `full`, the names of the columns (as a list of strings) will be returned as the first element in the return value.

If *return-type* is `set`, this function will return a *statement object* instead. This object can be examined by using the `sqlite-next`, `sqlite-columns` and `sqlite-more-p` functions. If the result set is small, it's often more convenient to just return the data directly, but if the result set is large (or if you won't be using all the data from the set), using the `set` method will allocate a lot less memory, and is therefore more memory-efficient.

sqlite-next *statement* [Function]

This function returns the next row in the result set *statement*, typically an object returned by `sqlite-select`.

```
(sqlite-next stmt)
⇒ ("bar" 2)
```

sqlite-columns *statement* [Function]

This function returns the column names of the result set *statement*, typically an object returned by `sqlite-select`.

```
(sqlite-columns stmt)
```

```
⇒ ("name" "issue")
```

sqlite-more-p *statement*

[Function]

This predicate says whether there is more data to be fetched from the result set *statement*, typically an object returned by **sqlite-select**.

sqlite-finalize *statement*

[Function]

If *statement* is not going to be used any more, calling this function will free the resources used by *statement*. This is usually not necessary—when the *statement* object is garbage-collected, Emacs will automatically free its resources.

sqlite-transaction *db*

[Function]

Start a transaction in *db*. When in a transaction, other readers of the database won't access the results until the transaction has been committed by **sqlite-commit**.

sqlite-commit *db*

[Function]

End a transaction in *db* and write the data out to its file.

sqlite-rollback *db*

[Function]

End a transaction in *db* and discard any changes that have been made by the transaction.

with-sqlite-transaction *db body...*

[Macro]

Like **progn** (see Section 11.1 [Sequencing], page 158), but executes *body* with a transaction held, and commits the transaction at the end if *body* completes normally. If *body* signals an error, or committing the transaction fails, the changes in *db* performed by *body* are rolled back. The macro returns the value of *body* if it completes normally and commit succeeds.

sqlite-pragma *db pragma*

[Function]

Execute *pragma* in *db*. A *pragma* is usually a command that affects the database overall, instead of any particular table. For instance, to make SQLite automatically garbage collect data that's no longer needed, you can say:

```
(sqlite-pragma db "auto_vacuum = FULL")
```

This function returns **non-nil** on success and **nil** if the pragma failed. Many pragmas can only be issued when the database is brand new and empty.

sqlite-load-extension *db module*

[Function]

Load the named extension *module* into the database *db*. Extensions are usually shared-library files; on GNU and Unix systems, they have the **.so** file-name extension.

sqlite-version

[Function]

Return a string denoting the version of the SQLite library in use.

If you wish to list the contents of an SQLite file, you can use the **sqlite-mode-open-file** command. This will pop to a buffer using **sqlite-mode**, which allows you to examine (and alter) the contents of an SQLite database.

33.30 Parsing HTML and XML

Emacs can be compiled with built-in `libxml2` support.

`libxml-available-p` [Function]

This function returns non-`nil` if built-in `libxml2` support is available in this Emacs session.

When `libxml2` support is available, the following functions can be used to parse HTML or XML text into Lisp object trees.

`libxml-parse-html-region &optional start end base-url` [Function]
`discard-comments`

This function parses the text between `start` and `end` as HTML, and returns a list representing the HTML *parse tree*. It attempts to handle real-world HTML by robustly coping with syntax mistakes.

If `start` or `end` are `nil`, they default to the values from `point-min` and `point-max`, respectively.

The optional argument `base-url`, if non-`nil`, should be used for warnings and errors reported by the `libxml2` library, but Emacs currently calls the library with errors and warnings disabled, so this argument is not used.

If the optional argument `discard-comments` is non-`nil`, any top-level comment is discarded. (This argument is obsolete and will be removed in future Emacs versions. To remove comments, use the `xml-remove-comments` utility function on the data before you call the parsing function.)

In the parse tree, each HTML node is represented by a list in which the first element is a symbol representing the node name, the second element is an alist of node attributes, and the remaining elements are the subnodes.

The following example demonstrates this. Given this (malformed) HTML document:

```
<html><head></head><body width=101><div class=thing>Foo<div>Yes
```

A call to `libxml-parse-html-region` returns this DOM (document object model):

```
(html nil
  (head nil)
  (body ((width . "101")))
  (div ((class . "thing"))
    "Foo"
    (div nil
      "Yes"))))
```

`shr-insert-document dom` [Function]

This function renders the parsed HTML in `dom` into the current buffer. The argument `dom` should be a list as generated by `libxml-parse-html-region`. This function is, e.g., used by *The Emacs Web Wowser Manual*.

`libxml-parse-xml-region &optional start end base-url` [Function]
`discard-comments`

This function is the same as `libxml-parse-html-region`, except that it parses the text as XML rather than HTML (so it is stricter about syntax).

33.30.1 Document Object Model

The DOM returned by `libxml-parse-html-region` (and the other XML parsing functions) is a tree structure where each node has a node name (called a *tag*), and optional key/value *attribute* list, and then a list of *child nodes*. The child nodes are either strings or DOM objects.

```
(body ((width . "101"))
  (div ((class . "thing"))
    "Foo"
    (div nil
      "Yes")))
```

dom-node tag &optional attributes &rest children [Function]

This function creates a DOM node of type *tag*. If given, *attributes* should be a key/value pair list. If given, *children* should be DOM nodes.

The following functions can be used to work with this structure. Each function takes a DOM node, or a list of nodes. In the latter case, only the first node in the list is used.

Simple accessors:

dom-tag node

Return the *tag* (also called “node name”) of the node.

dom-attr node attribute

Return the value of *attribute* in the node. A common usage would be:

```
(dom-attr img 'href)
=> "https://fsf.org/logo.png"
```

dom-children node

Return all the children of the node.

dom-non-text-children node

Return all the non-string children of the node.

dom-attributes node

Return the key/value pair list of attributes of the node.

dom-text node

Return all the textual elements of the node as a concatenated string.

dom-texts node

Return all the textual elements of the node, as well as the textual elements of all the children of the node, recursively, as a concatenated string. This function also takes an optional separator to be inserted between the textual elements.

dom-parent dom node

Return the parent of *node* in *dom*.

dom-remove dom node

Remove *node* from *dom*.

The following are functions for altering the DOM.

dom-set-attribute node attribute value

Set the *attribute* of the node to *value*.

dom-remove-attribute *node attribute*
 Remove attribute from *node*.

dom-append-child *node child*
 Append *child* as the last child of *node*.

dom-add-child-before *node child before*
 Add *child* to *node*'s child list before the *before* node. If *before* is `nil`, make *child* the first child.

dom-set-attributes *node attributes*
 Replace all the attributes of the node with a new key/value list.

The following are functions for searching for elements in the DOM. They all return lists of matching nodes.

dom-by-tag *dom tag*
 Return all nodes in *dom* that are of type *tag*. A typical use would be:

```
(dom-by-tag dom 'td)
=> '((td ...) (td ...) (td ...))
```

dom-by-class *dom match*
 Return all nodes in *dom* that have class names that match *match*, which is a regular expression.

dom-by-style *dom style*
 Return all nodes in *dom* that have styles that match *match*, which is a regular expression.

dom-by-id *dom style*
 Return all nodes in *dom* that have IDs that match *match*, which is a regular expression.

dom-search *dom predicate*
 Return all nodes in *dom* where *predicate* returns a non-`nil` value. *predicate* is called with the node to be tested as its parameter.

dom-strings *dom*
 Return all strings in *dom*.

Utility functions:

dom-pp *dom &optional remove-empty*
 Pretty-print *dom* at point. If *remove-empty*, don't print textual nodes that just contain white-space.

dom-print *dom &optional pretty xml*
 Print *dom* at point. If *xml* is non-`nil`, print as XML; otherwise, print as HTML. If *pretty* is non-`nil`, indent the HTML/XML logically.

33.31 Parsing and generating JSON values

When Emacs is compiled with JSON (*JavaScript Object Notation*) support, it provides several functions to convert between Lisp objects and JSON values. Any JSON value can be converted to a Lisp object, but not vice versa. Specifically:

- JSON uses three keywords: `true`, `null`, `false`. `true` is represented by the symbol `t`. By default, the remaining two are represented, respectively, by the symbols `:null` and `:false`.
- JSON only has floating-point numbers. They can represent both Lisp integers and Lisp floating-point numbers.
- JSON strings are always Unicode strings encoded in UTF-8. Lisp strings can contain non-Unicode characters.
- JSON has only one sequence type, the array. JSON arrays are represented using Lisp vectors.
- JSON has only one map type, the object. JSON objects are represented using Lisp hash-tables, alists or plists. When an alist or plist contains several elements with the same key, Emacs uses only the first element for serialization, in accordance with the behavior of `assq`.

Note that `nil`, being both a valid alist and a valid plist, represents `{}`, the empty JSON object; not `null`, `false`, or an empty array, all of which are different JSON values.

json-available-p [Function]

This predicate returns non-`nil` if Emacs has been built with JSON support, and the library is available on the current system.

If some Lisp object can't be represented in JSON, the serialization functions will signal an error of type `wrong-type-argument`. The parsing functions can also signal the following errors:

json-unavailable

Signaled when the parsing library isn't available.

json-end-of-file

Signaled when encountering a premature end of the input text.

json-trailing-content

Signaled when encountering unexpected input after the first JSON object parsed.

json-parse-error

Signaled when encountering invalid JSON syntax.

Top-level values and the subobjects within these top-level values can be serialized to JSON. Likewise, the parsing functions will return any of the possible types described above.

json-serialize object &rest args

[Function]

This function returns a new Lisp string which contains the JSON representation of `object`. The argument `args` is a list of keyword/argument pairs. The following keywords are accepted:

:null-object

The value decides which Lisp object to use to represent the JSON keyword `null`. It defaults to the symbol `:null`.

:false-object

The value decides which Lisp object to use to represent the JSON keyword `false`. It defaults to the symbol `:false`.

json-insert object &rest args

[Function]

This function inserts the JSON representation of `object` into the current buffer before point. The argument `args` are interpreted as in `json-parse-string`.

json-parse-string string &rest args

[Function]

This function parses the JSON value in `string`, which must be a Lisp string. If `string` doesn't contain a valid JSON object, this function signals the `json-parse-error` error.

The argument `args` is a list of keyword/argument pairs. The following keywords are accepted:

:object-type

The value decides which Lisp object to use for representing the key-value mappings of a JSON object. It can be either `hash-table`, the default, to make hashtables with strings as keys; `alist` to use alists with symbols as keys; or `plist` to use plists with keyword symbols as keys.

:array-type

The value decides which Lisp object to use for representing a JSON array. It can be either `array`, the default, to use Lisp arrays; or `list` to use lists.

:null-object

The value decides which Lisp object to use to represent the JSON keyword `null`. It defaults to the symbol `:null`.

:false-object

The value decides which Lisp object to use to represent the JSON keyword `false`. It defaults to the symbol `:false`.

json-parse-buffer &rest args

[Function]

This function reads the next JSON value from the current buffer, starting at point. It moves point to the position immediately after the value if contains a valid JSON object; otherwise it signals the `json-parse-error` error and doesn't move point. The arguments `args` are interpreted as in `json-parse-string`.

33.32 JSONRPC communication

The `jsonrpc` library implements the JSONRPC specification, version 2.0, as it is described in <https://www.jsonrpc.org/>. As the name suggests, JSONRPC is a generic *Remote Procedure Call* protocol designed around JSON objects, which you can convert to and from Lisp objects (see Section 33.31 [Parsing JSON], page 955).

33.32.1 Overview

Quoting from the spec (<https://www.jsonrpc.org/>), JSONRPC "is transport agnostic in that the concepts can be used within the same process, over sockets, over http, or in many various message passing environments."

To model this agnosticism, the `jsonrpc` library uses objects of a `jsonrpc-connection` class, which represent a connection to a remote JSON endpoint (for details on Emacs's object system, see *EIEIO*). In modern object-oriented parlance, this class is “abstract”, i.e. the actual class of a useful connection object is always a subclass of `jsonrpc-connection`. Nevertheless, we can define two distinct APIs around the `jsonrpc-connection` class:

1. A user interface for building JSONRPC applications

In this scenario, the JSONRPC application selects a concrete subclass of `jsonrpc-connection`, and proceeds to create objects of that subclass using `make-instance`. To initiate a contact to the remote endpoint, the JSONRPC application passes this object to the functions `jsonrpc-notify`, `jsonrpc-request`, and/or `jsonrpc-async-request`. For handling remotely initiated contacts, which generally come in asynchronously, the instantiation should include `:request-dispatcher` and `:notification-dispatcher` initargs, which are both functions of 3 arguments: the connection object; a symbol naming the JSONRPC method invoked remotely; and a JSONRPC `params` object.

The function passed as `:request-dispatcher` is responsible for handling the remote endpoint's requests, which expect a reply from the local endpoint (in this case, the program you're building). Inside that function, you may either return locally (a normal return) or non-locally (an error return). A local return value must be a Lisp object that can be serialized as JSON (see Section 33.31 [Parsing JSON], page 955). This determines a success response, and the object is forwarded to the server as the JSONRPC `result` object. A non-local return, achieved by calling the function `jsonrpc-error`, causes an error response to be sent to the server. The details of the accompanying JSONRPC `error` are filled out with whatever was passed to `jsonrpc-error`. A non-local return triggered by an unexpected error of any other type also causes an error response to be sent (unless you have set `debug-on-error`, in which case this calls the Lisp debugger, see Section 19.1.1 [Error Debugging], page 333).

2. A inheritance interface for building JSONRPC transport implementations

In this scenario, `jsonrpc-connection` is subclassed to implement a different underlying transport strategy (for details on how to subclass, see Section “Inheritance” in `eieio`). Users of the application-building interface can then instantiate objects of this concrete class (using the `make-instance` function) and connect to JSONRPC endpoints using that strategy.

This API has mandatory and optional parts.

To allow its users to initiate JSONRPC contacts (notifications or requests) or reply to endpoint requests, the subclass must have an implementation of the `jsonrpc-connection-send` method.

Likewise, for handling the three types of remote contacts (requests, notifications, and responses to local requests), the transport implementation must arrange for the function `jsonrpc-connection-receive` to be called after noticing a new JSONRPC message on the wire (whatever that “wire” may be).

Finally, and optionally, the `jsonrpc-connection` subclass should implement the `jsonrpc-shutdown` and `jsonrpc-running-p` methods if these concepts apply to the transport. If they do, then any system resources (e.g. processes, timers, etc.) used

to listen for messages on the wire should be released in `jsonrpc-shutdown`, i.e. they should only be needed while `jsonrpc-running-p` is non-nil.

33.32.2 Process-based JSONRPC connections

For convenience, the `jsonrpc` library comes with a built-in `jsonrpc-process-connection` transport implementation that can talk to local subprocesses (using the standard input and standard output); or TCP hosts (using sockets); or any other remote endpoint that Emacs's process object can represent (see Chapter 40 [Processes], page 1078).

Using this transport, the JSONRPC messages are encoded on the wire as plain text and prefaced by some basic HTTP-style enveloping headers, such as “Content-Length”.

For an example of an application using this transport scheme on top of JSONRPC, see the Language Server Protocol (<https://microsoft.github.io/language-server-protocol/specification>).

Along with the mandatory `:request-dispatcher` and `:notification-dispatcher` initargs, users of the `jsonrpc-process-connection` class should pass the following initargs as keyword-value pairs to `make-instance`:

`:process` Value must be a live process object or a function of no arguments producing one such object. If passed a process object, the object is expected to contain a pre-established connection; otherwise, the function is called immediately after the object is made.

`:on-shutdown`
 Value must be a function of a single argument, the `jsonrpc-process-connection` object. The function is called after the underlying process object has been deleted (either deliberately by `jsonrpc-shutdown`, or unexpectedly, because of some external cause).

33.32.3 JSONRPC JSON object format

JSONRPC JSON objects are exchanged as Lisp plists (see Section 5.9 [Property Lists], page 99): JSON-compatible plists are handed to the dispatcher functions and, likewise, JSON-compatible plists should be given to `jsonrpc-notify`, `jsonrpc-request`, and `jsonrpc-async-request`.

To facilitate handling plists, this library makes liberal use of `cl-lib` library (see *Common Lisp Extensions for GNU Emacs Lisp*) and suggests (but doesn't force) its clients to do the same. A macro `jsonrpc-lambda` can be used to create a lambda for destructuring a JSON-object like in this example:

```
(jsonrpc-async-request
  myproc :frobinate `(:foo "trix")
  :success-fn (jsonrpc-lambda (&key bar baz &allow-other-keys)
    (message "Server replied back with %s and %s!"
            bar baz))
  :error-fn (jsonrpc-lambda (&key code message _data)
    (message "Sadly, server reports %s: %s"
            code message)))
```

33.32.4 Deferred JSONRPC requests

In many RPC situations, synchronization between the two communicating endpoints is a matter of correctly designing the RPC application: when synchronization is needed, requests (which are blocking) should be used; when it isn't, notifications should suffice. However, when Emacs acts as one of these endpoints, asynchronous events (e.g. timer- or process-related) may be triggered while there is still uncertainty about the state of the remote endpoint. Furthermore, acting on these events may only sometimes demand synchronization, depending on the event's specific nature.

The `:deferred` keyword argument to `jsonrpc-request` and `jsonrpc-async-request` is designed to let the caller indicate that the specific request needs synchronization and its actual issuance may be delayed to the future, until some condition is satisfied. Specifying `:deferred` for a request doesn't mean it *will* be delayed, only that it *can* be. If the request isn't sent immediately, `jsonrpc` will make renewed efforts to send it at certain key times during communication, such as when receiving or sending other messages to the endpoint.

Before any attempt to send the request, the application-specific conditions are checked. Since the `jsonrpc` library can't know what these conditions are, the program can use the `jsonrpc-connection-ready-p` generic function (see Section 13.8 [Generic Functions], page 245) to specify them. The default method for this function returns `t`, but you can add overriding methods that return `nil` in some situations, based on the arguments passed to it, which are the `jsonrpc-connection` object (see Section 33.32.1 [JSONRPC Overview], page 956) and whichever value you passed as the `:deferred` keyword argument.

33.33 Atomic Change Groups

In database terminology, an *atomic* change is an indivisible change—it can succeed entirely or it can fail entirely, but it cannot partly succeed. A Lisp program can make a series of changes to one or several buffers as an *atomic change group*, meaning that either the entire series of changes will be installed in their buffers or, in case of an error, none of them will be.

To do this for one buffer, the one already current, simply write a call to `atomic-change-group` around the code that makes the changes, like this:

```
(atomic-change-group
  (insert foo)
  (delete-region x y))
```

If an error (or other nonlocal exit) occurs inside the body of `atomic-change-group`, it unmakes all the changes in that buffer that were during the execution of the body. This kind of change group has no effect on any other buffers—any such changes remain.

If you need something more sophisticated, such as to make changes in various buffers constitute one atomic group, you must directly call lower-level functions that `atomic-change-group` uses.

prepare-change-group &**optional buffer** [Function]

This function sets up a change group for buffer *buffer*, which defaults to the current buffer. It returns a handle that represents the change group. You must use this handle to activate the change group and subsequently to finish it.

To use the change group, you must *activate* it. You must do this before making any changes in the text of *buffer*.

activate-change-group *handle*

[Function]

This function activates the change group that *handle* designates.

After you activate the change group, any changes you make in that buffer become part of it. Once you have made all the desired changes in the buffer, you must *finish* the change group. There are two ways to do this: you can either accept (and finalize) all the changes, or cancel them all.

accept-change-group *handle*

[Function]

This function accepts all the changes in the change group specified by *handle*, making them final.

cancel-change-group *handle*

[Function]

This function cancels and undoes all the changes in the change group specified by *handle*.

You can cause some or all of the changes in a change group to be considered as a single unit for the purposes of the *undo* commands (see Section 33.9 [Undo], page 895) by using **undo-amalgamate-change-group**.

undo-amalgamate-change-group

[Function]

Amalgamate all the changes made in the change-group since the state identified by *handle*. This function removes all undo boundaries between undo records of changes since the state described by *handle*. Usually, *handle* is the handle returned by **prepare-change-group**, in which case all the changes since the beginning of the change-group are amalgamated into a single undo unit.

Your code should use **unwind-protect** to make sure the group is always finished. The call to **activate-change-group** should be inside the **unwind-protect**, in case the user types *C-g* just after it runs. (This is one reason why **prepare-change-group** and **activate-change-group** are separate functions, because normally you would call **prepare-change-group** before the start of that **unwind-protect**.) Once you finish the group, don't use the handle again—in particular, don't try to finish the same group twice.

To make a multibuffer change group, call **prepare-change-group** once for each buffer you want to cover, then use **nconc** to combine the returned values, like this:

```
(nconc (prepare-change-group buffer-1)
       (prepare-change-group buffer-2))
```

You can then activate the multibuffer change group with a single call to **activate-change-group**, and finish it with a single call to **accept-change-group** or **cancel-change-group**.

Nested use of several change groups for the same buffer works as you would expect. Non-nested use of change groups for the same buffer will get Emacs confused, so don't let it happen; the first change group you start for any given buffer should be the last one finished.

33.34 Change Hooks

These hook variables let you arrange to take notice of changes in buffers (or in a particular buffer, if you make them buffer-local). See also Section 33.19.4 [Special Properties], page 924, for how to detect changes to specific parts of the text.

The functions you use in these hooks should save and restore the match data if they do anything that uses regular expressions; otherwise, they will interfere in bizarre ways with the editing operations that call them.

`before-change-functions`

[Variable]

This variable holds a list of functions to call when Emacs is about to modify a buffer. Each function gets two arguments, the beginning and end of the region that is about to change, represented as integers. The buffer that is about to change is always the current buffer when the function is called.

`after-change-functions`

[Variable]

This variable holds a list of functions to call after Emacs modifies a buffer. Each function receives three arguments: the beginning and end of the region just changed, and the length of the text that existed before the change. All three arguments are integers. The buffer that has been changed is always the current buffer when the function is called.

The length of the old text is the difference between the buffer positions before and after that text as it was before the change. As for the changed text, its length is simply the difference between the first two arguments.

Output of messages into the `*Messages*` buffer does not call these functions, and neither do certain internal buffer changes, such as changes in buffers created by Emacs internally for certain jobs, that should not be visible to Lisp programs.

The vast majority of buffer changing primitives will call `before-change-functions` and `after-change-functions` in balanced pairs, once for each change, where the arguments to these hooks exactly delimit the change being made. Yet, hook functions should not rely on this always being the case, because some complex primitives call `before-change-functions` once before making changes, and then call `after-change-functions` zero or more times, depending on how many individual changes the primitive is making. When that happens, the arguments to `before-change-functions` will enclose a region in which the individual changes are made, but won't necessarily be the minimal such region, and the arguments to each successive call of `after-change-functions` will then delimit the part of text being changed exactly. In general, we advise using either the before- or the after-change hook, but not both.

`combine-after-change-calls body...`

[Macro]

The macro executes `body` normally, but arranges to call the after-change functions just once for a series of several changes—if that seems safe.

If a program makes several text changes in the same area of the buffer, using the macro `combine-after-change-calls` around that part of the program can make it run considerably faster when after-change hooks are in use. When the after-change hooks are ultimately called, the arguments specify a portion of the buffer including all of the changes made within the `combine-after-change-calls` body.

Warning: You must not alter the values of `after-change-functions` within the body of a `combine-after-change-calls` form.

Warning: If the changes you combine occur in widely scattered parts of the buffer, this will still work, but it is not advisable, because it may lead to inefficient behavior for some change hook functions.

`combine-change-calls` *beg end body...* [Macro]

This executes *body* normally, except any buffer changes it makes do not trigger the calls to `before-change-functions` and `after-change-functions`. Instead there is a single call of each of these hooks for the region enclosed by *beg* and *end*, the parameters supplied to `after-change-functions` reflecting the changes made to the size of the region by *body*.

The result of this macro is the result returned by *body*.

This macro is useful when a function makes a possibly large number of repetitive changes to the buffer, and the change hooks would otherwise take a long time to run, were they to be run for each individual buffer modification. Emacs itself uses this macro, for example, in the commands `comment-region` and `uncomment-region`.

Warning: You must not alter the values of `before-change-functions` or `after-change-function` within *body*.

Warning: You must not make any buffer changes outside of the region specified by *beg* and *end*.

`first-change-hook` [Variable]

This variable is a normal hook that is run whenever a buffer is changed that was previously in the unmodified state.

`inhibit-modification-hooks` [Variable]

If this variable is `non-nil`, all of the change hooks are disabled; none of them run. This affects all the hook variables described above in this section, as well as the hooks attached to certain special text properties (see Section 33.19.4 [Special Properties], page 924) and overlay properties (see Section 41.9.2 [Overlay Properties], page 1153). Also, this variable is bound to `non-nil` while running those same hook variables, so that by default modifying the buffer from a modification hook does not cause other modification hooks to be run. If you do want modification hooks to be run in a particular piece of code that is itself run from a modification hook, then rebinding locally `inhibit-modification-hooks` to `nil`. However, doing this may cause recursive calls to the modification hooks, so be sure to prepare for that (for example, by binding some variable which tells your hook to do nothing).

We recommend that you only bind this variable for modifications that do not result in lasting changes to buffer text contents (for example face changes or temporary modifications). If you need to delay change hooks during a series of changes (typically for performance reasons), use `combine-change-calls` or `combine-after-change-calls` instead.

34 Non-ASCII Characters

This chapter covers the special issues relating to characters and how they are stored in strings and buffers.

34.1 Text Representations

Emacs buffers and strings support a large repertoire of characters from many different scripts, allowing users to type and display text in almost any known written language.

To support this multitude of characters and scripts, Emacs closely follows the *Unicode Standard*. The Unicode Standard assigns a unique number, called a *codepoint*, to each and every character. The range of codepoints defined by Unicode, or the Unicode *codespace*, is 0..#x10FFFF (in hexadecimal notation), inclusive. Emacs extends this range with codepoints in the range #x110000..#x3FFFFFF, which it uses for representing characters that are not unified with Unicode and raw 8-bit bytes that cannot be interpreted as characters. Thus, a character codepoint in Emacs is a 22-bit integer.

To conserve memory, Emacs does not hold fixed-length 22-bit numbers that are codepoints of text characters within buffers and strings. Rather, Emacs uses a variable-length internal representation of characters, that stores each character as a sequence of 1 to 5 8-bit bytes, depending on the magnitude of its codepoint¹. For example, any ASCII character takes up only 1 byte, a Latin-1 character takes up 2 bytes, etc. We call this representation of text *multibyte*.

Outside Emacs, characters can be represented in many different encodings, such as ISO-8859-1, GB-2312, Big-5, etc. Emacs converts between these external encodings and its internal representation, as appropriate, when it reads text into a buffer or a string, or when it writes text to a disk file or passes it to some other process.

Occasionally, Emacs needs to hold and manipulate encoded text or binary non-text data in its buffers or strings. For example, when Emacs visits a file, it first reads the file's text verbatim into a buffer, and only then converts it to the internal representation. Before the conversion, the buffer holds encoded text.

Encoded text is not really text, as far as Emacs is concerned, but rather a sequence of raw 8-bit bytes. We call buffers and strings that hold encoded text *unibyte* buffers and strings, because Emacs treats them as a sequence of individual bytes. Usually, Emacs displays unibyte buffers and strings as octal codes such as \237. We recommend that you never use unibyte buffers and strings except for manipulating encoded text or binary non-text data.

In a buffer, the buffer-local value of the variable `enable-multibyte-characters` specifies the representation used. The representation for a string is determined and recorded in the string when the string is constructed.

`enable-multibyte-characters` [Variable]

This variable specifies the current buffer's text representation. If it is `non-nil`, the buffer contains multibyte text; otherwise, it contains unibyte encoded text or binary non-text data.

¹ This internal representation is based on one of the encodings defined by the Unicode Standard, called *UTF-8*, for representing any Unicode codepoint, but Emacs extends UTF-8 to represent the additional codepoints it uses for raw 8-bit bytes and characters not unified with Unicode.

You cannot set this variable directly; instead, use the function `set-buffer-multibyte` to change a buffer's representation.

position-bytes *position*

[Function]

Buffer positions are measured in character units. This function returns the byte-position corresponding to buffer position *position* in the current buffer. This is 1 at the start of the buffer, and counts upward in bytes. If *position* is out of range, the value is `nil`.

byte-to-position *byte-position*

[Function]

Return the buffer position, in character units, corresponding to given *byte-position* in the current buffer. If *byte-position* is out of range, the value is `nil`. In a multibyte buffer, an arbitrary value of *byte-position* can be not at character boundary, but inside a multibyte sequence representing a single character; in this case, this function returns the buffer position of the character whose multibyte sequence includes *byte-position*. In other words, the value does not change for all byte positions that belong to the same character.

The following two functions are useful when a Lisp program needs to map buffer positions to byte offsets in a file visited by the buffer.

bufferpos-to-filepos *position* &**optional** *quality* *coding-system*

[Function]

This function is similar to `position-bytes`, but instead of byte position in the current buffer it returns the offset from the beginning of the current buffer's file of the byte that corresponds to the given character *position* in the buffer. The conversion requires to know how the text is encoded in the buffer's file; this is what the *coding-system* argument is for, defaulting to the value of `buffer-file-coding-system`. The optional argument *quality* specifies how accurate the result should be; it should be one of the following:

exact The result must be accurate. The function may need to encode and decode a large part of the buffer, which is expensive and can be slow.

approximate

The value can be an approximation. The function may avoid expensive processing and return an inexact result.

nil

If the exact result needs expensive processing, the function will return `nil` rather than an approximation. This is the default if the argument is omitted.

filepos-to-bufferpos *byte* &**optional** *quality* *coding-system*

[Function]

This function returns the buffer position corresponding to a file position specified by *byte*, a zero-base byte offset from the file's beginning. The function performs the conversion opposite to what `bufferpos-to-filepos` does. Optional arguments *quality* and *coding-system* have the same meaning and values as for `bufferpos-to-filepos`.

multibyte-string-p *string*

[Function]

Return `t` if *string* is a multibyte string, `nil` otherwise. This function also returns `nil` if *string* is some object other than a string.

string-bytes *string* [Function]

This function returns the number of bytes in *string*. If *string* is a multibyte string, this can be greater than (`length string`).

unibyte-string &*rest* *bytes* [Function]

This function concatenates all its argument *bytes* and makes the result a unibyte string.

34.2 Disabling Multibyte Characters

By default, Emacs starts in multibyte mode: it stores the contents of buffers and strings using an internal encoding that represents non-ASCII characters using multi-byte sequences. Multibyte mode allows you to use all the supported languages and scripts without limitations.

Under very special circumstances, you may want to disable multibyte character support, for a specific buffer. When multibyte characters are disabled in a buffer, we call that *unibyte mode*. In unibyte mode, each character in the buffer has a character code ranging from 0 through 255 (0377 octal); 0 through 127 (0177 octal) represent ASCII characters, and 128 (0200 octal) through 255 (0377 octal) represent non-ASCII characters.

To edit a particular file in unibyte representation, visit it using `find-file-literally`. See Section 26.1.1 [Visiting Functions], page 608. You can convert a multibyte buffer to unibyte by saving it to a file, killing the buffer, and visiting the file again with `find-file-literally`. Alternatively, you can use `C-x RET c` (`universal-coding-system-argument`) and specify ‘`raw-text`’ as the coding system with which to visit or save a file. See Section “Specifying a Coding System for File Text” in *GNU Emacs Manual*. Unlike `find-file-literally`, finding a file as ‘`raw-text`’ doesn’t disable format conversion, uncompression, or auto mode selection.

The buffer-local variable `enable-multibyte-characters` is `non-nil` in multibyte buffers, and `nil` in unibyte ones. The mode line also indicates whether a buffer is multibyte or not. With a graphical display, in a multibyte buffer, the portion of the mode line that indicates the character set has a tooltip that (amongst other things) says that the buffer is multibyte. In a unibyte buffer, the character set indicator is absent. Thus, in a unibyte buffer (when using a graphical display) there is normally nothing before the indication of the visited file’s end-of-line convention (colon, backslash, etc.), unless you are using an input method.

You can turn off multibyte support in a specific buffer by invoking the command `toggle-enable-multibyte-characters` in that buffer.

34.3 Converting Text Representations

Emacs can convert unibyte text to multibyte; it can also convert multibyte text to unibyte, provided that the multibyte text contains only ASCII and 8-bit raw bytes. In general, these conversions happen when inserting text into a buffer, or when putting text from several strings together in one string. You can also explicitly convert a string’s contents to either representation.

Emacs chooses the representation for a string based on the text from which it is constructed. The general rule is to convert unibyte text to multibyte text when combining it with other multibyte text, because the multibyte representation is more general and can hold whatever characters the unibyte text has.

When inserting text into a buffer, Emacs converts the text to the buffer's representation, as specified by `enable-multibyte-characters` in that buffer. In particular, when you insert multibyte text into a unibyte buffer, Emacs converts the text to unibyte, even though this conversion cannot in general preserve all the characters that might be in the multibyte text. The other natural alternative, to convert the buffer contents to multibyte, is not acceptable because the buffer's representation is a choice made by the user that cannot be overridden automatically.

Converting unibyte text to multibyte text leaves ASCII characters unchanged, and converts bytes with codes 128 through 255 to the multibyte representation of raw eight-bit bytes.

Converting multibyte text to unibyte converts all ASCII and eight-bit characters to their single-byte form, but loses information for non-ASCII characters by discarding all but the low 8 bits of each character's codepoint. Converting unibyte text to multibyte and back to unibyte reproduces the original unibyte text.

The next two functions either return the argument *string*, or a newly created string with no text properties.

string-to-multibyte *string*

[Function]

This function returns a multibyte string containing the same sequence of characters as *string*. If *string* is a multibyte string, it is returned unchanged. The function assumes that *string* includes only ASCII characters and raw 8-bit bytes; the latter are converted to their multibyte representation corresponding to the codepoints `#x3FFF80` through `#x3FFFFF`, inclusive (see Section 34.1 [Text Representations], page 963).

string-to-unibyte *string*

[Function]

This function returns a unibyte string containing the same sequence of characters as *string*. If *string* is a unibyte string, it is returned unchanged. Otherwise, ASCII characters and characters in the `eight-bit` charset are converted to their corresponding byte values. Use this function for *string* arguments that contain only ASCII and eight-bit characters; the function signals an error if any other characters are encountered.

byte-to-string *byte*

[Function]

This function returns a unibyte string containing a single byte of character data, *byte*. It signals an error if *byte* is not an integer between 0 and 255.

multibyte-char-to-unibyte *char*

[Function]

This converts the multibyte character *char* to a unibyte character, and returns that character. If *char* is neither ASCII nor eight-bit, the function returns `-1`.

unibyte-char-to-multibyte *char*

[Function]

This converts the unibyte character *char* to a multibyte character, assuming *char* is either ASCII or raw 8-bit byte.

34.4 Selecting a Representation

Sometimes it is useful to examine an existing buffer or string as multibyte when it was unibyte, or vice versa.

set-buffer-multibyte *multibyte* [Function]

Set the representation type of the current buffer. If *multibyte* is non-*nil*, the buffer becomes multibyte. If *multibyte* is *nil*, the buffer becomes unibyte.

This function leaves the buffer contents unchanged when viewed as a sequence of bytes. As a consequence, it can change the contents viewed as characters; for instance, a sequence of three bytes which is treated as one character in multibyte representation will count as three characters in unibyte representation. Eight-bit characters representing raw bytes are an exception. They are represented by one byte in a unibyte buffer, but when the buffer is set to multibyte, they are converted to two-byte sequences, and vice versa.

This function sets `enable-multibyte-characters` to record which representation is in use. It also adjusts various data in the buffer (including overlays, text properties and markers) so that they cover the same text as they did before.

This function signals an error if the buffer is narrowed, since the narrowing might have occurred in the middle of multibyte character sequences.

This function also signals an error if the buffer is an indirect buffer. An indirect buffer always inherits the representation of its base buffer.

string-as-unibyte *string* [Function]

If *string* is already a unibyte string, this function returns *string* itself. Otherwise, it returns a new string with the same bytes as *string*, but treating each byte as a separate character (so that the value may have more characters than *string*); as an exception, each eight-bit character representing a raw byte is converted into a single byte. The newly-created string contains no text properties.

string-as-multibyte *string* [Function]

If *string* is a multibyte string, this function returns *string* itself. Otherwise, it returns a new string with the same bytes as *string*, but treating each multibyte sequence as one character. This means that the value may have fewer characters than *string* has. If a byte sequence in *string* is invalid as a multibyte representation of a single character, each byte in the sequence is treated as a raw 8-bit byte. The newly-created string contains no text properties.

34.5 Character Codes

The unibyte and multibyte text representations use different character codes. The valid character codes for unibyte representation range from 0 to #xFF (255)—the values that can fit in one byte. The valid character codes for multibyte representation range from 0 to #xFFFFFFF. In this code space, values 0 through #x7F (127) are for ASCII characters, and values #x80 (128) through #x3FFF7F (4194175) are for non-ASCII characters.

Emacs character codes are a superset of the Unicode standard. Values 0 through #x10FFFF (1114111) correspond to Unicode characters of the same codepoint; values #x110000 (1114112) through #x3FFF7F (4194175) represent characters that are not unified with Unicode; and values #x3FFF80 (4194176) through #x3FFFFF (4194303) represent eight-bit raw bytes.

characterp charcode

[Function]

This returns `t` if `charcode` is a valid character, and `nil` otherwise.

```
(characterp 65)
⇒ t
(characterp 4194303)
⇒ t
(characterp 4194304)
⇒ nil
```

max-char &optional unicode

[Function]

This function returns the largest value that a valid character codepoint can have in Emacs. If the optional argument `unicode` is non-`nil`, it returns the largest character codepoint defined by the Unicode Standard (which is smaller than the maximum codepoint supported by Emacs).

```
(characterp (max-char))
⇒ t
(characterp (1+ (max-char)))
⇒ nil
```

char-from-name string &optional ignore-case

[Function]

This function returns the character whose Unicode name is `string`. If `ignore-case` is non-`nil`, case is ignored in `string`. This function returns `nil` if `string` does not name a character.

```
; ; U+03A3
(= (char-from-name "GREEK CAPITAL LETTER SIGMA") #x03A3)
⇒ t
```

get-byte &optional pos string

[Function]

This function returns the byte at character position `pos` in the current buffer. If the current buffer is unibyte, this is literally the byte at that position. If the buffer is multibyte, byte values of ASCII characters are the same as character codepoints, whereas eight-bit raw bytes are converted to their 8-bit codes. The function signals an error if the character at `pos` is non-ASCII.

The optional argument `string` means to get a byte value from that string instead of the current buffer.

34.6 Character Properties

A *character property* is a named attribute of a character that specifies how the character behaves and how it should be handled during text processing and display. Thus, character properties are an important part of specifying the character's semantics.

On the whole, Emacs follows the Unicode Standard in its implementation of character properties. In particular, Emacs supports the Unicode Character Property Model (<https://www.unicode.org/reports/tr23/>), and the Emacs character property database is derived from the Unicode Character Database (UCD). See the Character Properties chapter of the Unicode Standard (<https://www.unicode.org/versions/Unicode15.0.0/ch04.pdf>), for a detailed description of Unicode character properties and their meaning. This section

assumes you are already familiar with that chapter of the Unicode Standard, and want to apply that knowledge to Emacs Lisp programs.

In Emacs, each property has a name, which is a symbol, and a set of possible values, whose types depend on the property; if a character does not have a certain property, the value is `nil`. As a general rule, the names of character properties in Emacs are produced from the corresponding Unicode properties by downcasing them and replacing each ‘`_`’ character with a dash ‘`-`’. For example, `Canonical_Combining_Class` becomes `canonical-combining-class`. However, sometimes we shorten the names to make their use easier.

Some codepoints are left *unassigned* by the UCD—they don’t correspond to any character. The Unicode Standard defines default values of properties for such codepoints; they are mentioned below for each property.

Here is the full list of value types for all the character properties that Emacs knows about:

name Corresponds to the `Name` Unicode property. The value is a string consisting of upper-case Latin letters A to Z, digits, spaces, and hyphen ‘`-`’ characters. For unassigned codepoints, the value is `nil`.

general-category

Corresponds to the `General_Category` Unicode property. The value is a symbol whose name is a 2-letter abbreviation of the character’s classification. For unassigned codepoints, the value is `Cn`.

canonical-combining-class

Corresponds to the `Canonical_Combining_Class` Unicode property. The value is an integer. For unassigned codepoints, the value is zero.

bidi-class

Corresponds to the Unicode `Bidi_Class` property. The value is a symbol whose name is the Unicode *directional type* of the character. Emacs uses this property when it reorders bidirectional text for display (see Section 41.27 [Bidirectional Display], page 1250). For unassigned codepoints, the value depends on the code blocks to which the codepoint belongs: most unassigned codepoints get the value of `L` (strong L), but some get values of `AL` (Arabic letter) or `R` (strong R).

decomposition

Corresponds to the Unicode properties `Decomposition_Type` and `Decomposition_Value`. The value is a list, whose first element may be a symbol representing a compatibility formatting tag, such as `small`²; the other elements are characters that give the compatibility decomposition sequence of this character. For characters that don’t have decomposition sequences, and for unassigned codepoints, the value is a list with a single member, the character itself.

decimal-digit-value

Corresponds to the Unicode `Numeric_Value` property for characters whose `Numeric_Type` is ‘Decimal’. The value is an integer, or `nil` if the character

² The Unicode specification writes these tag names inside ‘`<...>`’ brackets, but the tag names in Emacs do not include the brackets; e.g., Unicode specifies ‘`<small>`’ where Emacs uses ‘`small`’.

has no decimal digit value. For unassigned codepoints, the value is `nil`, which means NaN, or “not a number”.

digit-value

Corresponds to the Unicode `Numeric_Value` property for characters whose `Numeric_Type` is ‘Digit’. The value is an integer. Examples of such characters include compatibility subscript and superscript digits, for which the value is the corresponding number. For characters that don’t have any numeric value, and for unassigned codepoints, the value is `nil`, which means NaN.

numeric-value

Corresponds to the Unicode `Numeric_Value` property for characters whose `Numeric_Type` is ‘Numeric’. The value of this property is a number. Examples of characters that have this property include fractions, subscripts, superscripts, Roman numerals, currency numerators, and encircled numbers. For example, the value of this property for the character U+2155 VULGAR FRACTION ONE FIFTH is 0.2. For characters that don’t have any numeric value, and for unassigned codepoints, the value is `nil`, which means NaN.

mirrored Corresponds to the Unicode `Bidi_Mirrored` property. The value of this property is a symbol, either `Y` or `N`. For unassigned codepoints, the value is `N`.

mirroring

Corresponds to the Unicode `Bidi_Mirroring_Glyph` property. The value of this property is a character whose glyph represents the mirror image of the character’s glyph, or `nil` if there’s no defined mirroring glyph. All the characters whose `mirrored` property is `N` have `nil` as their `mirroring` property; however, some characters whose `mirrored` property is `Y` also have `nil` for `mirroring`, because no appropriate characters exist with mirrored glyphs. Emacs uses this property to display mirror images of characters when appropriate (see Section 41.27 [Bidirectional Display], page 1250). For unassigned codepoints, the value is `nil`.

paired-bracket

Corresponds to the Unicode `Bidi_Paired_Bracket` property. The value of this property is the codepoint of a character’s paired bracket, or `nil` if the character is not a bracket character. This establishes a mapping between characters that are treated as bracket pairs by the Unicode Bidirectional Algorithm; Emacs uses this property when it decides how to reorder for display parentheses, braces, and other similar characters (see Section 41.27 [Bidirectional Display], page 1250).

bracket-type

Corresponds to the Unicode `Bidi_Paired_Bracket_Type` property. For characters whose `paired-bracket` property is non-`nil`, the value of this property is a symbol, either `o` (for opening bracket characters) or `c` (for closing bracket characters). For characters whose `paired-bracket` property is `nil`, the value is the symbol `n` (None). Like `paired-bracket`, this property is used for bidirectional display.

old-name Corresponds to the Unicode `Unicode_1_Name` property. The value is a string. For unassigned codepoints, and characters that have no value for this property, the value is `nil`.

iso-10646-comment

Corresponds to the Unicode `ISO_Comment` property. The value is either a string or `nil`. For unassigned codepoints, the value is `nil`.

uppercase

Corresponds to the Unicode `Simple_Uppercase_Mapping` property. The value of this property is a single character. For unassigned codepoints, the value is `nil`, which means the character itself.

lowercase

Corresponds to the Unicode `Simple_Lowercase_Mapping` property. The value of this property is a single character. For unassigned codepoints, the value is `nil`, which means the character itself.

titlecase

Corresponds to the Unicode `Simple_Titlecase_Mapping` property. *Title case* is a special form of a character used when the first character of a word needs to be capitalized. The value of this property is a single character. For unassigned codepoints, the value is `nil`, which means the character itself.

special-uppercase

Corresponds to Unicode language- and context-independent special upper-casing rules. The value of this property is a string (which may be empty). For example mapping for U+00DF LATIN SMALL LETTER SHARP S is "SS". For characters with no special mapping, the value is `nil` which means `uppercase` property needs to be consulted instead.

special-lowercase

Corresponds to Unicode language- and context-independent special lower-casing rules. The value of this property is a string (which may be empty). For example mapping for U+0130 LATIN CAPITAL LETTER I WITH DOT ABOVE the value is "i\u0307" (i.e. 2-character string consisting of LATIN SMALL LETTER I followed by U+0307 COMBINING DOT ABOVE). For characters with no special mapping, the value is `nil` which means `lowercase` property needs to be consulted instead.

special-titlecase

Corresponds to Unicode unconditional special title-casing rules. The value of this property is a string (which may be empty). For example mapping for U+FB01 LATIN SMALL LIGATURE FI the value is "Fi". For characters with no special mapping, the value is `nil` which means `titlecase` property needs to be consulted instead.

get-char-code-property *char propname*

[Function]

This function returns the value of *char*'s *propname* property.

```
(get-char-code-property ?\s 'general-category)
⇒ Zs
(get-char-code-property ?1 'general-category)
⇒ Nd
```

```

;; U+2084
(get-char-code-property ?\N{SUBSCRIPT FOUR}
                       'digit-value)
⇒ 4
;; U+2155
(get-char-code-property ?\N{VULGAR FRACTION ONE FIFTH}
                       'numeric-value)
⇒ 0.2
;; U+2163
(get-char-code-property ?\N{ROMAN NUMERAL FOUR}
                       'numeric-value)
⇒ 4
(get-char-code-property ?\\( 'paired-bracket)
⇒ 41 ; closing parenthesis
(get-char-code-property ?\\) 'bracket-type)
⇒ c

```

char-code-property-description *prop value* [Function]

This function returns the description string of property *prop*'s *value*, or *nil* if *value* has no description.

```

(char-code-property-description 'general-category 'Zs)
⇒ "Separator, Space"
(char-code-property-description 'general-category 'Nd)
⇒ "Number, Decimal Digit"
(char-code-property-description 'numeric-value '1/5)
⇒ nil

```

put-char-code-property *char propname value* [Function]

This function stores *value* as the value of the property *propname* for the character *char*.

unicode-category-table [Variable]

The value of this variable is a char-table (see Section 6.6 [Char-Tables], page 119) that specifies, for each character, its Unicode **General_Category** property as a symbol.

char-script-table [Variable]

The value of this variable is a char-table that specifies, for each character, a symbol whose name is the script to which the character belongs, according to the Unicode Standard classification of the Unicode code space into script-specific blocks. This char-table has a single extra slot whose value is the list of all script symbols. Note that Emacs' classification of characters into scripts is not a 1-for-1 reflection of the Unicode standard, e.g. there is no 'symbol' script in Unicode.

char-width-table [Variable]

The value of this variable is a char-table that specifies the width of each character in columns that it will occupy on the screen.

printable-chars [Variable]

The value of this variable is a char-table that specifies, for each character, whether it is printable or not. That is, if evaluating (`aref printable-chars char`) results in `t`, the character is printable, and if it results in `nil`, it is not.

34.7 Character Sets

An Emacs *character set*, or *charset*, is a set of characters in which each character is assigned a numeric code point. (The Unicode Standard calls this a *coded character set*.) Each Emacs charset has a name which is a symbol. A single character can belong to any number of different character sets, but it will generally have a different code point in each charset. Examples of character sets include `ascii`, `iso-8859-1`, `greek-iso8859-7`, and `windows-1255`. The code point assigned to a character in a charset is usually different from its code point used in Emacs buffers and strings.

Emacs defines several special character sets. The character set `unicode` includes all the characters whose Emacs code points are in the range `0..#x10FFFF`. The character set `emacs` includes all ASCII and non-ASCII characters. Finally, the `eight-bit` charset includes the 8-bit raw bytes; Emacs uses it to represent raw bytes encountered in text.

charsetp object [Function]

Returns `t` if *object* is a symbol that names a character set, `nil` otherwise.

charset-list [Variable]

The value is a list of all defined character set names.

charset-priority-list &optional highestp [Function]

This function returns a list of all defined character sets ordered by their priority. If *highestp* is non-`nil`, the function returns a single character set of the highest priority.

set-charset-priority &rest charsets [Function]

This function makes *charsets* the highest priority character sets.

char-charset character &optional restriction [Function]

This function returns the name of the character set of highest priority that *character* belongs to. ASCII characters are an exception: for them, this function always returns `ascii`.

If *restriction* is non-`nil`, it should be a list of charsets to search. Alternatively, it can be a coding system, in which case the returned charset must be supported by that coding system (see Section 34.10 [Coding Systems], page 976).

charset-plist charset [Function]

This function returns the property list of the character set *charset*. Although *charset* is a symbol, this is not the same as the property list of that symbol. Charset properties include important information about the charset, such as its documentation string, short name, etc.

put-charset-property charset propname value [Function]

This function sets the *propname* property of *charset* to the given *value*.

get-charset-property *charset propname* [Function]

This function returns the value of *charsets* property *propname*.

list-charset-chars *charset* [Command]

This command displays a list of characters in the character set *charset*.

Emacs can convert between its internal representation of a character and the character's codepoint in a specific charset. The following two functions support these conversions.

decode-char *charset code-point* [Function]

This function decodes a character that is assigned a *code-point* in *charset*, to the corresponding Emacs character, and returns it. If *charset* doesn't contain a character of that code point, the value is `nil`.

For backward compatibility, if *code-point* doesn't fit in a Lisp fixnum (see Section 3.1 [Integer Basics], page 38), it can be specified as a cons cell (*high . low*), where *low* are the lower 16 bits of the value and *high* are the high 16 bits. This usage is obsolescent.

encode-char *char charset* [Function]

This function returns the code point assigned to the character *char* in *charset*. If *charset* doesn't have a codepoint for *char*, the value is `nil`.

The following function comes in handy for applying a certain function to all or part of the characters in a charset:

map-charset-chars *function charset &optional arg from-code to-code* [Function]

Call *function* for characters in *charset*. *function* is called with two arguments. The first one is a cons cell (*from . to*), where *from* and *to* indicate a range of characters contained in *charset*. The second argument passed to *function* is *arg*, or `nil` if *arg* is omitted.

By default, the range of codepoints passed to *function* includes all the characters in *charset*, but optional arguments *from-code* and *to-code* limit that to the range of characters between these two codepoints of *charset*. If either of them is `nil`, it defaults to the first or last codepoint of *charset*, respectively. Note that *from-code* and *to-code* are *charset*'s codepoints, not the Emacs codes of characters; by contrast, the values *from* and *to* in the cons cell passed to *function* are Emacs character codes. Those Emacs character codes are either Unicode code points, or Emacs internal code points that extend Unicode and are beyond the Unicode range of characters `0..#xFFFF` (see Section 34.1 [Text Representations], page 963). The latter happens rarely, with legacy CJK charsets for codepoints of *charset* which specify characters not yet unified with Unicode.

34.8 Scanning for Character Sets

Sometimes it is useful to find out which character set a particular character belongs to. One use for this is in determining which coding systems (see Section 34.10 [Coding Systems], page 976) are capable of representing all of the text in question; another is to determine the font(s) for displaying that text.

charset-after &optional pos [Function]

This function returns the charset of highest priority containing the character at position *pos* in the current buffer. If *pos* is omitted or `nil`, it defaults to the current value of point. If *pos* is out of range, the value is `nil`.

find-charset-region beg end &optional translation [Function]

This function returns a list of the character sets of highest priority that contain characters in the current buffer between positions *beg* and *end*.

The optional argument *translation* specifies a translation table to use for scanning the text (see Section 34.9 [Translation of Characters], page 975). If it is non-`nil`, then each character in the region is translated through this table, and the value returned describes the translated characters instead of the characters actually in the buffer.

find-charset-string string &optional translation [Function]

This function returns a list of character sets of highest priority that contain characters in *string*. It is just like `find-charset-region`, except that it applies to the contents of *string* instead of part of the current buffer.

34.9 Translation of Characters

A *translation table* is a char-table (see Section 6.6 [Char-Tables], page 119) that specifies a mapping of characters into characters. These tables are used in encoding and decoding, and for other purposes. Some coding systems specify their own particular translation tables; there are also default translation tables which apply to all other coding systems.

A translation table has two extra slots. The first is either `nil` or a translation table that performs the reverse translation; the second is the maximum number of characters to look up for translating sequences of characters (see the description of `make-translation-table-from-alist` below).

make-translation-table &rest translations [Function]

This function returns a translation table based on the argument *translations*. Each element of *translations* should be a list of elements of the form (*from* . *to*); this says to translate the character *from* into *to*.

The arguments and the forms in each argument are processed in order, and if a previous form already translates *to* to some other character, say *to-alt*, *from* is also translated to *to-alt*.

During decoding, the translation table's translations are applied to the characters that result from ordinary decoding. If a coding system has the property `:decode-translation-table`, that specifies the translation table to use, or a list of translation tables to apply in sequence. (This is a property of the coding system, as returned by `coding-system-get`, not a property of the symbol that is the coding system's name. See Section 34.10.1 [Basic Concepts of Coding Systems], page 977.) Finally, if `standard-translation-table-for-decode` is non-`nil`, the resulting characters are translated by that table.

During encoding, the translation table's translations are applied to the characters in the buffer, and the result of translation is actually encoded. If a coding system has property `:encode-translation-table`, that specifies the translation table to use, or a list of

translation tables to apply in sequence. In addition, if the variable `standard-translation-table-for-encode` is non-`nil`, it specifies the translation table to use for translating the result.

standard-translation-table-for-decode [Variable]

This is the default translation table for decoding. If a coding system specifies its own translation tables, the table that is the value of this variable, if non-`nil`, is applied after them.

standard-translation-table-for-encode [Variable]

This is the default translation table for encoding. If a coding system specifies its own translation tables, the table that is the value of this variable, if non-`nil`, is applied after them.

translation-table-for-input [Variable]

Self-inserting characters are translated through this translation table before they are inserted. Search commands also translate their input through this table, so they can compare more reliably with what's in the buffer.

This variable automatically becomes buffer-local when set.

make-translation-table-from-vector `vec` [Function]

This function returns a translation table made from `vec` that is an array of 256 elements to map bytes (values 0 through #xFF) to characters. Elements may be `nil` for untranslated bytes. The returned table has a translation table for reverse mapping in the first extra slot, and the value `1` in the second extra slot.

This function provides an easy way to make a private coding system that maps each byte to a specific character. You can specify the returned table and the reverse translation table using the properties `:decode-translation-table` and `:encode-translation-table` respectively in the `props` argument to `define-coding-system`.

make-translation-table-from-alist `alist` [Function]

This function is similar to `make-translation-table` but returns a complex translation table rather than a simple one-to-one mapping. Each element of `alist` is of the form (`from . to`), where `from` and `to` are either characters or vectors specifying a sequence of characters. If `from` is a character, that character is translated to `to` (i.e., to a character or a character sequence). If `from` is a vector of characters, that sequence is translated to `to`. The returned table has a translation table for reverse mapping in the first extra slot, and the maximum length of all the `from` character sequences in the second extra slot.

34.10 Coding Systems

When Emacs reads or writes a file, and when Emacs sends text to a subprocess or receives text from a subprocess, it normally performs character code conversion and end-of-line conversion as specified by a particular *coding system*.

How to define a coding system is an arcane matter, and is not documented here.

34.10.1 Basic Concepts of Coding Systems

Character code conversion involves conversion between the internal representation of characters used inside Emacs and some other encoding. Emacs supports many different encodings, in that it can convert to and from them. For example, it can convert text to or from encodings such as Latin 1, Latin 2, Latin 3, Latin 4, Latin 5, and several variants of ISO 2022. In some cases, Emacs supports several alternative encodings for the same characters; for example, there are three coding systems for the Cyrillic (Russian) alphabet: ISO, Alternativnyj, and KOI8.

Every coding system specifies a particular set of character code conversions, but the coding system `undecided` is special: it leaves the choice unspecified, to be chosen heuristically for each file or string, based on the file's or string's data, when they are decoded or encoded. The coding system `prefer-utf-8` is like `undecided`, but it prefers to choose `utf-8` when possible.

In general, a coding system doesn't guarantee roundtrip identity: decoding a byte sequence using a coding system, then encoding the resulting text in the same coding system, can produce a different byte sequence. But some coding systems do guarantee that the byte sequence will be the same as what you originally decoded. Here are a few examples:

`iso-8859-1`, `utf-8`, `big5`, `shift_jis`, `euc-jp`

Encoding buffer text and then decoding the result can also fail to reproduce the original text. For instance, if you encode a character with a coding system which does not support that character, the result is unpredictable, and thus decoding it using the same coding system may produce a different text. Currently, Emacs can't report errors that result from encoding unsupported characters.

End of line conversion handles three different conventions used on various systems for representing end of line in files. The Unix convention, used on GNU and Unix systems, is to use the linefeed character (also called newline). The DOS convention, used on MS-Windows and MS-DOS systems, is to use a carriage return and a linefeed at the end of a line. The Mac convention is to use just carriage return. (This was the convention used in Classic Mac OS.)

Base coding systems such as `latin-1` leave the end-of-line conversion unspecified, to be chosen based on the data. *Variant coding systems* such as `latin-1-unix`, `latin-1-dos` and `latin-1-mac` specify the end-of-line conversion explicitly as well. Most base coding systems have three corresponding variants whose names are formed by adding '`-unix`', '`-dos`' and '`-mac`'.

The coding system `raw-text` is special in that it prevents character code conversion, and causes the buffer visited with this coding system to be a unibyte buffer. For historical reasons, you can save both unibyte and multibyte text with this coding system. When you use `raw-text` to encode multibyte text, it does perform one character code conversion: it converts eight-bit characters to their single-byte external representation. `raw-text` does not specify the end-of-line conversion, allowing that to be determined as usual by the data, and has the usual three variants which specify the end-of-line conversion.

`no-conversion` (and its alias `binary`) is equivalent to `raw-text-unix`: it specifies no conversion of either character codes or end-of-line.

The coding system `utf-8-emacs` specifies that the data is represented in the internal Emacs encoding (see Section 34.1 [Text Representations], page 963). This is like `raw-text` in

that no code conversion happens, but different in that the result is multibyte data. The name `emacs-internal` is an alias for `utf-8-emacs-unix` (so it forces no conversion of end-of-line, unlike `utf-8-emacs`, which can decode all 3 kinds of end-of-line conventions).

coding-system-get coding-system property [Function]

This function returns the specified property of the coding system `coding-system`. Most coding system properties exist for internal purposes, but one that you might find useful is `:mime-charset`. That property's value is the name used in MIME for the character coding which this coding system can read and write. Examples:

```
(coding-system-get 'iso-latin-1 :mime-charset)
⇒ iso-8859-1
(coding-system-get 'iso-2022-cn :mime-charset)
⇒ iso-2022-cn
(coding-system-get 'cyrillic-koi8 :mime-charset)
⇒ koi8-r
```

The value of the `:mime-charset` property is also defined as an alias for the coding system.

coding-system-aliases coding-system [Function]

This function returns the list of aliases of `coding-system`.

34.10.2 Encoding and I/O

The principal purpose of coding systems is for use in reading and writing files. The function `insert-file-contents` uses a coding system to decode the file data, and `write-region` uses one to encode the buffer contents.

You can specify the coding system to use either explicitly (see Section 34.10.6 [Specifying Coding Systems], page 986), or implicitly using a default mechanism (see Section 34.10.5 [Default Coding Systems], page 983). But these methods may not completely specify what to do. For example, they may choose a coding system such as `undecided` which leaves the character code conversion to be determined from the data. In these cases, the I/O operation finishes the job of choosing a coding system. Very often you will want to find out afterwards which coding system was chosen.

buffer-file-coding-system [Variable]

This buffer-local variable records the coding system used for saving the buffer and for writing part of the buffer with `write-region`. If the text to be written cannot be safely encoded using the coding system specified by this variable, these operations select an alternative encoding by calling the function `select-safe-coding-system` (see Section 34.10.4 [User-Chosen Coding Systems], page 982). If selecting a different encoding requires to ask the user to specify a coding system, `buffer-file-coding-system` is updated to the newly selected coding system.

`buffer-file-coding-system` does *not* affect sending text to a subprocess.

save-buffer-coding-system [Variable]

This variable specifies the coding system for saving the buffer (by overriding `buffer-file-coding-system`). Note that it is not used for `write-region`.

When a command to save the buffer starts out to use `buffer-file-coding-system` (or `save-buffer-coding-system`), and that coding system cannot handle the actual text in the buffer, the command asks the user to choose another coding system (by calling `select-safe-coding-system`). After that happens, the command also updates `buffer-file-coding-system` to represent the coding system that the user specified.

`last-coding-system-used`

[Variable]

I/O operations for files and subprocesses set this variable to the coding system name that was used. The explicit encoding and decoding functions (see Section 34.10.7 [Explicit Encoding], page 988) set it too.

Warning: Since receiving subprocess output sets this variable, it can change whenever Emacs waits; therefore, you should copy the value shortly after the function call that stores the value you are interested in.

The variable `selection-coding-system` specifies how to encode selections for the window system. See Section 30.20 [Window System Selections], page 840.

`file-name-coding-system`

[Variable]

The variable `file-name-coding-system` specifies the coding system to use for encoding file names. Emacs encodes file names using that coding system for all file operations. If `file-name-coding-system` is `nil`, Emacs uses a default coding system determined by the selected language environment. In the default language environment, any non-ASCII characters in file names are not encoded specially; they appear in the file system using the internal Emacs representation.

Warning: if you change `file-name-coding-system` (or the language environment) in the middle of an Emacs session, problems can result if you have already visited files whose names were encoded using the earlier coding system and are handled differently under the new coding system. If you try to save one of these buffers under the visited file name, saving may use the wrong file name, or it may get an error. If such a problem happens, use `C-x C-w` to specify a new file name for that buffer.

On Windows 2000 and later, Emacs by default uses Unicode APIs to pass file names to the OS, so the value of `file-name-coding-system` is largely ignored. Lisp applications that need to encode or decode file names on the Lisp level should use `utf-8 coding-system` when `system-type` is `windows-nt`; the conversion of UTF-8 encoded file names to the encoding appropriate for communicating with the OS is performed internally by Emacs.

34.10.3 Coding Systems in Lisp

Here are the Lisp facilities for working with coding systems:

`coding-system-list &optional base-only`

[Function]

This function returns a list of all coding system names (symbols). If `base-only` is `non-nil`, the value includes only the base coding systems. Otherwise, it includes alias and variant coding systems as well.

`coding-system-p object`

[Function]

This function returns `t` if `object` is a coding system name or `nil`.

check-coding-system *coding-system* [Function]

This function checks the validity of *coding-system*. If that is valid, it returns *coding-system*. If *coding-system* is **nil**, the function returns **nil**. For any other values, it signals an error whose **error-symbol** is **coding-system-error** (see Section 11.7.3.1 [Signaling Errors], page 180).

coding-system-eol-type *coding-system* [Function]

This function returns the type of end-of-line (a.k.a. *eol*) conversion used by *coding-system*. If *coding-system* specifies a certain *eol* conversion, the return value is an integer 0, 1, or 2, standing for **unix**, **dos**, and **mac**, respectively. If *coding-system* doesn't specify *eol* conversion explicitly, the return value is a vector of coding systems, each one with one of the possible *eol* conversion types, like this:

```
(coding-system-eol-type 'latin-1)
⇒ [latin-1-unix latin-1-dos latin-1-mac]
```

If this function returns a vector, Emacs will decide, as part of the text encoding or decoding process, what *eol* conversion to use. For decoding, the end-of-line format of the text is auto-detected, and the *eol* conversion is set to match it (e.g., DOS-style CRLF format will imply **dos** *eol* conversion). For encoding, the *eol* conversion is taken from the appropriate default coding system (e.g., default value of **buffer-file-coding-system** for **buffer-file-coding-system**), or from the default *eol* conversion appropriate for the underlying platform.

coding-system-change-eol-conversion *coding-system eol-type* [Function]

This function returns a coding system which is like *coding-system* except for its *eol* conversion, which is specified by *eol-type*. *eol-type* should be **unix**, **dos**, **mac**, or **nil**. If it is **nil**, the returned coding system determines the end-of-line conversion from the data.

eol-type may also be 0, 1 or 2, standing for **unix**, **dos** and **mac**, respectively.

coding-system-change-text-conversion *eol-coding text-coding* [Function]

This function returns a coding system which uses the end-of-line conversion of *eol-coding*, and the text conversion of *text-coding*. If *text-coding* is **nil**, it returns **undecided**, or one of its variants according to *eol-coding*.

find-coding-systems-region *from to* [Function]

This function returns a list of coding systems that could be used to encode a text between *from* and *to*. All coding systems in the list can safely encode any multibyte characters in that portion of the text.

If the text contains no multibyte characters, the function returns the list (**undecided**).

find-coding-systems-string *string* [Function]

This function returns a list of coding systems that could be used to encode the text of *string*. All coding systems in the list can safely encode any multibyte characters in *string*. If the text contains no multibyte characters, this returns the list (**undecided**).

find-coding-systems-for-Charsets *Charsets* [Function]

This function returns a list of coding systems that could be used to encode all the character sets in the list *Charsets*.

check-coding-systems-region *start end coding-system-list* [Function]

This function checks whether coding systems in the list *coding-system-list* can encode all the characters in the region between *start* and *end*. If all of the coding systems in the list can encode the specified text, the function returns `nil`. If some coding systems cannot encode some of the characters, the value is an alist, each element of which has the form `(coding-system1 pos1 pos2 ...)`, meaning that *coding-system1* cannot encode characters at buffer positions *pos1*, *pos2*,

start may be a string, in which case *end* is ignored and the returned value references string indices instead of buffer positions.

detect-coding-region *start end &optional highest* [Function]

This function chooses a plausible coding system for decoding the text from *start* to *end*. This text should be a byte sequence, i.e., unibyte text or multibyte text with only ASCII and eight-bit characters (see Section 34.10.7 [Explicit Encoding], page 988).

Normally this function returns a list of coding systems that could handle decoding the text that was scanned. They are listed in order of decreasing priority. But if *highest* is non-`nil`, then the return value is just one coding system, the one that is highest in priority.

If the region contains only ASCII characters except for such ISO-2022 control characters ISO-2022 as `ESC`, the value is `undecided` or `(undecided)`, or a variant specifying end-of-line conversion, if that can be deduced from the text.

If the region contains null bytes, the value is `no-conversion`, even if the region contains text encoded in some coding system.

detect-coding-string *string &optional highest* [Function]

This function is like **detect-coding-region** except that it operates on the contents of *string* instead of bytes in the buffer.

inhibit-null-byte-detection [Variable]

If this variable has a non-`nil` value, null bytes are ignored when detecting the encoding of a region or a string. This allows the encoding of text that contains null bytes to be correctly detected, such as Info files with Index nodes.

inhibit-iso-escape-detection [Variable]

If this variable has a non-`nil` value, ISO-2022 escape sequences are ignored when detecting the encoding of a region or a string. The result is that no text is ever detected as encoded in some ISO-2022 encoding, and all escape sequences become visible in a buffer. **Warning:** Use this variable with extreme caution, because many files in the Emacs distribution use ISO-2022 encoding.

coding-system-charset-list *coding-system* [Function]

This function returns the list of character sets (see Section 34.7 [Character Sets], page 973) supported by *coding-system*. Some coding systems that support too many character sets to list them all yield special values:

- If *coding-system* supports all Emacs characters, the value is `(emacs)`.
- If *coding-system* supports all Unicode characters, the value is `(unicode)`.
- If *coding-system* supports all ISO-2022 charsets, the value is `iso-2022`.

- If *coding-system* supports all the characters in the internal coding system used by Emacs version 21 (prior to the implementation of internal Unicode support), the value is `emacs-mule`.

See [Process Information], page 1095, in particular the description of the functions `process-coding-system` and `set-process-coding-system`, for how to examine or set the coding systems used for I/O to a subprocess.

34.10.4 User-Chosen Coding Systems

**`select-safe-coding-system from to &optional
default-coding-system accept-default-p file`** [Function]

This function selects a coding system for encoding specified text, asking the user to choose if necessary. Normally the specified text is the text in the current buffer between *from* and *to*. If *from* is a string, the string specifies the text to encode, and *to* is ignored.

If the specified text includes raw bytes (see Section 34.1 [Text Representations], page 963), `select-safe-coding-system` suggests `raw-text` for its encoding.

If *default-coding-system* is non-`nil`, that is the first coding system to try; if that can handle the text, `select-safe-coding-system` returns that coding system. It can also be a list of coding systems; then the function tries each of them one by one. After trying all of them, it next tries the current buffer's value of `buffer-file-coding-system` (if it is not `undecided`), then the default value of `buffer-file-coding-system` and finally the user's most preferred coding system, which the user can set using the command `prefer-coding-system` (see Section “Recognizing Coding Systems” in *The GNU Emacs Manual*).

If one of those coding systems can safely encode all the specified text, `select-safe-coding-system` chooses it and returns it. Otherwise, it asks the user to choose from a list of coding systems which can encode all the text, and returns the user's choice.

default-coding-system can also be a list whose first element is `t` and whose other elements are coding systems. Then, if no coding system in the list can handle the text, `select-safe-coding-system` queries the user immediately, without trying any of the three alternatives described above. This is handy for checking only the coding systems in the list.

The optional argument *accept-default-p* determines whether a coding system selected without user interaction is acceptable. If it's omitted or `nil`, such a silent selection is always acceptable. If it is non-`nil`, it should be a function; `select-safe-coding-system` calls this function with one argument, the base coding system of the selected coding system. If the function returns `nil`, `select-safe-coding-system` rejects the silently selected coding system, and asks the user to select a coding system from a list of possible candidates.

If the variable `select-safe-coding-system-accept-default-p` is non-`nil`, it should be a function taking a single argument. It is used in place of *accept-default-p*, overriding any value supplied for this argument.

As a final step, before returning the chosen coding system, `select-safe-coding-system` checks whether that coding system is consistent with what would be selected

if the contents of the region were read from a file. (If not, this could lead to data corruption in a file subsequently re-visited and edited.) Normally, `select-safe-coding-system` uses `buffer-file-name` as the file for this purpose, but if `file` is non-`nil`, it uses that file instead (this can be relevant for `write-region` and similar functions). If it detects an apparent inconsistency, `select-safe-coding-system` queries the user before selecting the coding system.

select-safe-coding-system-function [Variable]

This variable names the function to be called to request the user to select a proper coding system for encoding text when the default coding system for an output operation cannot safely encode that text. The default value of this variable is `select-safe-coding-system`. Emacs primitives that write text to files, such as `write-region`, or send text to other processes, such as `process-send-region`, normally call the value of this variable, unless `coding-system-for-write` is bound to a non-`nil` value (see Section 34.10.6 [Specifying Coding Systems], page 986).

Here are two functions you can use to let the user specify a coding system, with completion. See Section 21.6 [Completion], page 395.

read-coding-system *prompt* &**optional** *default* [Function]

This function reads a coding system using the minibuffer, prompting with string *prompt*, and returns the coding system name as a symbol. If the user enters null input, *default* specifies which coding system to return. It should be a symbol or a string.

read-non-nil-coding-system *prompt* [Function]

This function reads a coding system using the minibuffer, prompting with string *prompt*, and returns the coding system name as a symbol. If the user tries to enter null input, it asks the user to try again. See Section 34.10 [Coding Systems], page 976.

34.10.5 Default Coding Systems

This section describes variables that specify the default coding system for certain files or when running certain subprograms, and the function that I/O operations use to access them.

The idea of these variables is that you set them once and for all to the defaults you want, and then do not change them again. To specify a particular coding system for a particular operation in a Lisp program, don't change these variables; instead, override them using `coding-system-for-read` and `coding-system-for-write` (see Section 34.10.6 [Specifying Coding Systems], page 986).

auto-coding-regexp-alist [User Option]

This variable is an alist of text patterns and corresponding coding systems. Each element has the form `(regexp . coding-system)`; a file whose first few kilobytes match `regexp` is decoded with `coding-system` when its contents are read into a buffer. The settings in this alist take priority over `coding:` tags in the files and the contents of `file-coding-system-alist` (see below). The default value is set so that Emacs automatically recognizes mail files in Babyl format and reads them with no code conversions.

file-coding-system-alist [User Option]

This variable is an alist that specifies the coding systems to use for reading and writing particular files. Each element has the form (*pattern . coding*), where *pattern* is a regular expression that matches certain file names. The element applies to file names that match *pattern*.

The CDR of the element, *coding*, should be either a coding system, a cons cell containing two coding systems, or a function name (a symbol with a function definition). If *coding* is a coding system, that coding system is used for both reading the file and writing it. If *coding* is a cons cell containing two coding systems, its CAR specifies the coding system for decoding, and its CDR specifies the coding system for encoding.

If *coding* is a function name, the function should take one argument, a list of all arguments passed to `find-operation-coding-system`. It must return a coding system or a cons cell containing two coding systems. This value has the same meaning as described above.

If *coding* (or what returned by the above function) is `undecided`, the normal code-detection is performed.

auto-coding-alist [User Option]

This variable is an alist that specifies the coding systems to use for reading and writing particular files. Its form is like that of `file-coding-system-alist`, but, unlike the latter, this variable takes priority over any `coding:` tags in the file.

process-coding-system-alist [Variable]

This variable is an alist specifying which coding systems to use for a subprocess, depending on which program is running in the subprocess. It works like `file-coding-system-alist`, except that *pattern* is matched against the program name used to start the subprocess. The coding system or systems specified in this alist are used to initialize the coding systems used for I/O to the subprocess, but you can specify other coding systems later using `set-process-coding-system`.

Warning: Coding systems such as `undecided`, which determine the coding system from the data, do not work entirely reliably with asynchronous subprocess output. This is because Emacs handles asynchronous subprocess output in batches, as it arrives. If the coding system leaves the character code conversion unspecified, or leaves the end-of-line conversion unspecified, Emacs must try to detect the proper conversion from one batch at a time, and this does not always work.

Therefore, with an asynchronous subprocess, if at all possible, use a coding system which determines both the character code conversion and the end of line conversion—that is, one like `latin-1-unix`, rather than `undecided` or `latin-1`.

network-coding-system-alist [Variable]

This variable is an alist that specifies the coding system to use for network streams. It works much like `file-coding-system-alist`, with the difference that the *pattern* in an element may be either a port number or a regular expression. If it is a regular expression, it is matched against the network service name used to open the network stream.

default-process-coding-system

[Variable]

This variable specifies the coding systems to use for subprocess (and network stream) input and output, when nothing else specifies what to do.

The value should be a cons cell of the form (*input-coding* . *output-coding*). Here *input-coding* applies to input from the subprocess, and *output-coding* applies to output to it.

auto-coding-functions

[User Option]

This variable holds a list of functions that try to determine a coding system for a file based on its undecoded contents.

Each function in this list should be written to look at text in the current buffer, but should not modify it in any way. The buffer will contain the text of parts of the file. Each function should take one argument, *size*, which tells it how many characters to look at, starting from point. If the function succeeds in determining a coding system for the file, it should return that coding system. Otherwise, it should return `nil`.

The functions in this list could be called either when the file is visited and Emacs wants to decode its contents, and/or when the file's buffer is about to be saved and Emacs wants to determine how to encode its contents.

If a file has a ‘*coding:*’ tag, that takes precedence, so these functions won't be called.

find-auto-coding filename size

[Function]

This function tries to determine a suitable coding system for *filename*. It examines the buffer visiting the named file, using the variables documented above in sequence, until it finds a match for one of the rules specified by these variables. It then returns a cons cell of the form (*coding* . *source*), where *coding* is the coding system to use and *source* is a symbol, one of *auto-coding-alist*, *auto-coding-regexp-alist*, *:coding*, or *auto-coding-functions*, indicating which one supplied the matching rule. The value *:coding* means the coding system was specified by the *coding:* tag in the file (see Section “coding tag” in *The GNU Emacs Manual*). The order of looking for a matching rule is *auto-coding-alist* first, then *auto-coding-regexp-alist*, then the *coding:* tag, and lastly *auto-coding-functions*. If no matching rule was found, the function returns `nil`.

The second argument *size* is the size of text, in characters, following point. The function examines text only within *size* characters after point. Normally, the buffer should be positioned at the beginning when this function is called, because one of the places for the *coding:* tag is the first one or two lines of the file; in that case, *size* should be the size of the buffer.

set-auto-coding filename size

[Function]

This function returns a suitable coding system for file *filename*. It uses *find-auto-coding* to find the coding system. If no coding system could be determined, the function returns `nil`. The meaning of the argument *size* is like in *find-auto-coding*.

find-operation-coding-system operation &rest arguments

[Function]

This function returns the coding system to use (by default) for performing *operation* with *arguments*. The value has this form:

(*decoding-system* . *encoding-system*)

The first element, *decoding-system*, is the coding system to use for decoding (in case *operation* does decoding), and *encoding-system* is the coding system for encoding (in case *operation* does encoding).

The argument *operation* is a symbol; it should be one of `write-region`, `start-process`, `call-process`, `call-process-region`, `insert-file-contents`, or `open-network-stream`. These are the names of the Emacs I/O primitives that can do character code and eol conversion.

The remaining arguments should be the same arguments that might be given to the corresponding I/O primitive. Depending on the primitive, one of those arguments is selected as the *target*. For example, if *operation* does file I/O, whichever argument specifies the file name is the target. For subprocess primitives, the process name is the target. For `open-network-stream`, the target is the service name or port number.

Depending on *operation*, this function looks up the target in `file-coding-system-alist`, `process-coding-system-alist`, or `network-coding-system-alist`. If the target is found in the alist, `find-operation-coding-system` returns its association in the alist; otherwise it returns `nil`.

If *operation* is `insert-file-contents`, the argument corresponding to the target may be a cons cell of the form `(filename . buffer)`. In that case, *filename* is a file name to look up in `file-coding-system-alist`, and *buffer* is a buffer that contains the file's contents (not yet decoded). If `file-coding-system-alist` specifies a function to call for this file, and that function needs to examine the file's contents (as it usually does), it should examine the contents of *buffer* instead of reading the file.

34.10.6 Specifying a Coding System for One Operation

You can specify the coding system for a specific operation by binding the variables `coding-system-for-read` and/or `coding-system-for-write`.

`coding-system-for-read`

[Variable]

If this variable is non-`nil`, it specifies the coding system to use for reading a file, or for input from a synchronous subprocess.

It also applies to any asynchronous subprocess or network stream, but in a different way: the value of `coding-system-for-read` when you start the subprocess or open the network stream specifies the input decoding method for that subprocess or network stream. It remains in use for that subprocess or network stream unless and until overridden.

The right way to use this variable is to bind it with `let` for a specific I/O operation. Its global value is normally `nil`, and you should not globally set it to any other value. Here is an example of the right way to use the variable:

```
;; Read the file with no character code conversion.
(let ((coding-system-for-read 'no-conversion))
  (insert-file-contents filename))
```

When its value is non-`nil`, this variable takes precedence over all other methods of specifying a coding system to use for input, including `file-coding-system-alist`, `process-coding-system-alist` and `network-coding-system-alist`.

coding-system-for-write

[Variable]

This works much like `coding-system-for-read`, except that it applies to output rather than input. It affects writing to files, as well as sending output to subprocesses and net connections. It also applies to encoding command-line arguments with which Emacs invokes subprocesses.

When a single operation does both input and output, as do `call-process-region` and `start-process`, both `coding-system-for-read` and `coding-system-for-write` affect it.

coding-system-require-warning

[Variable]

Binding `coding-system-for-write` to a non-`nil` value prevents output primitives from calling the function specified by `select-safe-coding-system-function` (see Section 34.10.4 [User-Chosen Coding Systems], page 982). This is because `C-x RET c` (`universal-coding-system-argument`) works by binding `coding-system-for-write`, and Emacs should obey user selection. If a Lisp program binds `coding-system-for-write` to a value that might not be safe for encoding the text to be written, it can also bind `coding-system-require-warning` to a non-`nil` value, which will force the output primitives to check the encoding by calling the value of `select-safe-coding-system-function` even though `coding-system-for-write` is non-`nil`. Alternatively, call `select-safe-coding-system` explicitly before using the specified encoding.

inhibit-eol-conversion

[User Option]

When this variable is non-`nil`, no end-of-line conversion is done, no matter which coding system is specified. This applies to all the Emacs I/O and subprocess primitives, and to the explicit encoding and decoding functions (see Section 34.10.7 [Explicit Encoding], page 988).

Sometimes, you need to prefer several coding systems for some operation, rather than fix a single one. Emacs lets you specify a priority order for using coding systems. This ordering affects the sorting of lists of coding systems returned by functions such as `find-coding-systems-region` (see Section 34.10.3 [Lisp and Coding Systems], page 979).

coding-system-priority-list &optional highestp

[Function]

This function returns the list of coding systems in the order of their current priorities. Optional argument `highestp`, if non-`nil`, means return only the highest priority coding system.

set-coding-system-priority &rest coding-systems

[Function]

This function puts `coding-systems` at the beginning of the priority list for coding systems, thus making their priority higher than all the rest.

with-coding-priority coding-systems &rest body

[Macro]

This macro executes `body`, like `progn` does (see Section 11.1 [Sequencing], page 158), with `coding-systems` at the front of the priority list for coding systems. `coding-systems` should be a list of coding systems to prefer during execution of `body`.

34.10.7 Explicit Encoding and Decoding

All the operations that transfer text in and out of Emacs have the ability to use a coding system to encode or decode the text. You can also explicitly encode and decode text using the functions in this section.

The result of encoding, and the input to decoding, are not ordinary text. They logically consist of a series of byte values; that is, a series of ASCII and eight-bit characters. In unibyte buffers and strings, these characters have codes in the range 0 through #xFF (255). In a multibyte buffer or string, eight-bit characters have character codes higher than #xFF (see Section 34.1 [Text Representations], page 963), but Emacs transparently converts them to their single-byte values when you encode or decode such text.

The usual way to read a file into a buffer as a sequence of bytes, so you can decode the contents explicitly, is with `insert-file-contents-literally` (see Section 26.3 [Reading from Files], page 614); alternatively, specify a non-`nil` `rawfile` argument when visiting a file with `find-file-noselect`. These methods result in a unibyte buffer.

The usual way to use the byte sequence that results from explicitly encoding text is to copy it to a file or process—for example, to write it with `write-region` (see Section 26.4 [Writing to Files], page 616), and suppress encoding by binding `coding-system-for-write` to `no-conversion`.

Here are the functions to perform explicit encoding or decoding. The encoding functions produce sequences of bytes; the decoding functions are meant to operate on sequences of bytes. All of these functions discard text properties. They also set `last-coding-system-used` to the precise coding system they used.

encode-coding-region *start end coding-system &optional destination* [Command]

This command encodes the text from *start* to *end* according to coding system *coding-system*. Normally, the encoded text replaces the original text in the buffer, but the optional argument *destination* can change that. If *destination* is a buffer, the encoded text is inserted in that buffer after point (point does not move); if it is `t`, the command returns the encoded text as a unibyte string without inserting it.

If encoded text is inserted in some buffer, this command returns the length of the encoded text.

The result of encoding is logically a sequence of bytes, but the buffer remains multibyte if it was multibyte before, and any 8-bit bytes are converted to their multibyte representation (see Section 34.1 [Text Representations], page 963).

Do *not* use `undecided` for *coding-system* when encoding text, since that may lead to unexpected results. Instead, use `select-safe-coding-system` (see Section 34.10.4 [User-Chosen Coding Systems], page 982) to suggest a suitable encoding, if there's no obvious pertinent value for *coding-system*.

encode-coding-string *string coding-system &optional nocopy buffer* [Function]

This function encodes the text in *string* according to coding system *coding-system*. It returns a new string containing the encoded text, except when *nocopy* is `non-nil`, in which case the function may return *string* itself if the encoding operation is trivial. The result of encoding is a unibyte string.

decode-coding-region *start end coding-system &optional destination* [Command]

This command decodes the text from *start* to *end* according to coding system *coding-system*. To make explicit decoding useful, the text before decoding ought to be a sequence of byte values, but both multibyte and unibyte buffers are acceptable (in the multibyte case, the raw byte values should be represented as eight-bit characters). Normally, the decoded text replaces the original text in the buffer, but the optional argument *destination* can change that. If *destination* is a buffer, the decoded text is inserted in that buffer after point (point does not move); if it is **t**, the command returns the decoded text as a multibyte string without inserting it.

If decoded text is inserted in some buffer, this command returns the length of the decoded text. If that buffer is a unibyte buffer (see Section 34.4 [Selecting a Representation], page 966), the internal representation of the decoded text (see Section 34.1 [Text Representations], page 963) is inserted into the buffer as individual bytes.

This command puts a **charset** text property on the decoded text. The value of the property states the character set used to decode the original text.

This command detects the encoding of the text if necessary. If *coding-system* is **undecided**, the command detects the encoding of the text based on the byte sequences it finds in the text, and also detects the type of end-of-line convention used by the text (see Section 34.10.3 [Lisp and Coding Systems], page 979). If *coding-system* is **undecided-eol-type**, where *eol-type* is **unix**, **dos**, or **mac**, then the command detects only the encoding of the text. Any *coding-system* that doesn't specify *eol-type*, as in **utf-8**, causes the command to detect the end-of-line convention; specify the encoding completely, as in **utf-8-unix**, if the EOL convention used by the text is known in advance, to prevent any automatic detection.

decode-coding-string *string coding-system &optional nocopy buffer* [Function]

This function decodes the text in *string* according to *coding-system*. It returns a new string containing the decoded text, except when *nocopy* is non-**nil**, in which case the function may return *string* itself if the decoding operation is trivial. To make explicit decoding useful, the contents of *string* ought to be a unibyte string with a sequence of byte values, but a multibyte string is also acceptable (assuming it contains 8-bit bytes in their multibyte form).

This function detects the encoding of the string if needed, like **decode-coding-region** does.

If optional argument *buffer* specifies a buffer, the decoded text is inserted in that buffer after point (point does not move). In this case, the return value is the length of the decoded text. If that buffer is a unibyte buffer, the internal representation of the decoded text is inserted into it as individual bytes.

This function puts a **charset** text property on the decoded text. The value of the property states the character set used to decode the original text:

```
(decode-coding-string "Gr\374ss Gott" 'latin-1)
⇒ #("Grüss Gott" 0 9 (charset iso-8859-1))
```

decode-coding-inserted-region *from* *to* *filename* &optional *visit* [Function]
beg *end* *replace*

This function decodes the text from *from* to *to* as if it were being read from file *filename* using **insert-file-contents** using the rest of the arguments provided.

The normal way to use this function is after reading text from a file without decoding, if you decide you would rather have decoded it. Instead of deleting the text and reading it again, this time with decoding, you can call this function.

34.10.8 Terminal I/O Encoding

Emacs can use coding systems to decode keyboard input and encode terminal output. This is useful for terminals that transmit or display text using a particular encoding, such as Latin-1. Emacs does not set **last-coding-system-used** when encoding or decoding terminal I/O.

keyboard-coding-system &optional *terminal* [Function]

This function returns the coding system used for decoding keyboard input from *terminal*. A value of **no-conversion** means no decoding is done. If *terminal* is omitted or **nil**, it means the selected frame's terminal. See Section 30.2 [Multiple Terminals], page 787.

set-keyboard-coding-system *coding-system* &optional *terminal* [Command]

This command specifies *coding-system* as the coding system to use for decoding keyboard input from *terminal*. If *coding-system* is **nil**, that means not to decode keyboard input. If *terminal* is a frame, it means that frame's terminal; if it is **nil**, that means the currently selected frame's terminal. See Section 30.2 [Multiple Terminals], page 787. Note that on modern MS-Windows systems Emacs always uses Unicode input when decoding keyboard input, so the encoding set by this command has no effect on Windows.

terminal-coding-system &optional *terminal* [Function]

This function returns the coding system that is in use for encoding terminal output from *terminal*. A value of **no-conversion** means no encoding is done. If *terminal* is a frame, it means that frame's terminal; if it is **nil**, that means the currently selected frame's terminal.

set-terminal-coding-system *coding-system* &optional *terminal* [Command]

This command specifies *coding-system* as the coding system to use for encoding terminal output from *terminal*. If *coding-system* is **nil**, that means not to encode terminal output. If *terminal* is a frame, it means that frame's terminal; if it is **nil**, that means the currently selected frame's terminal.

34.11 Input Methods

Input methods provide convenient ways of entering non-ASCII characters from the keyboard. Unlike coding systems, which translate non-ASCII characters to and from encodings meant to be read by programs, input methods provide human-friendly commands. (See Section “Input Methods” in *The GNU Emacs Manual*, for information on how users use input methods to enter text.) How to define input methods is not yet documented in this manual, but here we describe how to use them.

Each input method has a name, which is currently a string; in the future, symbols may also be usable as input method names.

current-input-method [Variable]

This variable holds the name of the input method now active in the current buffer. (It automatically becomes local in each buffer when set in any fashion.) It is `nil` if no input method is active in the buffer now.

default-input-method [User Option]

This variable holds the default input method for commands that choose an input method. Unlike `current-input-method`, this variable is normally global.

set-input-method *input-method* [Command]

This command activates input method *input-method* for the current buffer. It also sets `default-input-method` to *input-method*. If *input-method* is `nil`, this command deactivates any input method for the current buffer.

read-input-method-name *prompt* &optional *default inhibit-null* [Function]

This function reads an input method name with the minibuffer, prompting with *prompt*. If *default* is non-`nil`, that is returned by default, if the user enters empty input. However, if *inhibit-null* is non-`nil`, empty input signals an error.

The returned value is a string.

input-method-alist [Variable]

This variable defines all the supported input methods. Each element defines one input method, and should have the form:

```
(input-method language-env activate-func
title description args...)
```

Here *input-method* is the input method name, a string; *language-env* is another string, the name of the language environment this input method is recommended for. (That serves only for documentation purposes.)

activate-func is a function to call to activate this method. The *args*, if any, are passed as arguments to *activate-func*. All told, the arguments to *activate-func* are *input-method* and the *args*.

title is a string to display in the mode line while this method is active. *description* is a string describing this method and what it is good for.

The fundamental interface to input methods is through the variable `input-method-function`. See Section 22.8.2 [Reading One Event], page 462, and Section 22.8.4 [Invoking the Input Method], page 467.

34.12 Locales

In POSIX, locales control which language to use in language-related features. These Emacs variables control how Emacs interacts with these features.

locale-coding-system [Variable]

This variable specifies the coding system to use for decoding system error messages and—on X Window system only—keyboard input, for sending batch output to the

standard output and error streams, for encoding the format argument to `format-time-string`, and for decoding the return value of `format-time-string`.

system-messages-locale

[Variable]

This variable specifies the locale to use for generating system error messages. Changing the locale can cause messages to come out in a different language or in a different orthography. If the variable is `nil`, the locale is specified by environment variables in the usual POSIX fashion.

system-time-locale

[Variable]

This variable specifies the locale to use for formatting time values. Changing the locale can cause messages to appear according to the conventions of a different language. If the variable is `nil`, the locale is specified by environment variables in the usual POSIX fashion.

locale-info item

[Function]

This function returns locale data *item* for the current POSIX locale, if available. *item* should be one of these symbols:

codeset Return the character set as a string (locale item `CODESET`).

days Return a 7-element vector of day names (locale items `DAY_1` through `DAY_7`);

months Return a 12-element vector of month names (locale items `MON_1` through `MON_12`).

paper Return a list (*width height*) of 2 integers, for the default paper size measured in millimeters (locale items `_NL_PAPER_WIDTH` and `_NL_PAPER_HEIGHT`).

If the system can't provide the requested information, or if *item* is not one of those symbols, the value is `nil`. All strings in the return value are decoded using `locale-coding-system`. See Section “Locales” in *The GNU Libc Manual*, for more information about locales and locale items.

35 Searching and Matching

GNU Emacs provides two ways to search through a buffer for specified text: exact string searches and regular expression searches. After a regular expression search, you can examine the *match data* to determine which text matched the whole regular expression or various portions of it.

The ‘`skip-chars...`’ functions also perform a kind of searching. See Section 31.2.7 [Skipping Characters], page 863. To search for changes in character properties, see Section 33.19.3 [Property Search], page 921.

35.1 Searching for Strings

These are the primitive functions for searching through the text in a buffer. They are meant for use in programs, but you may call them interactively. If you do so, they prompt for the search string; the arguments *limit* and *noerror* are `nil`, and *repeat* is 1. For more details on interactive searching, see Section “Searching and Replacement” in *The GNU Emacs Manual*.

These search functions convert the search string to multibyte if the buffer is multibyte; they convert the search string to unibyte if the buffer is unibyte. See Section 34.1 [Text Representations], page 963.

search-forward *string* &**optional** *limit* *noerror* *count* [Command]

This function searches forward from point for an exact match for *string*. If successful, it sets point to the end of the occurrence found, and returns the new value of point. If no match is found, the value and side effects depend on *noerror* (see below).

In the following example, point is initially at the beginning of the line. Then (`(search-forward "fox")`) moves point after the last letter of ‘`fox`’:

```
----- Buffer: foo -----
*The quick brown fox jumped over the lazy dog.
----- Buffer: foo -----  
  

(search-forward "fox")
⇒ 20  
  

----- Buffer: foo -----
The quick brown fox* jumped over the lazy dog.
----- Buffer: foo -----
```

The argument *limit* specifies the bound to the search, and should be a position in the current buffer. No match extending after that position is accepted. If *limit* is omitted or `nil`, it defaults to the end of the accessible portion of the buffer.

What happens when the search fails depends on the value of *noerror*. If *noerror* is `nil`, a `search-failed` error is signaled. If *noerror* is `t`, `search-forward` returns `nil` and does nothing. If *noerror* is neither `nil` nor `t`, then `search-forward` moves point to the upper bound and returns `nil`.

The argument *noerror* only affects valid searches which fail to find a match. Invalid arguments cause errors regardless of *noerror*.

If *count* is a positive number *n*, the search is done *n* times; each successive search starts at the end of the previous match. If all these successive searches succeed, the function call succeeds, moving point and returning its new value. Otherwise the function call fails, with results depending on the value of *noerror*, as described above. If *count* is a negative number $-n$, the search is done *n* times in the opposite (backward) direction.

search-backward *string* &optional *limit* *noerror* *count* [Command]

This function searches backward from point for *string*. It is like **search-forward**, except that it searches backwards rather than forwards. Backward searches leave point at the beginning of the match.

word-search-forward *string* &optional *limit* *noerror* *count* [Command]

This function searches forward from point for a word match for *string*. If it finds a match, it sets point to the end of the match found, and returns the new value of point.

Word matching regards *string* as a sequence of words, disregarding punctuation that separates them. It searches the buffer for the same sequence of words. Each word must be distinct in the buffer (searching for the word ‘ball’ does not match the word ‘balls’), but the details of punctuation and spacing are ignored (searching for ‘ball boy’ does match ‘ball. Boy!’).

In this example, point is initially at the beginning of the buffer; the search leaves it between the ‘y’ and the ‘!’.

```
----- Buffer: foo -----
*He said "Please! Find
the ball boy!"
----- Buffer: foo -----
```

```
(word-search-forward "Please find the ball, boy.")
⇒ 39
```

```
----- Buffer: foo -----
He said "Please! Find
the ball boy*!"
----- Buffer: foo -----
```

If *limit* is non-*nil*, it must be a position in the current buffer; it specifies the upper bound to the search. The match found must not extend after that position.

If *noerror* is *nil*, then **word-search-forward** signals an error if the search fails. If *noerror* is *t*, then it returns *nil* instead of signaling an error. If *noerror* is neither *nil* nor *t*, it moves point to *limit* (or the end of the accessible portion of the buffer) and returns *nil*.

If *count* is a positive number, it specifies how many successive occurrences to search for. Point is positioned at the end of the last match. If *count* is a negative number, the search is backward and point is positioned at the beginning of the last match.

Internally, **word-search-forward** and related functions use the function **word-search-regexp** to convert *string* to a regular expression that ignores punctuation.

word-search-forward-lax *string &optional limit noerror count* [Command]

This command is identical to `word-search-forward`, except that the beginning or the end of *string* need not match a word boundary, unless *string* begins or ends in whitespace. For instance, searching for ‘ball boy’ matches ‘ball boyee’, but does not match ‘balls boy’.

word-search-backward *string &optional limit noerror count* [Command]

This function searches backward from point for a word match to *string*. This function is just like `word-search-forward` except that it searches backward and normally leaves point at the beginning of the match.

word-search-backward-lax *string &optional limit noerror count* [Command]

This command is identical to `word-search-backward`, except that the beginning or the end of *string* need not match a word boundary, unless *string* begins or ends in whitespace.

35.2 Searching and Case

By default, searches in Emacs ignore the case of the text they are searching through; if you specify searching for ‘FOO’, then ‘Foo’ or ‘foo’ is also considered a match. This applies to regular expressions, too; thus, ‘[aB]’ would match ‘a’ or ‘A’ or ‘b’ or ‘B’.

If you do not want this feature, set the variable `case-fold-search` to `nil`. Then all letters must match exactly, including case. This is a buffer-local variable; altering the variable affects only the current buffer. (See Section 12.11.1 [Intro to Buffer-Local], page 207.) Alternatively, you may change the default value. In Lisp code, you will more typically use `let` to bind `case-fold-search` to the desired value.

Note that the user-level incremental search feature handles case distinctions differently. When the search string contains only lower case letters, the search ignores case, but when the search string contains one or more upper case letters, the search becomes case-sensitive. But this has nothing to do with the searching functions used in Lisp code. See Section “Incremental Search” in *The GNU Emacs Manual*.

case-fold-search [User Option]

This buffer-local variable determines whether searches should ignore case. If the variable is `nil` they do not ignore case; otherwise (and by default) they do ignore case.

case-replace [User Option]

This variable determines whether the higher-level replacement functions should preserve case. If the variable is `nil`, that means to use the replacement text verbatim. A non-`nil` value means to convert the case of the replacement text according to the text being replaced.

This variable is used by passing it as an argument to the function `replace-match`. See Section 35.6.1 [Replacing Match], page 1012.

35.3 Regular Expressions

A *regular expression*, or *regexp* for short, is a pattern that denotes a (possibly infinite) set of strings. Searching for matches for a regexp is a very powerful operation. This section explains how to write regexps; the following section says how to search for them.

For interactive development of regular expressions, you can use the `M-x re-builder` command. It provides a convenient interface for creating regular expressions, by giving immediate visual feedback in a separate buffer. As you edit the regexp, all its matches in the target buffer are highlighted. Each parenthesized sub-expression of the regexp is shown in a distinct face, which makes it easier to verify even very complex regexps.

Note that by default Emacs search ignores case (see Section 35.2 [Searching and Case], page 995). To enable case-sensitive regexp search and match, bind `case-fold-search` to `nil` around the code you want to be case-sensitive.

35.3.1 Syntax of Regular Expressions

Regular expressions have a syntax in which a few characters are special constructs and the rest are *ordinary*. An ordinary character is a simple regular expression that matches that character and nothing else. The special characters are '.', '*', '+', '?', '[', '^', '\$', and '\'; no new special characters will be defined in the future. The character '[' is special if it ends a character alternative (see later). The character '-' is special inside a character alternative. A '[' and balancing ']' enclose a character class inside a character alternative. Any other character appearing in a regular expression is ordinary, unless a '\' precedes it.

For example, 'f' is not a special character, so it is ordinary, and therefore 'f' is a regular expression that matches the string 'f' and no other string. (It does *not* match the string 'fg', but it does match a *part* of that string.) Likewise, 'o' is a regular expression that matches only 'o'.

Any two regular expressions *a* and *b* can be concatenated. The result is a regular expression that matches a string if *a* matches some amount of the beginning of that string and *b* matches the rest of the string.

As a simple example, we can concatenate the regular expressions 'f' and 'o' to get the regular expression 'fo', which matches only the string 'fo'. Still trivial. To do something more powerful, you need to use one of the special regular expression constructs.

35.3.1.1 Special Characters in Regular Expressions

Here is a list of the characters that are special in a regular expression.

'.'	(Period)	is a special character that matches any single character except a newline. Using concatenation, we can make regular expressions like 'a.b', which matches any three-character string that begins with 'a' and ends with 'b'.
'*'		is not a construct by itself; it is a postfix operator that means to match the preceding regular expression repetitively as many times as possible. Thus, 'o*' matches any number of 'o's (including no 'o's).
'*'		always applies to the <i>smallest</i> possible preceding expression. Thus, 'fo*' has a repeating 'o', not a repeating 'fo'. It matches 'f', 'fo', 'foo', and so on.
		The matcher processes a '*' construct by matching, immediately, as many repetitions as can be found. Then it continues with the rest of the pattern. If that fails, backtracking occurs, discarding some of the matches of the '*'-modified construct in the hope that this will make it possible to match the rest of the pattern. For example, in matching 'ca*ar' against the string 'caaar', the 'a*' construct matches 'aa', and then the 'ar' part of the pattern is matched.

first tries to match all three ‘a’s; but the rest of the pattern is ‘ar’ and there is only ‘r’ left to match, so this try fails. The next alternative is for ‘a*’ to match only two ‘a’s. With this choice, the rest of the regexp matches successfully.

‘+’ is a postfix operator, similar to ‘*’ except that it must match the preceding expression at least once. So, for example, ‘ca+r’ matches the strings ‘car’ and ‘caaaar’ but not the string ‘cr’, whereas ‘ca*r’ matches all three strings.

‘?’ is a postfix operator, similar to ‘*’ except that it must match the preceding expression either once or not at all. For example, ‘ca?r’ matches ‘car’ or ‘cr’; nothing else.

‘*?’ , ‘+?’ , ‘??’

are *non-greedy* variants of the operators ‘*’, ‘+’ and ‘?’ . Where those operators match the largest possible substring (consistent with matching the entire containing expression), the non-greedy variants match the smallest possible substring (consistent with matching the entire containing expression).

For example, the regular expression ‘c[ad]*a’ when applied to the string ‘cdaaada’ matches the whole string; but the regular expression ‘c[ad]*?a’, applied to that same string, matches just ‘cda’. (The smallest possible match here for ‘[ad]*?’ that permits the whole expression to match is ‘d’.)

‘[...]’ is a *character alternative*, which begins with ‘[’ and is terminated by ‘]’ . In the simplest case, the characters between the two brackets are what this character alternative can match.

Thus, ‘[ad]’ matches either one ‘a’ or one ‘d’, and ‘[ad]*’ matches any string composed of just ‘a’s and ‘d’s (including the empty string). It follows that ‘c[ad]*r’ matches ‘cr’ , ‘car’ , ‘cdr’ , ‘cadhaar’ , etc.

You can also include character ranges in a character alternative, by writing the starting and ending characters with a ‘-’ between them. Thus, ‘[a-z]’ matches any lower-case ASCII letter. Ranges may be intermixed freely with individual characters, as in ‘[a-z\$%.]’ , which matches any lower case ASCII letter or ‘\$’ , ‘%’ or period. However, the ending character of one range should not be the starting point of another one; for example, ‘[a-m-z]’ should be avoided.

A character alternative can also specify named character classes (see Section 35.3.1.2 [Char Classes], page 1000). For example, ‘[:ascii:]’ matches any ASCII character. Using a character class is equivalent to mentioning each of the characters in that class; but the latter is not feasible in practice, since some classes include thousands of different characters. A character class should not appear as the lower or upper bound of a range.

The usual regexp special characters are not special inside a character alternative. A completely different set of characters is special: ‘]’ , ‘-’ and ‘^’ . To include ‘]’ in a character alternative, put it at the beginning. To include ‘^’ , put it anywhere but at the beginning. To include ‘-’ , put it at the end. Thus, ‘[]^-]’ matches all three of these special characters. You cannot use ‘\’ to escape these three characters, since ‘\’ is not special here.

The following aspects of ranges are specific to Emacs, in that POSIX allows but does not require this behavior and programs other than Emacs may behave differently:

1. If `case-fold-search` is non-`nil`, ‘[a-z]’ also matches upper-case letters.
2. A range is not affected by the locale’s collation sequence: it always represents the set of characters with codepoints ranging between those of its bounds, so that ‘[a-z]’ matches only ASCII letters, even outside the C or POSIX locale.
3. If the lower bound of a range is greater than its upper bound, the range is empty and represents no characters. Thus, ‘[z-a]’ always fails to match, and ‘[^z-a]’ matches any character, including newline. However, a reversed range should always be from the letter ‘z’ to the letter ‘a’ to make it clear that it is not a typo; for example, ‘[+-*/]’ should be avoided, because it matches only ‘/’ rather than the likely-intended four characters.
4. If the end points of a range are raw 8-bit bytes (see Section 34.1 [Text Representations], page 963), or if the range start is ASCII and the end is a raw byte (as in ‘[a-\377]’), the range will match only ASCII characters and raw 8-bit bytes, but not non-ASCII characters. This feature is intended for searching text in unibyte buffers and strings.

Some kinds of character alternatives are not the best style even though they have a well-defined meaning in Emacs. They include:

1. Although a range’s bound can be almost any character, it is better style to stay within natural sequences of ASCII letters and digits because most people have not memorized character code tables. For example, ‘[.-9]’ is less clear than ‘[./0-9]’, and ‘[~-~]’ is less clear than ‘[`a-z{|}{|}`]’. Unicode character escapes can help here; for example, for most programmers ‘[--]’ is less clear than ‘[\u0E01-\u0E3A\u0E3F-\u0E5B]’.
2. Although a character alternative can include duplicates, it is better style to avoid them. For example, ‘[XYa-yYb-zA-Z]’ is less clear than ‘[XYa-zA-Z]’.
3. Although a range can denote just one, two, or three characters, it is simpler to list the characters. For example, ‘[a-a0]’ is less clear than ‘[a0]’, ‘[i-j]’ is less clear than ‘[ij]’, and ‘[i-k]’ is less clear than ‘[ijk]’.
4. Although a ‘-’ can appear at the beginning of a character alternative or as the upper bound of a range, it is better style to put ‘-’ by itself at the end of a character alternative. For example, although ‘[-a-z]’ is valid, ‘[a-z-]’ is better style; and although ‘[*--]’ is valid, ‘[*+, -]’ is clearer.

‘[^ ...]’ ‘[^’ begins a *complemented character alternative*. This matches any character except the ones specified. Thus, ‘[^a-zA-Z0-9]’ matches all characters *except* ASCII letters and digits.

‘^’ is not special in a character alternative unless it is the first character. The character following the ‘^’ is treated as if it were first (in other words, ‘-’ and ‘]’ are not special there).

A complemented character alternative can match a newline, unless newline is mentioned as one of the characters not to match. This is in contrast to the handling of regexps in programs such as `grep`.

You can specify named character classes, just like in character alternatives. For instance, ‘`[^[:ascii:]]`’ matches any non-ASCII character. See Section 35.3.1.2 [Char Classes], page 1000.

‘`^`’ When matching a buffer, ‘`^`’ matches the empty string, but only at the beginning of a line in the text being matched (or the beginning of the accessible portion of the buffer). Otherwise it fails to match anything. Thus, ‘`^foo`’ matches a ‘`foo`’ that occurs at the beginning of a line.

When matching a string instead of a buffer, ‘`^`’ matches at the beginning of the string or after a newline character.

For historical compatibility reasons, ‘`^`’ can be used only at the beginning of the regular expression, or after ‘`\C`’, ‘`\(?:`’ or ‘`\|`’.

‘`$`’ is similar to ‘`^`’ but matches only at the end of a line (or the end of the accessible portion of the buffer). Thus, ‘`x+$`’ matches a string of one ‘`x`’ or more at the end of a line.

When matching a string instead of a buffer, ‘`$`’ matches at the end of the string or before a newline character.

For historical compatibility reasons, ‘`$`’ can be used only at the end of the regular expression, or before ‘`\)`’ or ‘`\|`’.

‘`\`’ has two functions: it quotes the special characters (including ‘`\`’), and it introduces additional special constructs.

Because ‘`\`’ quotes special characters, ‘`\$`’ is a regular expression that matches only ‘`$`’, and ‘`\[`’ is a regular expression that matches only ‘`[`’, and so on.

Note that ‘`\`’ also has special meaning in the read syntax of Lisp strings (see Section 2.4.8 [String Type], page 20), and must be quoted with ‘`\`’. For example, the regular expression that matches the ‘`\`’ character is ‘`\\\`’. To write a Lisp string that contains the characters ‘`\\\`’, Lisp syntax requires you to quote each ‘`\`’ with another ‘`\`’. Therefore, the read syntax for a regular expression matching ‘`\`’ is “`\\\\\\`”.

Please note: For historical compatibility, special characters are treated as ordinary ones if they are in contexts where their special meanings make no sense. For example, ‘`*foo`’ treats ‘`*`’ as ordinary since there is no preceding expression on which the ‘`*`’ can act. It is poor practice to depend on this behavior; quote the special character anyway, regardless of where it appears.

As a ‘`\`’ is not special inside a character alternative, it can never remove the special meaning of ‘`-`’, ‘`^`’ or ‘`]`’. You should not quote these characters when they have no special meaning. This would not clarify anything, since backslashes can legitimately precede these characters where they *have* special meaning, as in ‘`[^\]`’ (“`[\\\]`” for Lisp string syntax), which matches any single character except a backslash.

In practice, most ‘`]`’ that occur in regular expressions close a character alternative and hence are special. However, occasionally a regular expression may try to match a complex

pattern of literal ‘[’ and ‘]’. In such situations, it sometimes may be necessary to carefully parse the regexp from the start to determine which square brackets enclose a character alternative. For example, ‘[^][]’ consists of the complemented character alternative ‘[^] []’, (which matches any single character that is not a square bracket), followed by a literal ‘]’.

The exact rules are that at the beginning of a regexp, ‘[’ is special and ‘]’ not. This lasts until the first unquoted ‘[’, after which we are in a character alternative; ‘[’ is no longer special (except when it starts a character class) but ‘]’ is special, unless it immediately follows the special ‘[’ or that ‘[’ followed by a ‘^’. This lasts until the next special ‘]’ that does not end a character class. This ends the character alternative and restores the ordinary syntax of regular expressions; an unquoted ‘[’ is special again and a ‘]’ not.

35.3.1.2 Character Classes

Below is a table of the classes you can use in a character alternative, and what they mean. Note that the ‘[’ and ‘]’ characters that enclose the class name are part of the name, so a regular expression using these classes needs one more pair of brackets. For example, a regular expression matching a sequence of one or more letters and digits would be ‘[[[:alnum:]]]+’, not ‘[:alnum:]+’.

‘[:ascii:]’

This matches any ASCII character (codes 0–127).

‘[:alnum:]’

This matches any letter or digit. For multibyte characters, it matches characters whose Unicode ‘general-category’ property (see Section 34.6 [Character Properties], page 968) indicates they are alphabetic or decimal number characters.

‘[:alpha:]’

This matches any letter. For multibyte characters, it matches characters whose Unicode ‘general-category’ property (see Section 34.6 [Character Properties], page 968) indicates they are alphabetic characters.

‘[:blank:]’

This matches horizontal whitespace, as defined by Annex C of the Unicode Technical Standard #18. In particular, it matches spaces, tabs, and other characters whose Unicode ‘general-category’ property (see Section 34.6 [Character Properties], page 968) indicates they are spacing separators.

‘[:cntrl:]’

This matches any character whose code is in the range 0–31.

‘[:digit:]’

This matches ‘0’ through ‘9’. Thus, ‘[-+[:digit:]]’ matches any digit, as well as ‘+’ and ‘-’.

‘[:graph:]’

This matches graphic characters—everything except spaces, ASCII and non-ASCII control characters, surrogates, and codepoints unassigned by Unicode, as indicated by the Unicode ‘general-category’ property (see Section 34.6 [Character Properties], page 968).

`'[:lower:]'`

This matches any lower-case letter, as determined by the current case table (see Section 4.10 [Case Tables], page 74). If `case-fold-search` is non-`nil`, this also matches any upper-case letter. Note that a buffer can have its own local case table different from the default one.

`'[:multibyte:]'`

This matches any multibyte character (see Section 34.1 [Text Representations], page 963).

`'[:nonascii:]'`

This matches any non-ASCII character.

`'[:print:]'`

This matches any printing character—either spaces or graphic characters matched by `'[:graph:]'`.

`'[:punct:]'`

This matches any punctuation character. (At present, for multibyte characters, it matches anything that has non-word syntax, and thus its exact definition can vary from one major mode to another, since the syntax of a character depends on the major mode.)

`'[:space:]'`

This matches any character that has whitespace syntax (see Section 36.2.1 [Syntax Class Table], page 1023). Note that the syntax of a character, and thus which characters are considered “whitespace”, depends on the major mode.

`'[:unibyte:]'`

This matches any unibyte character (see Section 34.1 [Text Representations], page 963).

`'[:upper:]'`

This matches any upper-case letter, as determined by the current case table (see Section 4.10 [Case Tables], page 74). If `case-fold-search` is non-`nil`, this also matches any lower-case letter. Note that a buffer can have its own local case table different from the default one.

`'[:word:]'`

This matches any character that has word syntax (see Section 36.2.1 [Syntax Class Table], page 1023). Note that the syntax of a character, and thus which characters are considered “word-constituent”, depends on the major mode.

`'[:xdigit:]'`

This matches the hexadecimal digits: ‘0’ through ‘9’, ‘a’ through ‘f’ and ‘A’ through ‘F’.

35.3.1.3 Backslash Constructs in Regular Expressions

For the most part, ‘\’ followed by any character matches only that character. However, there are several exceptions: certain sequences starting with ‘\’ that have special meanings. Here is a table of the special ‘\’ constructs.

'\|' specifies an alternative. Two regular expressions *a* and *b* with '\|' in between form an expression that matches anything that either *a* or *b* matches.

Thus, 'foo\|bar' matches either 'foo' or 'bar' but no other string.

'\|' applies to the largest possible surrounding expressions. Only a surrounding '\(... \)' grouping can limit the grouping power of '\|'.

If you need full backtracking capability to handle multiple uses of '\|', use the POSIX regular expression functions (see Section 35.5 [POSIX Regexp], page 1011).

'\{m\}' is a postfix operator that repeats the previous pattern exactly *m* times. Thus, 'x\{5\}' matches the string 'xxxxx' and nothing else. 'c[ad]\{3\}r' matches string such as 'caaar', 'cdddr', 'cadar', and so on.

'\{m,n\}' is a more general postfix operator that specifies repetition with a minimum of *m* repeats and a maximum of *n* repeats. If *m* is omitted, the minimum is 0; if *n* is omitted, there is no maximum. For both forms, *m* and *n*, if specified, may be no larger than $2^{16} - 1$.

For example, 'c[ad]\{1,2\}r' matches the strings 'car', 'cdr', 'caar', 'cadr', 'cdar', and 'cddr', and nothing else.

'\{0,1\}' or '\{,1\}' is equivalent to '?'.

'\{0,\}' or '\{,,\}' is equivalent to '*'.

'\{1,\}' is equivalent to '+'.

'\(\dots\)'

is a grouping construct that serves three purposes:

1. To enclose a set of '\|' alternatives for other operations. Thus, the regular expression '\(foo\|bar\)\x' matches either 'foox' or 'barx'.
2. To enclose a complicated expression for the postfix operators '*', '+' and '?' to operate on. Thus, 'ba\(\na\)*' matches 'ba', 'bana', 'banana', 'bananana', etc., with any number (zero or more) of 'na' strings.
3. To record a matched substring for future reference with '\digit' (see below).

This last application is not a consequence of the idea of a parenthetical grouping; it is a separate feature that was assigned as a second meaning to the same '\(\dots\)' construct because, in practice, there was usually no conflict between the two meanings. But occasionally there is a conflict, and that led to the introduction of shy groups.

'\(?:\dots\)'

is the *shy group* construct. A shy group serves the first two purposes of an ordinary group (controlling the nesting of other operators), but it does not get a number, so you cannot refer back to its value with '\digit'. Shy groups are particularly useful for mechanically-constructed regular expressions, because they can be added automatically without altering the numbering of ordinary, non-shy groups.

Shy groups are also called *non-capturing* or *unnumbered groups*.

‘\(?num: . . . \)’

is the *explicitly numbered group* construct. Normal groups get their number implicitly, based on their position, which can be inconvenient. This construct allows you to force a particular group number. There is no particular restriction on the numbering, e.g., you can have several groups with the same number in which case the last one to match (i.e., the rightmost match) will win. Implicitly numbered groups always get the smallest integer larger than the one of any previous group.

`\digit` matches the same text that matched the *digit*th occurrence of a grouping (`\(\dots\)``) construct.

In other words, after the end of a group, the matcher remembers the beginning and end of the text matched by that group. Later on in the regular expression you can use ‘\’ followed by *digit* to match that same text, whatever it may have been.

The strings matching the first nine grouping constructs appearing in the entire regular expression passed to a search or matching function are assigned numbers 1 through 9 in the order that the open parentheses appear in the regular expression. So you can use '\1' through '\9' to refer to the text matched by the corresponding grouping constructs.

For example, ‘\(.*\)\1’ matches any newline-free string that is composed of two identical halves. The ‘\(.*\)’ matches the first half, which may be anything, but the ‘\1’ that follows must match the same exact text.

If a '\(\(...\)' construct matches more than once (which can happen, for instance, if it is followed by '*'), only the last match is recorded.

If a particular grouping construct in the regular expression was never matched—for instance, if it appears inside of an alternative that wasn't used, or inside of a repetition that repeated zero times—then the corresponding ‘\digit’ construct never matches anything. To use an artificial example, ‘\(\mathit{foo}(\mathit{b}*\backslash)\|\mathit{lose}\)\2’ cannot match ‘lose’: the second alternative inside the larger group matches it, but then ‘\2’ is undefined and can't match anything. But it can match ‘foabb’, because the first alternative matches ‘foob’ and ‘\2’ matches ‘b’.

'\w'

matches any word-constituent character. The editor syntax table determines which characters these are. See Chapter 36 [Syntax Tables], page 1022.

'\W'

matches any character that is not a word constituent.

‘\scode’

matches any character whose syntax is *code*. Here *code* is a character that represents a syntax code: thus, ‘w’ for word constituent, ‘-’ for whitespace, ‘(’ for open parenthesis, etc. To represent whitespace syntax, use either ‘-’ or a space character. See Section 36.2.1 [Syntax Class Table], page 1023, for a list of syntax codes and the characters that stand for them.

‘\Scode’

matches any character whose syntax is not code.

‘\ccode’

matches any character whose category is *code*. Here *code* is a character that represents a category: for example, in the standard category table, ‘c’ stands for Chinese characters and ‘g’ stands for Greek characters. You can see the list of

all the currently defined categories with `M-x describe-categories RET`. You can also define your own categories in addition to the standard ones using the `define-category` function (see Section 36.8 [Categories], page 1036).

`'\C{code}'` matches any character whose category is not `code`.

The following regular expression constructs match the empty string—that is, they don't consume any characters—but whether they match depends on the context. For all, the beginning and end of the accessible portion of the buffer are treated as if they were the actual beginning and end of the buffer.

- `'\``'` matches the empty string, but only at the beginning of the buffer or string being matched against.
- `'\''` matches the empty string, but only at the end of the buffer or string being matched against.
- `'\='` matches the empty string, but only at point. (This construct is not defined when matching against a string.)
- `'\b'` matches the empty string, but only at the beginning or end of a word. Thus, `'\bfoo\b'` matches any occurrence of ‘`foo`’ as a separate word. `'\bballs?\b'` matches ‘`ball`’ or ‘`balls`’ as a separate word.
- `'\b'` matches at the beginning or end of the buffer (or string) regardless of what text appears next to it.
- `'\B'` matches the empty string, but *not* at the beginning or end of a word, nor at the beginning or end of the buffer (or string).
- `'\<'` matches the empty string, but only at the beginning of a word. `'\<'` matches at the beginning of the buffer (or string) only if a word-constituent character follows.
- `'\>'` matches the empty string, but only at the end of a word. `'\>'` matches at the end of the buffer (or string) only if the contents end with a word-constituent character.
- `'_<'` matches the empty string, but only at the beginning of a symbol. A symbol is a sequence of one or more word or symbol constituent characters. `'_<'` matches at the beginning of the buffer (or string) only if a symbol-constituent character follows.
- `'_>'` matches the empty string, but only at the end of a symbol. `'_>'` matches at the end of the buffer (or string) only if the contents end with a symbol-constituent character.

Not every string is a valid regular expression. For example, a string that ends inside a character alternative without a terminating ‘`]`’ is invalid, and so is a string that ends with a single ‘`\`’. If an invalid regular expression is passed to any of the search functions, an `invalid-regexp` error is signaled.

35.3.2 Complex Regexp Example

Here is a complicated regexp which was formerly used by Emacs to recognize the end of a sentence together with any whitespace that follows. (Nowadays Emacs uses a similar but more complex default regexp constructed by the function `sentence-end`. See Section 35.8 [Standard Regexps], page 1020.)

Below, we show first the regexp as a string in Lisp syntax (to distinguish spaces from tab characters), and then the result of evaluating it. The string constant begins and ends with a double-quote. ‘\”’ stands for a double-quote as part of the string, ‘\\’ for a backslash as part of the string, ‘\t’ for a tab and ‘\n’ for a newline.

```
"[.?!] []\"{}]*\\($\\| $\\|\\t\\| \\)[ \\t\\n]*"
⇒ "[.?!] []\"{}]*\\($\\| $\\| \\| \\)[
]*"
```

In the output, tab and newline appear as themselves.

This regular expression contains four parts in succession and can be deciphered as follows:

`[.?!]` The first part of the pattern is a character alternative that matches any one of three characters: period, question mark, and exclamation mark. The match must begin with one of these three characters. (This is one point where the new default regexp used by Emacs differs from the old. The new value also allows some non-ASCII characters that end a sentence without any following whitespace.)

`[]\"{}]*`

The second part of the pattern matches any closing braces and quotation marks, zero or more of them, that may follow the period, question mark or exclamation mark. The \” is Lisp syntax for a double-quote in a string. The ‘*’ at the end indicates that the immediately preceding regular expression (a character alternative, in this case) may be repeated zero or more times.

`\\($\\| $\\|\\t\\| \\)`

The third part of the pattern matches the whitespace that follows the end of a sentence: the end of a line (optionally with a space), or a tab, or two spaces. The double backslashes mark the parentheses and vertical bars as regular expression syntax; the parentheses delimit a group and the vertical bars separate alternatives. The dollar sign is used to match the end of a line.

`[\\t\\n]*` Finally, the last part of the pattern matches any additional whitespace beyond the minimum needed to end a sentence.

35.3.3 Regular Expression Functions

These functions operate on regular expressions.

`regexp-quote string`

[Function]

This function returns a regular expression whose only exact match is *string*. Using this regular expression in `looking-at` will succeed only if the next characters in the buffer are *string*; using it in a search function will succeed if the text being searched contains *string*. See Section 35.4 [Regexp Search], page 1008.

This allows you to request an exact string match or search when calling a function that wants a regular expression.

```
(regexp-quote "^The cat$")
⇒ "\^The cat\$"
```

One use of `regexp-quote` is to combine an exact string match with context described as a regular expression. For example, this searches for the string that is the value of `string`, surrounded by whitespace:

```
(re-search-forward
(concat "\s- " (regexp-quote string) "\s-"))
```

The returned string may be `string` itself if it does not contain any special characters.

`regexp-opt` *strings* &`optional` *paren*

[Function]

This function returns an efficient regular expression that will match any of the strings in the list `strings`. This is useful when you need to make matching or searching as fast as possible—for example, for Font Lock mode¹.

If `strings` is the empty list, the return value is a regexp that never matches anything.

The optional argument `paren` can be any of the following:

- a string The resulting regexp is preceded by `paren` and followed by ‘\’, e.g. use “\\(?1:” to produce an explicitly numbered group.
- `words` The resulting regexp is surrounded by ‘\<\(’ and ‘\)\>’.
- `symbols` The resulting regexp is surrounded by ‘_<\(’ and ‘\)_>’ (this is often appropriate when matching programming-language keywords and the like).
- `non-nil` The resulting regexp is surrounded by ‘\(\(’ and ‘\)\’.
- `nil` The resulting regexp is surrounded by ‘\(?:’ and ‘\)\’, if it is necessary to ensure that a postfix operator appended to it will apply to the whole expression.

The returned regexp is ordered in such a way that it will always match the longest string possible.

Up to reordering, the resulting regexp of `regexp-opt` is equivalent to but usually more efficient than that of a simplified version:

```
(defun simplified-regexp-opt (strings &optional paren)
  (let ((parens
         (cond
           ((stringp paren)      (cons paren "\\\\")))
           ((eq paren 'words)    '("\\\<\\\(" . "\\\)\\\\>"))
           ((eq paren 'symbols)  '("\\\_\<\\\(" . "\\\)\\\\_>"))
           ((null paren)         '("\\\(?:" . "\\\)"))
           (t                   '("\\\(" . "\\\)")))))
```

¹ Note that `regexp-opt` does not guarantee that its result is absolutely the most efficient form possible. A hand-tuned regular expression can sometimes be slightly more efficient, but is almost never worth the effort.

```
(concat (car parens)
       (mapconcat 'regexp-quote strings "\\\\|")
       (cdr parens)))
```

regexp-opt-depth *regexp* [Function]

This function returns the total number of grouping constructs (parenthesized expressions) in *regexp*. This does not include shy groups (see Section 35.3.1.3 [Regexp Backslash], page 1001).

regexp-opt-charset *chars* [Function]

This function returns a regular expression matching a character in the list of characters *chars*.

```
(regexp-opt-charset '(?a ?b ?c ?d ?e))
⇒ "[a-e]"
```

regexp-unmatchable [Variable]

This variable contains a regexp that is guaranteed not to match any string at all. It is particularly useful as default value for variables that may be set to a pattern that actually matches something.

35.3.4 Problems with Regular Expressions

The Emacs regexp implementation, like many of its kind, is generally robust but occasionally causes trouble in either of two ways: matching may run out of internal stack space and signal an error, and it can take a long time to complete. The advice below will make these symptoms less likely and help alleviate problems that do arise.

- Anchor regexps at the beginning of a line, string or buffer using zero-width assertions ('^' and '\`'). This takes advantage of fast paths in the implementation and can avoid futile matching attempts. Other zero-width assertions may also bring benefits by causing a match to fail early.
- Avoid or-patterns in favor of character alternatives: write '[ab]' instead of 'a\b'. Recall that '\s-' and '\sw' are equivalent to '[:space:]' and '[:word:]', respectively.
- Since the last branch of an or-pattern does not add a backtrack point on the stack, consider putting the most likely matched pattern last. For example, '^\\(?:a\b|.b)*c' will run out of stack if trying to match a very long string of 'a's, but the equivalent '^\\(?:.b\b|a)*c' will not.

(It is a trade-off: successfully matched or-patterns run faster with the most frequently matched pattern first.)

- Try to ensure that any part of the text can only match in a single way. For example, 'a*a*' will match the same set of strings as 'a*', but the former can do so in many ways and will therefore cause slow backtracking if the match fails later on. Make or-pattern branches mutually exclusive if possible, so that matching will not go far into more than one branch before failing.

Be especially careful with nested repetitions: they can easily result in very slow matching in the presence of ambiguities. For example, '\(?:a*b*\)+c' will take a long time attempting to match even a moderately long string of 'a's before failing. The equivalent '\(?:a\b\)*c' is much faster, and '[ab]*c' better still.

- Don't use capturing groups unless they are really needed; that is, use '\(?:...\)' instead of '\(...\)' for bracketing purposes.

If you run into regexp stack overflow despite following the above advice, don't be afraid of performing the matching in multiple function calls, each using a simpler regexp where backtracking can more easily be contained.

35.4 Regular Expression Searching

In GNU Emacs, you can search for the next match for a regular expression (see Section 35.3.1 [Syntax of Regexp], page 996) either incrementally or not. For incremental search commands, see Section “Regular Expression Search” in *The GNU Emacs Manual*. Here we describe only the search functions useful in programs. The principal one is `re-search-forward`.

These search functions convert the regular expression to multibyte if the buffer is multibyte; they convert the regular expression to unibyte if the buffer is unibyte. See Section 34.1 [Text Representations], page 963.

`re-search-forward` *regexp* &***optional limit noerror count*** [Command]

This function searches forward in the current buffer for a string of text that is matched by the regular expression *regexp*. The function skips over any amount of text that is not matched by *regexp*, and leaves point at the end of the first match found. It returns the new value of point.

If *limit* is non-*nil*, it must be a position in the current buffer. It specifies the upper bound to the search. No match extending after that position is accepted. If *limit* is omitted or *nil*, it defaults to the end of the accessible portion of the buffer.

What `re-search-forward` does when the search fails depends on the value of *noerror*:

nil Signal a `search-failed` error.

t Do nothing and return *nil*.

anything else

Move point to *limit* (or the end of the accessible portion of the buffer) and return *nil*.

The argument *noerror* only affects valid searches which fail to find a match. Invalid arguments cause errors regardless of *noerror*.

If *count* is a positive number *n*, the search is done *n* times; each successive search starts at the end of the previous match. If all these successive searches succeed, the function call succeeds, moving point and returning its new value. Otherwise the function call fails, with results depending on the value of *noerror*, as described above. If *count* is a negative number *-n*, the search is done *n* times in the opposite (backward) direction.

In the following example, point is initially before the ‘T’. Evaluating the search call moves point to the end of that line (between the ‘t’ of ‘hat’ and the newline).

```
----- Buffer: foo -----
I read "*The cat in the hat
comes back" twice.
----- Buffer: foo -----
```

```
(re-search-forward "[a-z]+" nil t 5)
⇒ 27

----- Buffer: foo -----
I read "The cat in the hat*
comes back" twice.
----- Buffer: foo -----
```

re-search-backward *regexp &optional limit noerror count* [Command]

This function searches backward in the current buffer for a string of text that is matched by the regular expression *regexp*, leaving point at the beginning of the first text found.

This function is analogous to **re-search-forward**, but they are not simple mirror images. **re-search-forward** finds the match whose beginning is as close as possible to the starting point. If **re-search-backward** were a perfect mirror image, it would find the match whose end is as close as possible. However, in fact it finds the match whose beginning is as close as possible (and yet ends before the starting point). The reason for this is that matching a regular expression at a given spot always works from beginning to end, and starts at a specified beginning position.

A true mirror-image of **re-search-forward** would require a special feature for matching regular expressions from end to beginning. It's not worth the trouble of implementing that.

string-match *regexp string &optional start inhibit-modify* [Function]

This function returns the index of the start of the first match for the regular expression *regexp* in *string*, or *nil* if there is no match. If *start* is non-*nil*, the search starts at that index in *string*.

For example,

```
(string-match
  "quick" "The quick brown fox jumped quickly.")
⇒ 4
(string-match
  "quick" "The quick brown fox jumped quickly." 8)
⇒ 27
```

The index of the first character of the string is 0, the index of the second character is 1, and so on.

By default, if this function finds a match, the index of the first character beyond the match is available as (**match-end** 0). See Section 35.6 [Match Data], page 1011. If *inhibit-modify* is non-*nil*, the match data isn't modified.

```
(string-match
  "quick" "The quick brown fox jumped quickly." 8)
⇒ 27

(match-end 0)
⇒ 32
```

string-match-p *regexp string &optional start* [Function]

This predicate function does what `string-match` does, but it avoids modifying the match data.

looking-at *regexp &optional inhibit-modify* [Function]

This function determines whether the text in the current buffer directly following point matches the regular expression *regexp*. “Directly following” means precisely that: the search is “anchored” and it can succeed only starting with the first character following point. The result is `t` if so, `nil` otherwise.

This function does not move point, but it does update the match data (if *inhibit-modify* is `nil` or missing, which is the default). See Section 35.6 [Match Data], page 1011. As a convenience, instead of using the *inhibit-modify* argument, you can use `looking-at-p`, described below.

In this example, point is located directly before the ‘T’. If it were anywhere else, the result would be `nil`.

```
----- Buffer: foo -----
I read "*The cat in the hat
comes back" twice.
----- Buffer: foo -----
```

```
(looking-at "The cat in the hat$")
⇒ t
```

looking-back *regexp limit &optional greedy* [Function]

This function returns `t` if *regexp* matches the text immediately before point (i.e., ending at point), and `nil` otherwise.

Because regular expression matching works only going forward, this is implemented by searching backwards from point for a match that ends at point. That can be quite slow if it has to search a long distance. You can bound the time required by specifying a non-`nil` value for *limit*, which says not to search before *limit*. In this case, the match that is found must begin at or after *limit*. Here’s an example:

```
----- Buffer: foo -----
I read "*The cat in the hat
comes back" twice.
----- Buffer: foo -----
```

```
(looking-back "read \"\" 3)
⇒ t
(looking-back "read \"\" 4)
⇒ nil
```

If *greedy* is non-`nil`, this function extends the match backwards as far as possible, stopping when a single additional previous character cannot be part of a match for *regexp*. When the match is extended, its starting position is allowed to occur before *limit*.

As a general recommendation, try to avoid using `looking-back` wherever possible, since it is slow. For this reason, there are no plans to add a `looking-back-p` function.

looking-at-p *regexp*

[Function]

This predicate function works like `looking-at`, but without updating the match data.

search-spaces-regexp

[Variable]

If this variable is non-`nil`, it should be a regular expression that says how to search for whitespace. In that case, any group of spaces in a regular expression being searched for stands for use of this regular expression. However, spaces inside of constructs such as ‘[...]’ and ‘*’, ‘+’, ‘?’ are not affected by `search-spaces-regexp`.

Since this variable affects all regular expression search and match constructs, you should bind it temporarily for as small as possible a part of the code, and only where the Lisp code affected by the binding performs searches whose regexp was produced from interactive user input. In other words, this variable should only be used to tell regexp search primitives how to interpret whitespace typed by the user.

35.5 POSIX Regular Expression Searching

The usual regular expression functions do backtracking when necessary to handle the ‘\|’ and repetition constructs, but they continue this only until they find *some* match. Then they succeed and report the first match found.

This section describes alternative search functions which perform the full backtracking specified by the POSIX standard for regular expression matching. They continue backtracking until they have tried all possibilities and found all matches, so they can report the longest match, as required by POSIX. This is much slower, so use these functions only when you really need the longest match.

The POSIX search and match functions do not properly support the non-greedy repetition operators (see Section 35.3.1.1 [Regexp Special], page 996). This is because POSIX backtracking conflicts with the semantics of non-greedy repetition.

posix-search-forward *regexp* &**optional** *limit* *noerror* *count*

[Command]

This is like `re-search-forward` except that it performs the full backtracking specified by the POSIX standard for regular expression matching.

posix-search-backward *regexp* &**optional** *limit* *noerror* *count*

[Command]

This is like `re-search-backward` except that it performs the full backtracking specified by the POSIX standard for regular expression matching.

posix-looking-at *regexp* &**optional** *inhibit-modify*

[Function]

This is like `looking-at` except that it performs the full backtracking specified by the POSIX standard for regular expression matching.

posix-string-match *regexp* *string* &**optional** *start* *inhibit-modify*

[Function]

This is like `string-match` except that it performs the full backtracking specified by the POSIX standard for regular expression matching.

35.6 The Match Data

Emacs keeps track of the start and end positions of the segments of text found during a search; this is called the *match data*. Thanks to the match data, you can search for a

complex pattern, such as a date in a mail message, and then extract parts of the match under control of the pattern.

Because the match data normally describe the most recent search only, you must be careful not to do another search inadvertently between the search you wish to refer back to and the use of the match data. If you can't avoid another intervening search, you must save and restore the match data around it, to prevent it from being overwritten.

Notice that all functions are allowed to overwrite the match data unless they're explicitly documented not to do so. A consequence is that functions that are run implicitly in the background (see Section 42.11 [Timers], page 1281, and Section 42.12 [Idle Timers], page 1284) should likely save and restore the match data explicitly.

35.6.1 Replacing the Text that Matched

This function replaces all or part of the text matched by the last search. It works by means of the match data.

`replace-match replacement &optional fixedcase literal string subexp` [Function]

This function performs a replacement operation on a buffer or string.

If you did the last search in a buffer, you should omit the *string* argument or specify `nil` for it, and make sure that the current buffer is the one in which you performed the last search. Then this function edits the buffer, replacing the matched text with *replacement*. It leaves point at the end of the replacement text.

If you performed the last search on a string, pass the same string as *string*. Then this function returns a new string, in which the matched text is replaced by *replacement*.

If *fixedcase* is non-`nil`, then `replace-match` uses the replacement text without case conversion; otherwise, it converts the replacement text depending upon the capitalization of the text to be replaced. If the original text is all upper case, this converts the replacement text to upper case. If all words of the original text are capitalized, this capitalizes all the words of the replacement text. If all the words are one-letter and they are all upper case, they are treated as capitalized words rather than all-upper-case words.

If *literal* is non-`nil`, then *replacement* is inserted exactly as it is, the only alterations being case changes as needed. If it is `nil` (the default), then the character ‘\’ is treated specially. If a ‘\’ appears in *replacement*, then it must be part of one of the following sequences:

‘\&’ This stands for the entire text being replaced.

‘\n’, where *n* is a digit

This stands for the text that matched the *n*th subexpression in the original regexp. Subexpressions are those expressions grouped inside ‘\(...\)''. If the *n*th subexpression never matched, an empty string is substituted.

‘\\’ This stands for a single ‘\’ in the replacement text.

‘\?’ This stands for itself (for compatibility with `replace-regexp` and related commands; see Section “Regexp Replace” in *The GNU Emacs Manual*).

Any other character following ‘\’ signals an error.

The substitutions performed by ‘\&’ and ‘\n’ occur after case conversion, if any. Therefore, the strings they substitute are never case-converted.

If *subexp* is non-*nil*, that says to replace just subexpression number *subexp* of the regexp that was matched, not the entire match. For example, after matching ‘foo \(\ba*\r\)\’, calling `replace-match` with 1 as *subexp* means to replace just the text that matched ‘\(\ba*\r\)\’.

match-substitute-replacement *replacement* &*optional fixedcase* [Function]
literal string subexp

This function returns the text that would be inserted into the buffer by `replace-match`, but without modifying the buffer. It is useful if you want to present the user with actual replacement result, with constructs like ‘\n’ or ‘\&’ substituted with matched groups. Arguments *replacement* and optional *fixedcase*, *literal*, *string* and *subexp* have the same meaning as for `replace-match`.

35.6.2 Simple Match Data Access

This section explains how to use the match data to find out what was matched by the last search or match operation, if it succeeded.

You can ask about the entire matching text, or about a particular parenthetical subexpression of a regular expression. The *count* argument in the functions below specifies which. If *count* is zero, you are asking about the entire match. If *count* is positive, it specifies which subexpression you want.

Recall that the subexpressions of a regular expression are those expressions grouped with escaped parentheses, ‘\(\dots\)\’. The *count*th subexpression is found by counting occurrences of ‘\C’ from the beginning of the whole regular expression. The first subexpression is numbered 1, the second 2, and so on. Only regular expressions can have subexpressions—after a simple string search, the only information available is about the entire match.

Every successful search sets the match data. Therefore, you should query the match data immediately after searching, before calling any other function that might perform another search. Alternatively, you may save and restore the match data (see Section 35.6.4 [Saving Match Data], page 1016) around the call to functions that could perform another search. Or use the functions that explicitly do not modify the match data; e.g., `string-match-p`.

A search which fails may or may not alter the match data. In the current implementation, it does not, but we may change it in the future. Don’t try to rely on the value of the match data after a failing search.

match-string *count* &*optional in-string* [Function]

This function returns, as a string, the text matched in the last search or match operation. It returns the entire text if *count* is zero, or just the portion corresponding to the *count*th parenthetical subexpression, if *count* is positive.

If the last such operation was done against a string with `string-match`, then you should pass the same string as the argument *in-string*. After a buffer search or match, you should omit *in-string* or pass *nil* for it; but you should make sure that the current buffer when you call `match-string` is the one in which you did the searching or matching. Failure to follow this advice will lead to incorrect results.

The value is *nil* if *count* is out of range, or for a subexpression inside a ‘\|’ alternative that wasn’t used or a repetition that repeated zero times.

match-string-no-properties count &optional in-string [Function]

This function is like `match-string` except that the result has no text properties.

match-beginning count [Function]

If the last regular expression search found a match, this function returns the position of the start of the matching text or of a subexpression of it.

If *count* is zero, then the value is the position of the start of the entire match. Otherwise, *count* specifies a subexpression in the regular expression, and the value of the function is the starting position of the match for that subexpression.

The value is `nil` for a subexpression inside a ‘`\|`’ alternative that wasn’t used or a repetition that repeated zero times.

match-end count [Function]

This function is like `match-beginning` except that it returns the position of the end of the match, rather than the position of the beginning.

Here is an example of using the match data, with a comment showing the positions within the text:

```
(string-match "\\(qu\\)\\(ick\\)"
             "The quick fox jumped quickly."
             ;0123456789
⇒ 4

(match-string 0 "The quick fox jumped quickly.")
⇒ "quick"
(match-string 1 "The quick fox jumped quickly.")
⇒ "qu"
(match-string 2 "The quick fox jumped quickly.")
⇒ "ick"

(match-beginning 1)      ; The beginning of the match
⇒ 4                    ; with 'qu' is at index 4.

(match-beginning 2)      ; The beginning of the match
⇒ 6                    ; with 'ick' is at index 6.

(match-end 1)            ; The end of the match
⇒ 6                    ; with 'qu' is at index 6.

(match-end 2)            ; The end of the match
⇒ 9                    ; with 'ick' is at index 9.
```

Here is another example. Point is initially located at the beginning of the line. Searching moves point to between the space and the word ‘in’. The beginning of the entire match is at the 9th character of the buffer (‘T’), and the beginning of the match for the first subexpression is at the 13th character (‘c’).

```
(list
  (re-search-forward "The \\(cat \\)")
  (match-beginning 0)
  (match-beginning 1))
  ⇒ (17 9 13)

----- Buffer: foo -----
I read "The cat *in the hat comes back" twice.
^ ^  
9 13
----- Buffer: foo -----
```

(In this case, the index returned is a buffer position; the first character of the buffer counts as 1.)

35.6.3 Accessing the Entire Match Data

The functions `match-data` and `set-match-data` read or write the entire match data, all at once.

`match-data &optional integers reuse reseat`

[Function]

This function returns a list of positions (markers or integers) that record all the information on the text that the last search matched. Element zero is the position of the beginning of the match for the whole expression; element one is the position of the end of the match for the expression. The next two elements are the positions of the beginning and end of the match for the first subexpression, and so on. In general, element number $2n$ corresponds to `(match-beginning n)`; and element number $2n + 1$ corresponds to `(match-end n)`.

Normally all the elements are markers or `nil`, but if `integers` is non-`nil`, that means to use integers instead of markers. (In that case, the buffer itself is appended as an additional element at the end of the list, to facilitate complete restoration of the match data.) If the last match was done on a string with `string-match`, then integers are always used, since markers can't point into a string.

If `reuse` is non-`nil`, it should be a list. In that case, `match-data` stores the match data in `reuse`. That is, `reuse` is destructively modified. `reuse` does not need to have the right length. If it is not long enough to contain the match data, it is extended. If it is too long, the length of `reuse` stays the same, but the elements that were not used are set to `nil`. The purpose of this feature is to reduce the need for garbage collection.

If `reseat` is non-`nil`, all markers on the `reuse` list are reseated to point to nowhere.

As always, there must be no possibility of intervening searches between the call to a search function and the call to `match-data` that is intended to access the match data for that search.

```
(match-data)
  ⇒ (#<marker at 9 in foo>
      #<marker at 17 in foo>
      #<marker at 13 in foo>
      #<marker at 17 in foo>)
```

set-match-data *match-list* &**optional** *reseat* [Function]

This function sets the match data from the elements of *match-list*, which should be a list that was the value of a previous call to **match-data**. (More precisely, anything that has the same format will work.)

If *match-list* refers to a buffer that doesn't exist, you don't get an error; that sets the match data in a meaningless but harmless way.

If *reseat* is non-**nil**, all markers on the *match-list* list are reseated to point to nowhere.

store-match-data is a semi-obsolete alias for **set-match-data**.

35.6.4 Saving and Restoring the Match Data

When you call a function that may search, you may need to save and restore the match data around that call, if you want to preserve the match data from an earlier search for later use. Here is an example that shows the problem that arises if you fail to save the match data:

```
(re-search-forward "The \\(cat \\\")"
                  ⇒ 48
  (foo)           ; foo does more searching.
  (match-end 0)
                  ⇒ 61           ; Unexpected result—not 48!
```

You can save and restore the match data with **save-match-data**:

save-match-data *body...* [Macro]

This macro executes *body*, saving and restoring the match data around it. The return value is the value of the last form in *body*.

You could use **set-match-data** together with **match-data** to imitate the effect of the special form **save-match-data**. Here is how:

```
(let ((data (match-data)))
  (unwind-protect
    ...
    ; Ok to change the original match data.
    (set-match-data data)))
```

Emacs automatically saves and restores the match data when it runs process filter functions (see Section 40.9.2 [Filter Functions], page 1101) and process sentinels (see Section 40.10 [Sentinels], page 1105).

35.7 Search and Replace

If you want to find all matches for a regexp in part of the buffer and replace them, the most flexible way is to write an explicit loop using **re-search-forward** and **replace-match**, like this:

```
(while (re-search-forward "foo[ \t]+bar" nil t)
      (replace-match "foobar"))
```

See Section 35.6.1 [Replacing the Text that Matched], page 1012, for a description of **replace-match**.

It may be more convenient to limit the replacements to a specific region. The function **replace-regexp-in-region** does that.

replace-regexp-in-region *regexp replacement &optional start end* [Function]

This function replaces all the occurrences of *regexp* with *replacement* in the region of buffer text between *start* and *end*; *start* defaults to position of point, and *end* defaults to the last accessible position of the buffer. The search for *regexp* is case-sensitive, and *replacement* is inserted without changing its letter-case. The *replacement* string can use the same special elements starting with ‘\’ as **replace-match** does. The function returns the number of replaced occurrences, or **nil** if *regexp* is not found. The function preserves the position of point.

```
(replace-regexp-in-region "foo[ \t]+bar" "foobar")
```

replace-string-in-region *string replacement &optional start end* [Function]

This function works similarly to **replace-regexp-in-region**, but searches for, and replaces, literal *strings* instead of regular expressions.

Emacs also has special functions for replacing matches in a string.

replace-regexp-in-string *regexp rep string &optional fixedcase
literal subexp start* [Function]

This function copies *string* and searches it for matches for *regexp*, and replaces them with *rep*. It returns the modified copy. If *start* is non-**nil**, the search for matches starts at that index in *string*, and the returned value does not include the first *start* characters of *string*. To get the whole transformed string, concatenate the first *start* characters of *string* with the return value.

This function uses **replace-match** to do the replacement, and it passes the optional arguments *fixedcase*, *literal* and *subexp* along to **replace-match**.

Instead of a string, *rep* can be a function. In that case, **replace-regexp-in-string** calls *rep* for each match, passing the text of the match as its sole argument. It collects the value *rep* returns and passes that to **replace-match** as the replacement string. The match data at this point are the result of matching *regexp* against a substring of *string*.

string-replace *from-string to-string in-string* [Function]

This function replaces all occurrences of *from-string* with *to-string* in *in-string* and returns the result. It may return one of its arguments unchanged, a constant string or a new string. Case is significant, and text properties are ignored.

If you want to write a command along the lines of **query-replace**, you can use **perform-replace** to do the work.

perform-replace *from-string replacements query-flag regexp-flag
delimited-flag &optional repeat-count map start end backward
region-noncontiguous-p* [Function]

This function is the guts of **query-replace** and related commands. It searches for occurrences of *from-string* in the text between positions *start* and *end* and replaces some or all of them. If *start* is **nil** (or omitted), point is used instead, and the end of the buffer’s accessible portion is used for *end*. (If the optional argument *backward* is non-**nil**, the search starts at *end* and goes backward.)

If *query-flag* is `nil`, it replaces all occurrences; otherwise, it asks the user what to do about each one.

If *regexp-flag* is non-`nil`, then *from-string* is considered a regular expression; otherwise, it must match literally. If *delimited-flag* is non-`nil`, then only replacements surrounded by word boundaries are considered.

The argument *replacements* specifies what to replace occurrences with. If it is a string, that string is used. It can also be a list of strings, to be used in cyclic order.

If *replacements* is a cons cell, `(function . data)`, this means to call *function* after each match to get the replacement text. This function is called with two arguments: *data*, and the number of replacements already made.

If *repeat-count* is non-`nil`, it should be an integer. Then it specifies how many times to use each of the strings in the *replacements* list before advancing cyclically to the next one.

If *from-string* contains upper-case letters, then `perform-replace` binds `case-fold-search` to `nil`, and it uses the *replacements* without altering their case.

Normally, the keymap `query-replace-map` defines the possible user responses for queries. The argument *map*, if non-`nil`, specifies a keymap to use instead of `query-replace-map`.

Non-`nil` *region-noncontiguous-p* means that the region between *start* and *end* is composed of noncontiguous pieces. The most common example of this is a rectangular region, where the pieces are separated by newline characters.

This function uses one of two functions to search for the next occurrence of *from-string*. These functions are specified by the values of two variables: `replace-re-search-function` and `replace-search-function`. The former is called when the argument *regexp-flag* is non-`nil`, the latter when it is `nil`.

`query-replace-map` [Variable]

This variable holds a special keymap that defines the valid user responses for `perform-replace` and the commands that use it, as well as `y-or-n-p` and `map-y-or-n-p`. This map is unusual in two ways:

- The key bindings are not commands, just symbols that are meaningful to the functions that use this map.
- Prefix keys are not supported; each key binding must be for a single-event key sequence. This is because the functions don't use `read-key-sequence` to get the input; instead, they read a single event and look it up "by hand".

Here are the meaningful bindings for `query-replace-map`. Several of them are meaningful only for `query-replace` and friends.

<code>act</code>	Do take the action being considered—in other words, "yes".
<code>skip</code>	Do not take action for this question—in other words, "no".
<code>exit</code>	Answer this question "no", and give up on the entire series of questions, assuming that the answers will be "no".

exit-prefix

Like `exit`, but add the key that was pressed to `unread-command-events` (see Section 22.8.6 [Event Input Misc], page 468).

act-and-exit

Answer this question “yes”, and give up on the entire series of questions, assuming that subsequent answers will be “no”.

act-and-show

Answer this question “yes”, but show the results—don’t advance yet to the next question.

automatic

Answer this question and all subsequent questions in the series with “yes”, without further user interaction.

backup Move back to the previous place that a question was asked about.

undo Undo last replacement and move back to the place where that replacement was performed.

undo-all Undo all replacements and move back to the place where the first replacement was performed.

edit Enter a recursive edit to deal with this question—instead of any other action that would normally be taken.

edit-replacement

Edit the replacement for this question in the minibuffer.

delete-and-edit

Delete the text being considered, then enter a recursive edit to replace it.

recenter

scroll-up

scroll-down

scroll-other-window

scroll-other-window-down

Perform the specified window scroll operation, then ask the same question again. Only `y-or-n-p` and related functions use this answer.

quit Perform a quit right away. Only `y-or-n-p` and related functions use this answer.

help Display some help, then ask again.

multi-query-replace-map

[Variable]

This variable holds a keymap that extends `query-replace-map` by providing additional key bindings that are useful in multi-buffer replacements. The additional bindings are:

automatic-all

Answer this question and all subsequent questions in the series with “yes”, without further user interaction, for all remaining buffers.

exit-current

Answer this question “no”, and give up on the entire series of questions for the current buffer. Continue to the next buffer in the sequence.

replace-search-function [Variable]

This variable specifies a function that `perform-replace` calls to search for the next string to replace. Its default value is `search-forward`. Any other value should name a function of 3 arguments: the first 3 arguments of `search-forward` (see Section 35.1 [String Search], page 993).

replace-re-search-function [Variable]

This variable specifies a function that `perform-replace` calls to search for the next regexp to replace. Its default value is `re-search-forward`. Any other value should name a function of 3 arguments: the first 3 arguments of `re-search-forward` (see Section 35.4 [Regexp Search], page 1008).

35.8 Standard Regular Expressions Used in Editing

This section describes some variables that hold regular expressions used for certain purposes in editing:

page-delimiter [User Option]

This is the regular expression describing line-beginnings that separate pages. The default value is "`^\014`" (i.e., "`^\^L`" or "`^\C-1`"); this matches a line that starts with a formfeed character.

The following two regular expressions should *not* assume the match always starts at the beginning of a line; they should not use ‘`^`’ to anchor the match. Most often, the paragraph commands do check for a match only at the beginning of a line, which means that ‘`^`’ would be superfluous. When there is a nonzero left margin, they accept matches that start after the left margin. In that case, a ‘`^`’ would be incorrect. However, a ‘`^`’ is harmless in modes where a left margin is never used.

paragraph-separate [User Option]

This is the regular expression for recognizing the beginning of a line that separates paragraphs. (If you change this, you may have to change `paragraph-start` also.) The default value is "`[\t\f]*$`", which matches a line that consists entirely of spaces, tabs, and form feeds (after its left margin).

paragraph-start [User Option]

This is the regular expression for recognizing the beginning of a line that starts *or* separates paragraphs. The default value is "`\f\\|[\t]*$`", which matches a line containing only whitespace or starting with a form feed (after its left margin).

sentence-end [User Option]

If non-`nil`, the value should be a regular expression describing the end of a sentence, including the whitespace following the sentence. (All paragraph boundaries also end sentences, regardless.)

If the value is `nil`, as it is by default, then the function `sentence-end` constructs the regexp. That is why you should always call the function `sentence-end` to obtain the regexp to be used to recognize the end of a sentence.

sentence-end

[Function]

This function returns the value of the variable `sentence-end`, if non-nil. Otherwise it returns a default value based on the values of the variables `sentence-end-double-space` (see [Definition of sentence-end-double-space], page 901), `sentence-end-without-period`, and `sentence-end-without-space`.

36 Syntax Tables

A *syntax table* specifies the syntactic role of each character in a buffer. It can be used to determine where words, symbols, and other syntactic constructs begin and end. This information is used by many Emacs facilities, including Font Lock mode (see Section 24.6 [Font Lock Mode], page 563) and the various complex movement commands (see Section 31.2 [Motion], page 854).

36.1 Syntax Table Concepts

A syntax table is a data structure which can be used to look up the *syntax class* and other syntactic properties of each character. Syntax tables are used by Lisp programs for scanning and moving across text.

Internally, a syntax table is a char-table (see Section 6.6 [Char-Tables], page 119). The element at index *c* describes the character with code *c*; its value is a cons cell which specifies the syntax of the character in question. See Section 36.7 [Syntax Table Internals], page 1034, for details. However, instead of using `aset` and `aref` to modify and inspect syntax table contents, you should usually use the higher-level functions `char-syntax` and `modify-syntax-entry`, which are described in Section 36.3 [Syntax Table Functions], page 1027.

`syntax-table-p object` [Function]

This function returns `t` if *object* is a syntax table.

Each buffer has its own major mode, and each major mode has its own idea of the syntax class of various characters. For example, in Lisp mode, the character ‘;’ begins a comment, but in C mode, it terminates a statement. To support these variations, the syntax table is local to each buffer. Typically, each major mode has its own syntax table, which it installs in all buffers that use that mode. For example, the variable `emacs-lisp-mode-syntax-table` holds the syntax table used by Emacs Lisp mode, and `c-mode-syntax-table` holds the syntax table used by C mode. Changing a major mode’s syntax table alters the syntax in all of that mode’s buffers, as well as in any buffers subsequently put in that mode. Occasionally, several similar modes share one syntax table. See Section 24.2.9 [Example Major Modes], page 542, for an example of how to set up a syntax table.

A syntax table can *inherit* from another syntax table, which is called its *parent syntax table*. A syntax table can leave the syntax class of some characters unspecified, by giving them the “inherit” syntax class; such a character then acquires the syntax class specified by the parent syntax table (see Section 36.2.1 [Syntax Class Table], page 1023). Emacs defines a *standard syntax table*, which is the default parent syntax table, and is also the syntax table used by Fundamental mode.

`standard-syntax-table` [Function]

This function returns the standard syntax table, which is the syntax table used in Fundamental mode.

Syntax tables are not used by the Emacs Lisp reader, which has its own built-in syntactic rules which cannot be changed. (Some Lisp systems provide ways to redefine the read syntax, but we decided to leave this feature out of Emacs Lisp for simplicity.)

36.2 Syntax Descriptors

The *syntax class* of a character describes its syntactic role. Each syntax table specifies the syntax class of each character. There is no necessary relationship between the class of a character in one syntax table and its class in any other table.

Each syntax class is designated by a mnemonic character, which serves as the name of the class when you need to specify a class. Usually, this designator character is one that is often assigned that class; however, its meaning as a designator is unvarying and independent of what syntax that character currently has. Thus, ‘\’ as a designator character always stands for escape character syntax, regardless of whether the ‘\’ character actually has that syntax in the current syntax table.

A *syntax descriptor* is a Lisp string that describes the syntax class and other syntactic properties of a character. When you want to modify the syntax of a character, that is done by calling the function `modify-syntax-entry` and passing a syntax descriptor as one of its arguments (see Section 36.3 [Syntax Table Functions], page 1027).

The first character in a syntax descriptor must be a syntax class designator character. The second character, if present, specifies a matching character (e.g., in Lisp, the matching character for ‘(’ is ‘)’); a space specifies that there is no matching character. Then come characters specifying additional syntax properties (see Section 36.2.2 [Syntax Flags], page 1026).

If no matching character or flags are needed, only one character (specifying the syntax class) is sufficient.

For example, the syntax descriptor for the character ‘*’ in C mode is “. 23” (i.e., punctuation, matching character slot unused, second character of a comment-starter, first character of a comment-ender), and the entry for ‘/’ is ‘. 14’ (i.e., punctuation, matching character slot unused, first character of a comment-starter, second character of a comment-ender).

Emacs also defines *raw syntax descriptors*, which are used to describe syntax classes at a lower level. See Section 36.7 [Syntax Table Internals], page 1034.

36.2.1 Table of Syntax Classes

Here is a table of syntax classes, the characters that designate them, their meanings, and examples of their use.

Whitespace characters: ‘ ’ or ‘-’

Characters that separate symbols and words from each other. Typically, whitespace characters have no other syntactic significance, and multiple whitespace characters are syntactically equivalent to a single one. Space, tab, and formfeed are classified as whitespace in almost all major modes.

This syntax class can be designated by either ‘ ’ or ‘-’. Both designators are equivalent.

Word constituents: ‘w’

Parts of words in human languages. These are typically used in variable and command names in programs. All upper- and lower-case letters, and the digits, are typically word constituents.

Symbol constituents: ‘_’

Extra characters used in variable and command names along with word constituents. Examples include the characters ‘\$&*+-_<>’ in Lisp mode, which may be part of a symbol name even though they are not part of English words. In standard C, the only non-word-constituent character that is valid in symbols is underscore (‘_’).

Punctuation characters: ‘.’

Characters used as punctuation in a human language, or used in a programming language to separate symbols from one another. Some programming language modes, such as Emacs Lisp mode, have no characters in this class since the few characters that are not symbol or word constituents all have other uses. Other programming language modes, such as C mode, use punctuation syntax for operators.

Open parenthesis characters: ‘(’

Close parenthesis characters: ‘)’

Characters used in dissimilar pairs to surround sentences or expressions. Such a grouping is begun with an open parenthesis character and terminated with a close. Each open parenthesis character matches a particular close parenthesis character, and vice versa. Normally, Emacs indicates momentarily the matching open parenthesis when you insert a close parenthesis. See Section 41.22 [Blinking], page 1241.

In human languages, and in C code, the parenthesis pairs are ‘()’, ‘[]’, and ‘{}’. In Emacs Lisp, the delimiters for lists and vectors (‘()’ and ‘[]’) are classified as parenthesis characters.

String quotes: “”

Characters used to delimit string constants. The same string quote character appears at the beginning and the end of a string. Such quoted strings do not nest.

The parsing facilities of Emacs consider a string as a single token. The usual syntactic meanings of the characters in the string are suppressed.

The Lisp modes have two string quote characters: double-quote (“”) and vertical bar (‘|’). ‘|’ is not used in Emacs Lisp, but it is used in Common Lisp. C also has two string quote characters: double-quote for strings, and apostrophe (‘’’) for character constants.

Human text has no string quote characters. We do not want quotation marks to turn off the usual syntactic properties of other characters in the quotation.

Escape-syntax characters: ‘\’

Characters that start an escape sequence, such as is used in string and character constants. The character ‘\’ belongs to this class in both C and Lisp. (In C, it is used thus only inside strings, but it turns out to cause no trouble to treat it this way throughout C code.)

Characters in this class count as part of words if `words-include-escapes` is non-`nil`. See Section 31.2.2 [Word Motion], page 855.

Character quotes: ‘/’

Characters used to quote the following character so that it loses its normal syntactic meaning. This differs from an escape character in that only the character immediately following is ever affected.

Characters in this class count as part of words if `words-include-escapes` is non-`nil`. See Section 31.2.2 [Word Motion], page 855.

This class is used for backslash in TeX mode.

Paired delimiters: ‘\$’

Similar to string quote characters, except that the syntactic properties of the characters between the delimiters are not suppressed. Only TeX mode uses a paired delimiter presently—the ‘\$’ that both enters and leaves math mode.

Expression prefixes: ‘‘’

Characters used for syntactic operators that are considered as part of an expression if they appear next to one. In Lisp modes, these characters include the apostrophe, ‘‘’ (used for quoting), the comma, ‘,’ (used in macros), and ‘#’ (used in the read syntax for certain data types).

Comment starters: ‘<’

Comment enders: ‘>’

Characters used in various languages to delimit comments. Human text has no comment characters. In Lisp, the semicolon (‘;’) starts a comment and a newline or formfeed ends one.

Inherit standard syntax: ‘@’

This syntax class does not specify a particular syntax. It says to look in the parent syntax table to find the syntax of this character.

Generic comment delimiters: ‘!’

(This syntax class is also known as “comment-fence”.) Characters that start or end a special kind of comment. *Any* generic comment delimiter matches *any* generic comment delimiter, but they cannot match a comment starter or comment ender; generic comment delimiters can only match each other.

This syntax class is primarily meant for use with the `syntax-table` text property (see Section 36.4 [Syntax Properties], page 1029). You can mark any range of characters as forming a comment, by giving the first and last characters of the range `syntax-table` properties identifying them as generic comment delimiters.

Generic string delimiters: ‘|’

(This syntax class is also known as “string-fence”.) Characters that start or end a string. This class differs from the string quote class in that *any* generic string delimiter can match any other generic string delimiter; but they do not match ordinary string quote characters.

This syntax class is primarily meant for use with the `syntax-table` text property (see Section 36.4 [Syntax Properties], page 1029). You can mark any range of characters as forming a string constant, by giving the first and last characters of the range `syntax-table` properties identifying them as generic string delimiters.

36.2.2 Syntax Flags

In addition to the classes, entries for characters in a syntax table can specify flags. There are eight possible flags, represented by the characters ‘1’, ‘2’, ‘3’, ‘4’, ‘b’, ‘c’, ‘n’, and ‘p’.

All the flags except ‘p’ are used to describe comment delimiters. The digit flags are used for comment delimiters made up of 2 characters. They indicate that a character can *also* be part of a comment sequence, in addition to the syntactic properties associated with its character class. The flags are independent of the class and each other for the sake of characters such as ‘*’ in C mode, which is a punctuation character, *and* the second character of a start-of-comment sequence (‘/*’), *and* the first character of an end-of-comment sequence (‘*/’). The flags ‘b’, ‘c’, and ‘n’ are used to qualify the corresponding comment delimiter.

Here is a table of the possible flags for a character *c*, and what they mean:

- ‘1’ means *c* is the start of a two-character comment-start sequence.
- ‘2’ means *c* is the second character of such a sequence.
- ‘3’ means *c* is the start of a two-character comment-end sequence.
- ‘4’ means *c* is the second character of such a sequence.
- ‘b’ means that *c* as a comment delimiter belongs to the alternative “b” comment style. For a two-character comment starter, this flag is only significant on the second char, and for a 2-character comment ender it is only significant on the first char.
- ‘c’ means that *c* as a comment delimiter belongs to the alternative “c” comment style. For a two-character comment delimiter, ‘c’ on either character makes it of style “c”.
- ‘n’ on a comment delimiter character specifies that this kind of comment can be nested. Inside such a comment, only comments of the same style will be recognized. For a two-character comment delimiter, ‘n’ on either character makes it nestable.

Emacs supports several comment styles simultaneously in any one syntax table. A comment style is a set of flags ‘b’, ‘c’, and ‘n’, so there can be up to 8 different comment styles, each one named by the set of its flags. Each comment delimiter has a style and only matches comment delimiters of the same style. Thus if a comment starts with the comment-start sequence of style “bn”, it will extend until the next matching comment-end sequence of style “bn”. When the set of flags has neither flag ‘b’ nor flag ‘c’ set, the resulting style is called the “a” style.

The appropriate comment syntax settings for C++ can be as follows:

‘/’	‘124’
‘*’	‘23b’
newline	‘>’

This defines four comment-delimiting sequences:

- ‘/*’ This is a comment-start sequence for “b” style because the second character, ‘*’, has the ‘b’ flag.
- ‘//’ This is a comment-start sequence for “a” style because the second character, ‘/’, does not have the ‘b’ flag.
- ‘*/’ This is a comment-end sequence for “b” style because the first character, ‘*’, has the ‘b’ flag.

- newline This is a comment-end sequence for “a” style, because the newline character does not have the ‘b’ flag.
- ‘p’ identifies an additional prefix character for Lisp syntax. These characters are treated as whitespace when they appear between expressions. When they appear within an expression, they are handled according to their usual syntax classes.
The function `backward-prefix-chars` moves back over these characters, as well as over characters whose primary syntax class is prefix (‘’). See Section 36.5 [Motion and Syntax], page 1030.

36.3 Syntax Table Functions

In this section we describe functions for creating, accessing and altering syntax tables.

make-syntax-table &optional *table* [Function]

This function creates a new syntax table. If *table* is non-`nil`, the parent of the new syntax table is *table*; otherwise, the parent is the standard syntax table.

In the new syntax table, all characters are initially given the “inherit” (‘@’) syntax class, i.e., their syntax is inherited from the parent table (see Section 36.2.1 [Syntax Class Table], page 1023).

copy-syntax-table &optional *table* [Function]

This function constructs a copy of *table* and returns it. If *table* is omitted or `nil`, it returns a copy of the standard syntax table. Otherwise, an error is signaled if *table* is not a syntax table.

modify-syntax-entry *char* *syntax-descriptor* &optional *table* [Command]

This function sets the syntax entry for *char* according to *syntax-descriptor*. *char* must be a character, or a cons cell of the form (*min* . *max*); in the latter case, the function sets the syntax entries for all characters in the range between *min* and *max*, inclusive. The syntax is changed only for *table*, which defaults to the current buffer’s syntax table, and not in any other syntax table.

The argument *syntax-descriptor* is a syntax descriptor, i.e., a string whose first character is a syntax class designator and whose second and subsequent characters optionally specify a matching character and syntax flags. See Section 36.2 [Syntax Descriptors], page 1023. An error is signaled if *syntax-descriptor* is not a valid syntax descriptor.

This function always returns `nil`. The old syntax information in the table for this character is discarded.

Examples:

```
;; Put the space character in class whitespace.
(modify-syntax-entry ?\s " ")
⇒ nil
```

```
;; Make '$' an open parenthesis character,
;;   with '^' as its matching close.
(modify-syntax-entry ?$ "(")
⇒ nil
```

```

;; Make `~` a close parenthesis character,
;;   with `$' as its matching open.
(modify-syntax-entry ?^ ")$")
⇒ nil

;; Make `/` a punctuation character,
;;   the first character of a start-comment sequence,
;;   and the second character of an end-comment sequence.
;;   This is used in C mode.
(modify-syntax-entry ?/ ". 14")
⇒ nil

```

char-syntax *character*

[Function]

This function returns the syntax class of *character*, represented by its designator character (see Section 36.2.1 [Syntax Class Table], page 1023). This returns *only* the class, not its matching character or syntax flags.

The following examples apply to C mode. (We use **string** to make it easier to see the character returned by **char-syntax**.)

```

;; Space characters have whitespace syntax class.
(string (char-syntax ?\s))
⇒ " "

;; Forward slash characters have punctuation syntax.
;; Note that this char-syntax call does not reveal
;; that it is also part of comment-start and -end sequences.
(string (char-syntax ?/))
⇒ "."

;; Open parenthesis characters have open parenthesis syntax.
;; Note that this char-syntax call does not reveal that
;; it has a matching character, ')'.
(string (char-syntax ?\()))
⇒ "("

```

set-syntax-table *table*

[Function]

This function makes *table* the syntax table for the current buffer. It returns *table*.

syntax-table

[Function]

This function returns the current syntax table, which is the table for the current buffer.

describe-syntax &**optional** *buffer*

[Command]

This command displays the contents of the syntax table of *buffer* (by default, the current buffer) in a help buffer.

with-syntax-table *table* *body*...

[Macro]

This macro executes *body* using *table* as the current syntax table. It returns the value of the last form in *body*, after restoring the old current syntax table.

Since each buffer has its own current syntax table, we should make that more precise: `with-syntax-table` temporarily alters the current syntax table of whichever buffer is current at the time the macro execution starts. Other buffers are not affected.

36.4 Syntax Properties

When the syntax table is not flexible enough to specify the syntax of a language, you can override the syntax table for specific character occurrences in the buffer, by applying a `syntax-table` text property. See Section 33.19 [Text Properties], page 917, for how to apply text properties.

The valid values of `syntax-table` text property are:

`syntax-table`

If the property value is a syntax table, that table is used instead of the current buffer's syntax table to determine the syntax for the underlying text character.

`(syntax-code . matching-char)`

A cons cell of this format is a raw syntax descriptor (see Section 36.7 [Syntax Table Internals], page 1034), which directly specifies a syntax class for the underlying text character.

`nil`

If the property is `nil`, the character's syntax is determined from the current syntax table in the usual way.

`parse-sexp-lookup-properties`

[Variable]

If this is non-`nil`, the syntax scanning functions, like `forward-sexp`, pay attention to `syntax-table` text properties. Otherwise they use only the current syntax table.

`syntax-propertize-function`

[Variable]

This variable, if non-`nil`, should store a function for applying `syntax-table` properties to a specified stretch of text. It is intended to be used by major modes to install a function which applies `syntax-table` properties in some mode-appropriate way.

The function is called by `syntax-ppss` (see Section 36.6.2 [Position Parse], page 1032), and by Font Lock mode during syntactic fontification (see Section 24.6.8 [Syntactic Font Lock], page 575). It is called with two arguments, `start` and `end`, which are the starting and ending positions of the text on which it should act. It is allowed to arbitrarily move point within the region delimited by `start` and `end`; such motions don't need to use `save-excursion` (see Section 31.3 [Excursions], page 864). It is also allowed to call `syntax-ppss` on any position before `end`, but if a Lisp program calls `syntax-ppss` on some position and later modifies the buffer at some earlier position, then it is that program's responsibility to call `syntax-ppss-flush-cache` to flush the now obsolete info from the cache.

Caution: When this variable is non-`nil`, Emacs removes `syntax-table` text properties arbitrarily and relies on `syntax-propertize-function` to reapply them. Thus if this facility is used at all, the function must apply **all** `syntax-table` text properties used by the major mode. In particular, Modes derived from a CC Mode mode must not use this variable, since CC Mode uses other means to apply and remove these text properties.

syntax-propertize-extend-region-functions [Variable]

This abnormal hook is run by the syntax parsing code prior to calling `syntax-propertize-function`. Its role is to help locate safe starting and ending buffer positions for passing to `syntax-propertize-function`. For example, a major mode can add a function to this hook to identify multi-line syntactic constructs, and ensure that the boundaries do not fall in the middle of one.

Each function in this hook should accept two arguments, *start* and *end*. It should return either a cons cell of two adjusted buffer positions, (`new-start . new-end`), or `nil` if no adjustment is necessary. The hook functions are run in turn, repeatedly, until they all return `nil`.

36.5 Motion and Syntax

This section describes functions for moving across characters that have certain syntax classes.

skip-syntax-forward *syntaxes* &*optional limit* [Function]

This function moves point forward across characters having syntax classes mentioned in *syntaxes* (a string of syntax class characters). It stops when it encounters the end of the buffer, or position *limit* (if specified), or a character it is not supposed to skip. If *syntaxes* starts with ‘^’, then the function skips characters whose syntax is *not* in *syntaxes*.

The return value is the distance traveled, which is a nonnegative integer.

skip-syntax-backward *syntaxes* &*optional limit* [Function]

This function moves point backward across characters whose syntax classes are mentioned in *syntaxes*. It stops when it encounters the beginning of the buffer, or position *limit* (if specified), or a character it is not supposed to skip.

If *syntaxes* starts with ‘^’, then the function skips characters whose syntax is *not* in *syntaxes*.

The return value indicates the distance traveled. It is an integer that is zero or less.

backward-prefix-chars [Function]

This function moves point backward over any number of characters with expression prefix syntax. This includes both characters in the expression prefix syntax class, and characters with the ‘p’ flag.

36.6 Parsing Expressions

This section describes functions for parsing and scanning balanced expressions. We will refer to such expressions as *sexps*, following the terminology of Lisp, even though these functions can act on languages other than Lisp. Basically, a sexp is either a balanced parenthetical grouping, a string, or a symbol (i.e., a sequence of characters whose syntax is either word constituent or symbol constituent). However, characters in the expression prefix syntax class (see Section 36.2.1 [Syntax Class Table], page 1023) are treated as part of the sexp if they appear next to it.

The syntax table controls the interpretation of characters, so these functions can be used for Lisp expressions when in Lisp mode and for C expressions when in C mode. See

Section 31.2.6 [List Motion], page 861, for convenient higher-level functions for moving over balanced expressions.

A character's syntax controls how it changes the state of the parser, rather than describing the state itself. For example, a string delimiter character toggles the parser state between in-string and in-code, but the syntax of characters does not directly say whether they are inside a string. For example (note that 15 is the syntax code for generic string delimiters),

```
(put-text-property 1 9 'syntax-table '(15 . nil))
```

does not tell Emacs that the first eight chars of the current buffer are a string, but rather that they are all string delimiters. As a result, Emacs treats them as four consecutive empty string constants.

36.6.1 Motion Commands Based on Parsing

This section describes simple point-motion functions that operate based on parsing expressions.

scan-lists from count depth

[Function]

This function scans forward *count* balanced parenthetical groupings from position *from*. It returns the position where the scan stops. If *count* is negative, the scan moves backwards.

If *depth* is nonzero, treat the starting position as being *depth* parentheses deep. The scanner moves forward or backward through the buffer until the depth changes to zero *count* times. Hence, a positive value for *depth* has the effect of moving out *depth* levels of parenthesis from the starting position, while a negative *depth* has the effect of moving deeper by *-depth* levels of parenthesis.

Scanning ignores comments if `parse-sexp-ignore-comments` is non-nil.

If the scan reaches the beginning or end of the accessible part of the buffer before it has scanned over *count* parenthetical groupings, the return value is `nil` if the depth at that point is zero; if the depth is non-zero, a `scan-error` error is signaled.

scan-sexps from count

[Function]

This function scans forward *count* sexps from position *from*. It returns the position where the scan stops. If *count* is negative, the scan moves backwards.

Scanning ignores comments if `parse-sexp-ignore-comments` is non-nil.

If the scan reaches the beginning or end of (the accessible part of) the buffer while in the middle of a parenthetical grouping, an error is signaled. If it reaches the beginning or end between groupings but before *count* is used up, `nil` is returned.

forward-comment count

[Function]

This function moves point forward across *count* complete comments (that is, including the starting delimiter and the terminating delimiter if any), plus any whitespace encountered on the way. It moves backward if *count* is negative. If it encounters anything other than a comment or whitespace, it stops, leaving point at the place where it stopped. This includes (for instance) finding the end of a comment when moving forward and expecting the beginning of one. The function also stops immediately after moving over the specified number of complete comments. If *count* comments

are found as expected, with nothing except whitespace between them, it returns `t`; otherwise it returns `nil`.

This function cannot tell whether the comments it traverses are embedded within a string. If they look like comments, it treats them as comments.

To move forward over all comments and whitespace following point, use `(forward-comment (buffer-size))`. `(buffer-size)` is a good argument to use, because the number of comments in the buffer cannot exceed that many.

36.6.2 Finding the Parse State for a Position

For syntactic analysis, such as in indentation, often the useful thing is to compute the syntactic state corresponding to a given buffer position. This function does that conveniently.

`syntax-ppss &optional pos`

[Function]

This function returns the parser state that the parser would reach at position `pos` starting from the beginning of the visible portion of the buffer. See the next section for a description of the parser state.

The return value is the same as if you call the low-level parsing function `parse-partial-sexp` to parse from the beginning of the visible portion of the buffer to `pos` (see Section 36.6.4 [Low-Level Parsing], page 1033). However, `syntax-ppss` uses caches to speed up the computation. Due to this optimization, the second value (previous complete subexpression) and sixth value (minimum parenthesis depth) in the returned parser state are not meaningful.

This function has a side effect: it adds a buffer-local entry to `before-change-functions` (see Section 33.34 [Change Hooks], page 961) for `syntax-ppss-flush-cache` (see below). This entry keeps the cache consistent as the buffer is modified. However, the cache might not be updated if `syntax-ppss` is called while `before-change-functions` is temporarily let-bound, or if the buffer is modified without running the hook, such as when using `inhibit-modification-hooks`. In those cases, it is necessary to call `syntax-ppss-flush-cache` explicitly.

`syntax-ppss-flush-cache beg &rest ignored-args`

[Function]

This function flushes the cache used by `syntax-ppss`, starting at position `beg`. The remaining arguments, `ignored-args`, are ignored; this function accepts them so that it can be directly used on hooks such as `before-change-functions` (see Section 33.34 [Change Hooks], page 961).

36.6.3 Parser State

A *parser state* is a list of (currently) eleven elements describing the state of the syntactic parser, after it parses the text between a specified starting point and a specified end point in the buffer using `parse-partial-sexp` (see Section 36.6.4 [Low-Level Parsing], page 1033). Parsing functions such as `syntax-ppss` also return a parser state as the value. `parse-partial-sexp` can accept a parser state as an argument, for resuming parsing.

Here are the meanings of the elements of the parser state:

0. The depth in parentheses, counting from 0. **Warning:** this can be negative if there are more close parens than open parens between the parser's starting point and end point.

1. The character position of the start of the innermost parenthetical grouping containing the stopping point; `nil` if none.
2. The character position of the start of the last complete subexpression terminated; `nil` if none.
3. Non-`nil` if inside a string. More precisely, this is the character that will terminate the string, or `t` if a generic string delimiter character should terminate it.
4. `t` if inside a non-nestable comment (of any comment style; see Section 36.2.2 [Syntax Flags], page 1026); or the comment nesting level if inside a comment that can be nested.
5. `t` if the end point is just after a quote character.
6. The minimum parenthesis depth encountered during this scan.
7. What kind of comment is active: `nil` if not in a comment or in a comment of style ‘a’; 1 for a comment of style ‘b’; 2 for a comment of style ‘c’; and `syntax-table` for a comment that should be ended by a generic comment delimiter character.
8. The string or comment start position. While inside a comment, this is the position where the comment began; while inside a string, this is the position where the string began. When outside of strings and comments, this element is `nil`.
9. The list of the positions of the currently open parentheses, starting with the outermost.
10. When the last buffer position scanned was the (potential) first character of a two character construct (comment delimiter or escaped/char-quoted character pair), the `syntax-code` (see Section 36.7 [Syntax Table Internals], page 1034) of that position. Otherwise `nil`.

Elements 1, 2, and 6 are ignored in a state which you pass as an argument to `parse-partial-sexp` to continue parsing. Elements 9 and 10 are mainly used internally by the parser code.

Some additional useful information is available from a parser state using these functions:

`syntax-ppss-toplevel-pos state`

[Function]

This function extracts, from parser state `state`, the last position scanned in the parse which was at top level in grammatical structure. “At top level” means outside of any parentheses, comments, or strings.

The value is `nil` if `state` represents a parse which has arrived at a top level position.

`syntax-ppss-context state`

[Function]

Return `string` if the end position of the scan returning `state` is in a string, and `comment` if it’s in a comment. Otherwise return `nil`.

36.6.4 Low-Level Parsing

The most basic way to use the expression parser is to tell it to start at a given position with a certain state, and parse up to a specified end position.

`parse-partial-sexp start limit &optional target-depth stop-before state stop-comment`

This function parses a sexp in the current buffer starting at `start`, not scanning past `limit`. It stops at position `limit` or when certain criteria described below are met, and

sets point to the location where parsing stops. It returns a parser state describing the status of the parse at the point where it stops.

If the third argument *target-depth* is non-*nil*, parsing stops if the depth in parentheses becomes equal to *target-depth*. The depth starts at 0, or at whatever is given in *state*.

If the fourth argument *stop-before* is non-*nil*, parsing stops when it comes to any character that starts a sexp. If *stop-comment* is non-*nil*, parsing stops after the start of an unnested comment. If *stop-comment* is the symbol `syntax-table`, parsing stops after the start of an unnested comment or a string, or after the end of an unnested comment or a string, whichever comes first.

If *state* is `nil`, *start* is assumed to be at the top level of parenthesis structure, such as the beginning of a function definition. Alternatively, you might wish to resume parsing in the middle of the structure. To do this, you must provide a *state* argument that describes the initial status of parsing. The value returned by a previous call to `parse-partial-sexp` will do nicely.

36.6.5 Parameters to Control Parsing

`multibyte-syntax-as-symbol`

[Variable]

If this variable is non-*nil*, `scan-sexps` treats all non-ASCII characters as symbol constituents regardless of what the syntax table says about them. (However, `syntax-table` text properties can still override the syntax.)

`parse-sexp-ignore-comments`

[User Option]

If the value is non-*nil*, then comments are treated as whitespace by the functions in this section and by `forward-sexp`, `scan-lists` and `scan-sexps`.

The behavior of `parse-partial-sexp` is also affected by `parse-sexp-lookup-properties` (see Section 36.4 [Syntax Properties], page 1029).

`comment-end-can-be-escaped`

[Variable]

If this buffer local variable is non-*nil*, a single character which usually terminates a comment doesn't do so when that character is escaped. This is used in C and C++ Modes, where line comments starting with ‘//’ can be continued onto the next line by escaping the newline with ‘\’.

You can use `forward-comment` to move forward or backward over one comment or several comments.

36.7 Syntax Table Internals

Syntax tables are implemented as char-tables (see Section 6.6 [Char-Tables], page 119), but most Lisp programs don't work directly with their elements. Syntax tables do not store syntax data as syntax descriptors (see Section 36.2 [Syntax Descriptors], page 1023); they use an internal format, which is documented in this section. This internal format can also be assigned as syntax properties (see Section 36.4 [Syntax Properties], page 1029).

Each entry in a syntax table is a raw syntax descriptor: a cons cell of the form (`syntax-code . matching-char`). `syntax-code` is an integer which encodes the syntax class and

syntax flags, according to the table below. *matching-char*, if non-**nil**, specifies a matching character (similar to the second character in a syntax descriptor).

Use **aref** (see Section 6.3 [Array Functions], page 116) to get the raw syntax descriptor of a character, e.g. (**aref** (**syntax-table**) *ch*).

Here are the syntax codes corresponding to the various syntax classes:

<i>Code</i>	<i>Class</i>	<i>Code</i>	<i>Class</i>
0	whitespace	8	paired delimiter
1	punctuation	9	escape
2	word	10	character quote
3	symbol	11	comment-start
4	open parenthesis	12	comment-end
5	close parenthesis	13	inherit
6	expression prefix	14	generic comment
7	string quote	15	generic string

For example, in the standard syntax table, the entry for ‘(’ is (4 . 41). 41 is the character code for ‘)’.

Syntax flags are encoded in higher order bits, starting 16 bits from the least significant bit. This table gives the power of two which corresponds to each syntax flag.

<i>Prefix</i>	<i>Flag</i>	<i>Prefix</i>	<i>Flag</i>
‘1’	(ash 1 16)	‘p’	(ash 1 20)
‘2’	(ash 1 17)	‘b’	(ash 1 21)
‘3’	(ash 1 18)	‘n’	(ash 1 22)
‘4’	(ash 1 19)	‘c’	(ash 1 23)

string-to-syntax *desc* [Function]

Given a syntax descriptor *desc* (a string), this function returns the corresponding raw syntax descriptor.

syntax-class-to-char *syntax* [Function]

Given a raw syntax descriptor *syntax* (an integer), this function returns the corresponding syntax descriptor (a character).

syntax-after *pos* [Function]

This function returns the raw syntax descriptor for the character in the buffer after position *pos*, taking account of syntax properties as well as the syntax table. If *pos* is outside the buffer’s accessible portion (see Section 31.4 [Narrowing], page 865), the return value is **nil**.

syntax-class *syntax* [Function]

This function returns the syntax code for the raw syntax descriptor *syntax*. More precisely, it takes the raw syntax descriptor’s *syntax-code* component, masks off the high 16 bits which record the syntax flags, and returns the resulting integer.

If *syntax* is **nil**, the return value is **nil**. This is so that the expression

(**syntax-class** (**syntax-after** *pos*))

evaluates to **nil** if *pos* is outside the buffer’s accessible portion, without throwing errors or returning an incorrect code.

36.8 Categories

Categories provide an alternate way of classifying characters syntactically. You can define several categories as needed, then independently assign each character to one or more categories. Unlike syntax classes, categories are not mutually exclusive; it is normal for one character to belong to several categories.

Each buffer has a *category table* which records which categories are defined and also which characters belong to each category. Each category table defines its own categories, but normally these are initialized by copying from the standard categories table, so that the standard categories are available in all modes.

Each category has a name, which is an ASCII printing character in the range ‘ ’ to ‘~’. You specify the name of a category when you define it with `define-category`.

The category table is actually a char-table (see Section 6.6 [Char-Tables], page 119). The element of the category table at index *c* is a *category set*—a bool-vector—that indicates which categories character *c* belongs to. In this category set, if the element at index *cat* is *t*, that means category *cat* is a member of the set, and that character *c* belongs to category *cat*.

For the next three functions, the optional argument *table* defaults to the current buffer’s category table.

define-category *char docstring &optional table* [Function]

This function defines a new category, with name *char* and documentation *docstring*, for the category table *table*.

Here’s an example of defining a new category for characters that have strong right-to-left directionality (see Section 41.27 [Bidirectional Display], page 1250) and using it in a special category table. To obtain the information about the directionality of characters, the example code uses the ‘*bidi-class*’ Unicode property (see Section 34.6 [Character Properties], page 968).

```
(defvar special-category-table-for-bidi
  ;; Make an empty category-table.
  (let ((category-table (make-category-table))
        ;; Create a char-table which gives the 'bidi-class' Unicode
        ;; property for each character.
        (uniprop-table
         (unicode-property-table-internal 'bidi-class)))
    (define-category ?R "Characters of bidi-class R, AL, or RLO"
      category-table)
    ;; Modify the category entry of each character whose
    ;; 'bidi-class' Unicode property is R, AL, or RLO --
    ;; these have a right-to-left directionality.
    (map-char-table
     (lambda (key val)
       (if (memq val '(R AL RLO))
           (modify-category-entry key ?R category-table)))
     uniprop-table)
    category-table)))
```

category-docstring category &optional table [Function]

This function returns the documentation string of category *category* in category table *table*.

```
(category-docstring ?a)
  ⇒ "ASCII"
(category-docstring ?l)
  ⇒ "Latin"
```

get-unused-category &optional table [Function]

This function returns a category name (a character) which is not currently defined in *table*. If all possible categories are in use in *table*, it returns **nil**.

category-table [Function]

This function returns the current buffer's category table.

category-table-p object [Function]

This function returns **t** if *object* is a category table, otherwise **nil**.

standard-category-table [Function]

This function returns the standard category table.

copy-category-table &optional table [Function]

This function constructs a copy of *table* and returns it. If *table* is not supplied (or is **nil**), it returns a copy of the standard category table. Otherwise, an error is signaled if *table* is not a category table.

set-category-table table [Function]

This function makes *table* the category table for the current buffer. It returns *table*.

make-category-table [Function]

This creates and returns an empty category table. In an empty category table, no categories have been allocated, and no characters belong to any categories.

make-category-set categories [Function]

This function returns a new category set—a bool-vector—whose initial contents are the categories listed in the string *categories*. The elements of *categories* should be category names; the new category set has **t** for each of those categories, and **nil** for all other categories.

```
(make-category-set "al")
  ⇒ #&128"\0\0\0\0\0\0\0\0\0\0\0\0\2\20\0\0"
```

char-category-set char [Function]

This function returns the category set for character *char* in the current buffer's category table. This is the bool-vector which records which categories the character *char* belongs to. The function **char-category-set** does not allocate storage, because it returns the same bool-vector that exists in the category table.

```
(char-category-set ?a)
  ⇒ #&128"\0\0\0\0\0\0\0\0\0\0\0\0\2\20\0\0"
```

category-set-mnemonics *category-set* [Function]

This function converts the category set *category-set* into a string containing the characters that designate the categories that are members of the set.

```
(category-set-mnemonics (char-category-set ?a))  
⇒ "al"
```

modify-category-entry *char category &optional table reset* [Function]

This function modifies the category set of *char* in category table *table* (which defaults to the current buffer's category table). *char* can be a character, or a cons cell of the form *(min . max)*; in the latter case, the function modifies the category sets of all characters in the range between *min* and *max*, inclusive.

Normally, it modifies a category set by adding *category* to it. But if *reset* is non-*nil*, then it deletes *category* instead.

describe-categories &optional buffer-or-name [Command]

This function describes the category specifications in the current category table. It inserts the descriptions in a buffer, and then displays that buffer. If *buffer-or-name* is non-*nil*, it describes the category table of that buffer instead.

37 Parsing Program Source

Emacs provides various ways to parse program source text and produce a *syntax tree*. In a syntax tree, text is no longer considered a one-dimensional stream of characters, but a structured tree of nodes, where each node represents a piece of text. Thus, a syntax tree can enable interesting features like precise fontification, indentation, navigation, structured editing, etc.

Emacs has a simple facility for parsing balanced expressions (see Section 36.6 [Parsing Expressions], page 1030). There is also the SMIE library for generic navigation and indentation (see Section 24.7.1 [SMIE], page 581).

In addition to those, Emacs also provides integration with the tree-sitter library (<https://tree-sitter.github.io/tree-sitter>) if support for it was compiled in. The tree-sitter library implements an incremental parser and has support for a wide range of programming languages.

treesit-available-p [Function]

This function returns non-`nil` if tree-sitter features are available for the current Emacs session.

To be able to parse the program source using the tree-sitter library and access the syntax tree of the program, a Lisp program needs to load a language grammar library, and create a parser for that language and the current buffer. After that, the Lisp program can query the parser about specific nodes of the syntax tree. Then, it can access various kinds of information about each node, and search for nodes using a powerful pattern-matching syntax. This chapter explains how to do all this, and also how a Lisp program can work with source files that mix multiple programming languages.

37.1 Tree-sitter Language Grammar

Loading a language grammar

Tree-sitter relies on language grammar to parse text in that language. In Emacs, a language grammar is represented by a symbol. For example, the C language grammar is represented as the symbol `c`, and `c` can be passed to tree-sitter functions as the *language* argument.

Tree-sitter language grammars are distributed as dynamic libraries. In order to use a language grammar in Emacs, you need to make sure that the dynamic library is installed on the system. Emacs looks for language grammars in several places, in the following order:

- first, in the list of directories specified by the variable `treesit-extra-load-path`;
- then, in the `tree-sitter` subdirectory of the directory specified by `user-emacs-directory` (see Section 42.1.2 [Init File], page 1258);
- and finally, in the system’s default locations for dynamic libraries.

In each of these directories, Emacs looks for a file with file-name extensions specified by the variable `dynamic-library-suffixes`.

If Emacs cannot find the library or has problems loading it, Emacs signals the `treesit-load-language-error` error. The data of that signal could be one of the following:

(not-found *error-msg* ...)

This means that Emacs could not find the language grammar library.

(symbol-error *error-msg*)

This means that Emacs could not find in the library the expected function that every language grammar library should export.

(version-mismatch *error-msg*)

This means that the version of the language grammar library is incompatible with that of the tree-sitter library.

In all of these cases, *error-msg* might provide additional details about the failure.

treesit-language-available-p *language* &optional *detail*

[Function]

This function returns non-nil if the language grammar for *language* exists and can be loaded.

If *detail* is non-nil, return (t . nil) when *language* is available, and (nil . *data*) when it's unavailable. *data* is the signal data of **treesit-load-language-error**.

By convention, the file name of the dynamic library for *language* is *libtree-sitter-language.ext*, where *ext* is the system-specific extension for dynamic libraries. Also by convention, the function provided by that library is named **tree_sitter_***language*. If a language grammar library doesn't follow this convention, you should add an entry

(*language* *library-base-name* *function-name*)

to the list in the variable **treesit-load-name-override-list**, where *library-base-name* is the basename of the dynamic library's file name (usually, *libtree-sitter-language*), and *function-name* is the function provided by the library (usually, **tree_sitter_***language*). For example,

(cool-lang "libtree-sitter-coool" "tree_sitter_coooool")

for a language that considers itself too “cool” to abide by conventions.

treesit-library-abi-version &optional *min-compatible*

[Function]

This function returns the version of the language grammar Application Binary Interface (ABI) supported by the tree-sitter library. By default, it returns the latest ABI version supported by the library, but if *min-compatible* is non-nil, it returns the oldest ABI version which the library still can support. Language grammar libraries must be built for ABI versions between the oldest and the latest versions supported by the tree-sitter library, otherwise the library will be unable to load them.

treesit-language-abi-version *language*

[Function]

This function returns the ABI version of the language grammar library loaded by Emacs for *language*. If *language* is unavailable, this function returns nil.

Concrete syntax tree

A syntax tree is what a parser generates. In a syntax tree, each node represents a piece of text, and is connected to each other by a parent-child relationship. For example, if the source text is

1 + 2

its syntax tree could be

We can also represent it as an s-expression:

```
(root (expression (number) (operator) (number)))
```

Node types

Names like `root`, `expression`, `number`, and `operator` specify the *type* of the nodes. However, not all nodes in a syntax tree have a type. Nodes that don't have a type are known as *anonymous nodes*, and nodes with a type are *named nodes*. Anonymous nodes are tokens with fixed spellings, including punctuation characters like bracket ‘]’, and keywords like `return`.

Field names

To make the syntax tree easier to analyze, many language grammar assign *field names* to child nodes. For example, a `function_definition` node could have a `declarator` and a `body`:

```
(function_definition
  declarator: (declaration)
  body: (compound_statement))
```

Exploring the syntax tree

To aid in understanding the syntax of a language and in debugging Lisp programs that use the syntax tree, Emacs provides an “explore” mode, which displays the syntax tree of the source in the current buffer in real time. Emacs also comes with an “inspect mode”, which displays information of the nodes at point in the mode-line.

treesit-explore-mode

[Command]

This mode pops up a window displaying the syntax tree of the source in the current buffer. Selecting text in the source buffer highlights the corresponding nodes in the syntax tree display. Clicking on nodes in the syntax tree highlights the corresponding text in the source buffer.

treesit-inspect-mode

[Command]

This minor mode displays on the mode-line the node that *starts* at point. For example, the mode-line can display

```
parent field: (node (child (...)))
```

where *node*, *child*, etc., are nodes which begin at point. *parent* is the parent of *node*. *node* is displayed in a bold typeface. *field-names* are field names of *node* and of *child*, etc.

If no node starts at point, i.e., point is in the middle of a node, then the mode line displays the earliest node that spans point, and its immediate parent.

This minor mode doesn't create parsers on its own. It uses the first parser in (`treesit-parser-list`) (see Section 37.2 [Using Parser], page 1043).

Reading the grammar definition

Authors of language grammars define the *grammar* of a programming language, which determines how a parser constructs a concrete syntax tree out of the program text. In order to use the syntax tree effectively, you need to consult the *grammar file*.

The grammar file is usually `grammar.js` in a language grammar's project repository. The link to a language grammar's home page can be found on tree-sitter's homepage (<https://tree-sitter.github.io/tree-sitter>).

The grammar definition is written in JavaScript. For example, the rule matching a `function_definition` node may look like

```
function_definition: $ => seq(
  $.declaration_specifiers,
  field('declarator', $.declaration),
  field('body', $.compound_statement)
)
```

The rules are represented by functions that take a single argument `$`, representing the whole grammar. The function itself is constructed by other functions: the `seq` function puts together a sequence of children; the `field` function annotates a child with a field name. If we write the above definition in the so-called *Backus-Naur Form* (BNF) syntax, it would look like

```
function_definition :=
<declaration_specifiers> <declaration> <compound_statement>
```

and the node returned by the parser would look like

```
(function_definition
  (declaration_specifier)
  declarator: (declaration)
  body: (compound_statement))
```

Below is a list of functions that one can see in a grammar definition. Each function takes other rules as arguments and returns a new rule.

`seq(rule1, rule2, ...)`

matches each rule one after another.

`choice(rule1, rule2, ...)`

matches one of the rules in its arguments.

`repeat(rule)`

matches *rule zero or more* times. This is like the '*' operator in regular expressions.

```
repeat1(rule)
    matches rule one or more times. This is like the ‘+’ operator in regular expressions.

optional(rule)
    matches rule zero or one times. This is like the ‘?’ operator in regular expressions.

field(name, rule)
    assigns field name name to the child node matched by rule.

alias(rule, alias)
    makes nodes matched by rule appear as alias in the syntax tree generated by the parser. For example,
        alias(preprocessor_call_exp, call_expression)
    makes any node matched by preprocessor_call_exp appear as call_expression.
```

Below are grammar functions of lesser importance for reading a language grammar.

```
token(rule)
    marks rule to produce a single leaf node. That is, instead of generating a parent node with individual child nodes under it, everything is combined into a single leaf node. See Section 37.3 [Retrieving Nodes], page 1045.

token.immediate(rule)
    Normally, grammar rules ignore preceding whitespace; this changes rule to match only when there is no preceding whitespace.

prec(n, rule)
    gives rule the level-n precedence.

prec.left([n,] rule)
    marks rule as left-associative, optionally with level n.

prec.right([n,] rule)
    marks rule as right-associative, optionally with level n.

prec.dynamic(n, rule)
    this is like prec, but the precedence is applied at runtime instead.
```

The documentation of the tree-sitter project has more about writing a grammar (<https://tree-sitter.github.io/tree-sitter/creating-parsers>). Read especially “The Grammar DSL” section.

37.2 Using Tree-sitter Parser

This section describes how to create and configure a tree-sitter parser. In Emacs, each tree-sitter parser is associated with a buffer. As the user edits the buffer, the associated parser and syntax tree are automatically kept up-to-date.

treesit-max-buffer-size	[Variable]
--------------------------------	------------

This variable contains the maximum size of buffers in which tree-sitter can be activated. Major modes should check this value when deciding whether to enable tree-sitter features.

treesit-parser-create *language* &**optional** *buffer* *no-reuse* [Function]

Create a parser for the specified *buffer* and *language* (see Section 37.1 [Language Grammar], page 1039). If *buffer* is omitted or `nil`, it stands for the current buffer.

By default, this function reuses a parser if one already exists for *language* in *buffer*, but if *no-reuse* is non-`nil`, this function always creates a new parser.

If that buffer is an indirect buffer, its base buffer is used instead. That is, indirect buffers use their base buffer's parsers. If the base buffer is narrowed, an indirect buffer might not be able to retrieve information of the portion of the buffer text that is invisible in the base buffer. Lisp programs should widen as necessary should they want to use a parser in an indirect buffer.

Given a parser, we can query information about it.

treesit-parser-buffer *parser* [Function]

This function returns the buffer associated with *parser*.

treesit-parser-language *parser* [Function]

This function returns the language used by *parser*.

treesit-parser-p *object* [Function]

This function checks if *object* is a tree-sitter parser, and returns non-`nil` if it is, and `nil` otherwise.

There is no need to explicitly parse a buffer, because parsing is done automatically and lazily. A parser only parses when a Lisp program queries for a node in its syntax tree. Therefore, when a parser is first created, it doesn't parse the buffer; it waits until the Lisp program queries for a node for the first time. Similarly, when some change is made in the buffer, a parser doesn't re-parse immediately.

When a parser does parse, it checks for the size of the buffer. Tree-sitter can only handle buffers no larger than about 4GB. If the size exceeds that, Emacs signals the `treesit-buffer-too-large` error with signal data being the buffer size.

Once a parser is created, Emacs automatically adds it to the internal parser list. Every time a change is made to the buffer, Emacs updates parsers in this list so they can update their syntax tree incrementally.

treesit-parser-list &**optional** *buffer* [Function]

This function returns the parser list of *buffer*. If *buffer* is `nil` or omitted, it defaults to the current buffer. If that buffer is an indirect buffer, its base buffer is used instead. That is, indirect buffers use their base buffer's parsers.

treesit-parser-delete *parser* [Function]

This function deletes *parser*.

Normally, a parser "sees" the whole buffer, but when the buffer is narrowed (see Section 31.4 [Narrowing], page 865), the parser will only see the accessible portion of the buffer. As far as the parser can tell, the hidden region was deleted. When the buffer is later widened, the parser thinks text is inserted at the beginning and at the end. Although

parsers respect narrowing, modes should not use narrowing as a means to handle a multi-language buffer; instead, set the ranges in which the parser should operate. See Section 37.6 [Multiple Languages], page 1057.

Because a parser parses lazily, when the user or a Lisp program narrows the buffer, the parser is not affected immediately; as long as the mode doesn’t query for a node while the buffer is narrowed, the parser is oblivious of the narrowing.

Besides creating a parser for a buffer, a Lisp program can also parse a string. Unlike a buffer, parsing a string is a one-off operation, and there is no way to update the result.

treesit-parse-string *string language* [Function]

This function parses *string* using *language*, and returns the root node of the generated syntax tree.

Be notified by changes to the parse tree

A Lisp program might want to be notified of text affected by incremental parsing. For example, inserting a comment-closing token converts text before that token into a comment. Even though the text is not directly edited, it is deemed to be “changed” nevertheless.

Emacs lets a Lisp program register callback functions (a.k.a. *notifiers*) for these kinds of changes. A notifier function takes two arguments: *ranges* and *parser*. *ranges* is a list of cons cells of the form (*start . end*), where *start* and *end* mark the start and the end positions of a range. *parser* is the parser issuing the notification.

Every time a parser reparses a buffer, it compares the old and new parse-tree, computes the ranges in which nodes have changed, and passes the ranges to notifier functions. Note that the initial parse is also considered a “change”, so notifier functions are called on the initial parse, with range being the whole buffer.

treesit-parser-add-notifier *parser function* [Function]

This function adds *function* to *parser*’s list of after-change notifier functions. *function* must be a function symbol, not a lambda function (see Section 13.7 [Anonymous Functions], page 243).

treesit-parser-remove-notifier *parser function* [Function]

This function removes *function* from the list of *parser*’s after-change notifier functions. *function* must be a function symbol, rather than a lambda function.

treesit-parser-notifiers *parser* [Function]

This function returns the list of *parser*’s notifier functions.

37.3 Retrieving Nodes

Here are some terms and conventions we use when documenting tree-sitter functions.

A node in a syntax tree spans some portion of the program text in the buffer. We say that a node is “smaller” or “larger” than another if it spans, respectively, a smaller or larger portion of buffer text than the other node. Since nodes that are deeper (“lower”) in the tree are children of the nodes that are “higher” in the tree, it follows that a lower node will always be smaller than a node that is higher in the node hierarchy. A node that is higher

up in the syntax tree contains one or more smaller nodes as its children, and therefore spans a larger portion of buffer text.

When a function cannot find a node, it returns `nil`. For convenience, all functions that take a node as argument and return a node, also accept the node argument of `nil` and in that case just return `nil`.

Nodes are not automatically updated when the associated buffer is modified, and there is no way to update a node once it is retrieved. Using an outdated node signals the `treesit-node-outdated` error.

Retrieving nodes from syntax tree

treesit-node-at *pos* &optional *parser-or-lang* *named* [Function]

This function returns a *leaf* node at buffer position *pos*. A leaf node is a node that doesn't have any child nodes.

This function tries to return a node whose span covers *pos*: the node's beginning position is less than or equal to *pos*, and the node's end position is greater than or equal to *pos*.

If no leaf node's span covers *pos* (e.g., *pos* is in the whitespace between two leaf nodes), this function returns the first leaf node after *pos*.

Finally, if there is no leaf node after *pos*, return the first leaf node before *pos*.

If *parser-or-lang* is a parser object, this function uses that parser; if *parser-or-lang* is a language, this function uses the first parser for that language in the current buffer, or creates one if none exists; if *parser-or-lang* is `nil`, this function tries to guess the language at *pos* by calling `treesit-language-at` (see Section 37.6 [Multiple Languages], page 1057).

If this function cannot find a suitable node to return, it returns `nil`.

If *named* is non-`nil`, this function looks only for named nodes (see [tree-sitter named node], page 1041).

Example:

```
;; Find the node at point in a C parser's syntax tree.
(treesit-node-at (point) 'c)
⇒ #<treesit-node (primitive_type) in 23-27>
```

treesit-node-on *beg* *end* &optional *parser-or-lang* *named* [Function]

This function returns the *smallest* node that covers the region of buffer text between *beg* and *end*. In other words, the start of the node is before or at *beg*, and the end of the node is at or after *end*.

Beware: calling this function on an empty line that is not inside any top-level construct (function definition, etc.) most probably will give you the root node, because the root node is the smallest node that covers that empty line. Most of the time, you want to use `treesit-node-at` instead.

If *parser-or-lang* is a parser object, this function uses that parser; if *parser-or-lang* is a language, this function uses the first parser for that language in the current buffer, or creates one if none exists; if *parser-or-lang* is `nil`, this function tries to guess the language at *beg* by calling `treesit-language-at`.

If *named* is non-*nil*, this function looks for a named node only (see [tree-sitter named node], page 1041).

treesit-parser-root-node *parser* [Function]

This function returns the root node of the syntax tree generated by *parser*.

treesit-buffer-root-node &optional *language* [Function]

This function finds the first parser for *language* in the current buffer, or creates one if none exists, and returns the root node generated by that parser. If *language* is omitted, it uses the first parser in the parser list. If it cannot find an appropriate parser, it returns *nil*.

Given a node, a Lisp program can retrieve other nodes starting from it, or query for information about this node.

Retrieving nodes from other nodes

By kinship

treesit-node-parent *node* [Function]

This function returns the immediate parent of *node*.

If *node* is more than 1000 levels deep in a parse tree, the return value is undefined. Currently it returns *nil*, but that could change in the future.

treesit-node-child *node* *n* &optional *named* [Function]

This function returns the *n*'th child of *node*. If *named* is non-*nil*, it counts only named nodes (see [tree-sitter named node], page 1041).

For example, in a node that represents a string "text", there are three children nodes: the opening quote ", the string text *text*, and the closing quote ". Among these nodes, the first child is the opening quote ", and the first named child is the string *text*.

This function returns *nil* if there is no *n*'th child. *n* could be negative, e.g., -1 represents the last child.

treesit-node-children *node* &optional *named* [Function]

This function returns all of *node*'s children as a list. If *named* is non-*nil*, it retrieves only named nodes.

treesit-node-next-sibling *node* &optional *named* [Function]

This function finds the next sibling of *node*. If *named* is non-*nil*, it finds the next named sibling.

treesit-node-prev-sibling *node* &optional *named* [Function]

This function finds the previous sibling of *node*. If *named* is non-*nil*, it finds the previous named sibling.

By field name

To make the syntax tree easier to analyze, many language grammars assign *field names* to child nodes (see [tree-sitter node field name], page 1041). For example, a `function_definition` node could have a `declarator` node and a `body` node.

`treesit-node-child-by-field-name node field-name` [Function]

This function finds the child of `node` whose field name is `field-name`, a string.

```
;; Get the child that has "body" as its field name.
(treesit-node-child-by-field-name node "body")
⇒ #<treesit-node (compound_statement) in 45-89>
```

By position

`treesit-node-first-child-for-pos node pos &optional named` [Function]

This function finds the first child of `node` that extends beyond buffer position `pos`. “Extends beyond” means the end of the child node is greater or equal to `pos`. This function only looks for immediate children of `node`, and doesn’t look in its grandchildren. If `named` is non-`nil`, it looks for the first named child (see [tree-sitter named node], page 1041).

`treesit-node-descendant-for-range node beg end &optional named` [Function]

This function finds the *smallest* descendant node of `node` that spans the region of text between positions `beg` and `end`. It is similar to `treesit-node-at`. If `named` is non-`nil`, it looks for the smallest named child.

Searching for node

`treesit-search-subtree node predicate &optional backward all depth` [Function]

This function traverses the subtree of `node` (including `node` itself), looking for a node for which `predicate` returns non-`nil`. `predicate` is a regexp that is matched against each node’s type, or a predicate function that takes a node and returns non-`nil` if the node matches. The function returns the first node that matches, or `nil` if none does.

By default, this function only traverses named nodes, but if `all` is non-`nil`, it traverses all the nodes. If `backward` is non-`nil`, it traverses backwards (i.e., it visits the last child first when traversing down the tree). If `depth` is non-`nil`, it must be a number that limits the tree traversal to that many levels down the tree. If `depth` is `nil`, it defaults to 1000.

`treesit-search-forward start predicate &optional backward all` [Function]

Like `treesit-search-subtree`, this function also traverses the parse tree and matches each node with `predicate` (except for `start`), where `predicate` can be a regexp or a function. For a tree like the one below where `start` is marked ‘S’, this function traverses as numbered from 1 to 12:

Note that this function doesn't traverse the subtree of *start*, and it always traverses leaf nodes first, before moving upwards.

Like `treesit-search-subtree`, this function only searches for named nodes by default, but if *all* is non-`nil`, it searches for all nodes. If *backward* is non-`nil`, it searches backwards.

While `treesit-search-subtree` traverses the subtree of a node, this function starts with node *start* and traverses every node that comes after it in the buffer position order, i.e., nodes with start positions greater than the end position of *start*.

In the tree shown above, `treesit-search-subtree` traverses node ‘S’ (*start*) and nodes marked with `o`, whereas this function traverses the nodes marked with numbers. This function is useful for answering questions like “what is the first node after *start* in the buffer that satisfies some condition?”

`treesit-search-forward-goto` *node predicate &optional start backward all* [Function]

This function moves point to the start or end of the next node after *node* in the buffer that matches *predicate*. If *start* is non-`nil`, stop at the beginning rather than the end of a node.

This function guarantees that the matched node it returns makes progress in terms of buffer position: the start/end position of the returned node is always greater than that of *node*.

Arguments *predicate*, *backward*, and *all* are the same as in `treesit-search-forward`.

`treesit-induce-sparse-tree` *root predicate &optional process-fn depth* [Function]

This function creates a sparse tree from *root*'s subtree.

It takes the subtree under *root*, and combs it so only the nodes that match *predicate* are left. Like previous functions, the *predicate* can be a regexp string that matches against each node's type, or a function that takes a node and returns non-`nil` if it matches.

For example, given the subtree on the left that consists of both numbers and letters, if *predicate* is “letter only”, the returned tree is the one on the right.

If `process-fn` is non-`nil`, instead of returning the matched nodes, this function passes each node to `process-fn` and uses the returned value instead. If non-`nil`, `depth` limits the number of levels to go down from `root`. If `depth` is `nil`, it defaults to 1000.

Each node in the returned tree looks like `(tree-sitter-node . (child ...))`. The `tree-sitter-node` of the root of this tree will be `nil` if `root` doesn't match `predicate`. If no node matches `predicate`, the function returns `nil`.

More convenience functions

treesit-filter-child `node predicate &optional named` [Function]

This function finds immediate children of `node` that satisfy `predicate`.

The `predicate` function takes a node as argument and should return non-`nil` to indicate that the node should be kept. If `named` is non-`nil`, this function only examines named nodes.

treesit-parent-until `node predicate &optional include-node` [Function]

This function repeatedly finds the parents of `node`, and returns the parent that satisfies `predicate`, a function that takes a node as argument and returns a boolean that indicates a match. If no parent satisfies `predicate`, this function returns `nil`.

Normally this function only looks at the parents of `node` but not `node` itself. But if `include-node` is non-`nil`, this function returns `node` if `node` satisfies `predicate`.

treesit-parent-while `node predicate` [Function]

This function goes up the tree starting from `node`, and keeps doing so as long as the nodes satisfy `predicate`, a function that takes a node as argument. That is, this function returns the highest parent of `node` that still satisfies `predicate`. Note that if `node` satisfies `predicate` but its immediate parent doesn't, `node` itself is returned.

treesit-node-top-level `node &optional predicate include-node` [Function]

This function returns the highest parent of `node` that has the same type as `node`. If no such parent exists, it returns `nil`. Therefore this function is also useful for testing whether `node` is top-level.

If `predicate` is `nil`, this function uses `node`'s type to find the parent. If `predicate` is non-`nil`, this function searches the parent that satisfies `predicate`. If `include-node` is non-`nil`, this function returns `node` if `node` satisfies `predicate`.

37.4 Accessing Node Information

Basic information of Node

Every node is associated with a parser, and that parser is associated with a buffer. The following functions retrieve them.

treesit-node-parser *node* [Function]

This function returns *node*'s associated parser.

treesit-node-buffer *node* [Function]

This function returns *node*'s parser's associated buffer.

treesit-node-language *node* [Function]

This function returns *node*'s parser's associated language.

Each node represents a portion of text in the buffer. Functions below find relevant information about that text.

treesit-node-start *node* [Function]

Return the start position of *node*.

treesit-node-end *node* [Function]

Return the end position of *node*.

treesit-node-text *node* &optional *object* [Function]

Return the buffer text that *node* represents, as a string. (If *node* is retrieved from parsing a string, it will be the text from that string.)

Here are some predicates on tree-sitter nodes:

treesit-node-p *object* [Function]

Checks if *object* is a tree-sitter syntax node.

treesit-node-eq *node1* *node2* [Function]

Checks if *node1* and *node2* refer to the same node in a tree-sitter syntax tree. This function uses the same equivalence metric as `equal`. You can also compare nodes using `equal` (see Section 2.8 [Equality Predicates], page 34).

Property information

In general, nodes in a concrete syntax tree fall into two categories: *named nodes* and *anonymous nodes*. Whether a node is named or anonymous is determined by the language grammar (see [tree-sitter named node], page 1041).

Apart from being named or anonymous, a node can have other properties. A node can be “missing”: such nodes are inserted by the parser in order to recover from certain kinds of syntax errors, i.e., something should probably be there according to the grammar, but is not there. This can happen during editing of the program source, when the source is not yet in its final form.

A node can be “extra”: such nodes represent things like comments, which can appear anywhere in the text.

A node can be “outdated”, if its parser has reparsed at least once after the node was created.

A node “has error” if the text it spans contains a syntax error. It can be that the node itself has an error, or one of its descendants has an error.

A node is considered *live* if its parser is not deleted, and the buffer to which it belongs is a live buffer (see Section 28.10 [Killing Buffers], page 685).

treesit-node-check *node* *property* [Function]

This function returns non-nil if *node* has the specified *property*. *property* can be `named`, `missing`, `extra`, `outdated`, `has-error`, or `live`.

treesit-node-type *node* [Function]

Named nodes have “types” (see [tree-sitter node type], page 1041). For example, a named node can be a `string_literal` node, where `string_literal` is its type. The type of an anonymous node is just the text that the node represents; e.g., the type of a ‘,’ node is just ‘,’.

This function returns *node*’s type as a string.

Information as a child or parent

treesit-node-index *node* &optional *named* [Function]

This function returns the index of *node* as a child node of its parent. If *named* is non-nil, it only counts named nodes (see [tree-sitter named node], page 1041).

treesit-node-field-name *node* [Function]

A child of a parent node could have a field name (see [tree-sitter node field name], page 1041). This function returns the field name of *node* as a child of its parent.

treesit-node-field-name-for-child *node* *n* [Function]

This function returns the field name of the *n*’th child of *node*. It returns `nil` if there is no *n*’th child, or the *n*’th child doesn’t have a field name.

Note that *n* counts both named and anonymous children, and *n* can be negative, e.g., `-1` represents the last child.

treesit-node-child-count *node* &optional *named* [Function]

This function returns the number of children of *node*. If *named* is non-nil, it only counts named children (see [tree-sitter named node], page 1041).

37.5 Pattern Matching Tree-sitter Nodes

Tree-sitter lets Lisp programs match patterns using a small declarative language. This pattern matching consists of two steps: first tree-sitter matches a *pattern* against nodes in the syntax tree, then it *captures* specific nodes that matched the pattern and returns the captured nodes.

We describe first how to write the most basic query pattern and how to capture nodes in a pattern, then the pattern-matching function, and finally the more advanced pattern syntax.

Basic query syntax

A *query* consists of multiple *patterns*. Each pattern is an s-expression that matches a certain node in the syntax node. A pattern has the form (*type* (*child*...)).

For example, a pattern that matches a `binary_expression` node that contains `number_literal` child nodes would look like

```
(binary_expression (number_literal))
```

To capture a node using the query pattern above, append `@capture-name` after the node pattern you want to capture. For example,

```
(binary_expression (number_literal) @number-in-exp)
```

captures `number_literal` nodes that are inside a `binary_expression` node with the capture name `number-in-exp`.

We can capture the `binary_expression` node as well, with, for example, the capture name `biexp`:

```
(binary_expression
  (number_literal) @number-in-exp) @biexp
```

Query function

Now we can introduce the *query functions*.

`treesit-query-capture` *node* *query* &`optional` *beg* *end* *node-only* [Function]

This function matches patterns in *query* within *node*. The argument *query* can be either an s-expression, a string, or a compiled query object. For now, we focus on the s-expression syntax; string syntax and compiled queries are described at the end of the section.

The argument *node* can also be a parser or a language symbol. A parser means use its root node, a language symbol means find or create a parser for that language in the current buffer, and use the root node.

The function returns all the captured nodes in an alist with elements of the form (*capture_name* . *node*). If *node-only* is non-`nil`, it returns the list of *nodes* instead. By default the entire text of *node* is searched, but if *beg* and *end* are both non-`nil`, they specify the region of buffer text where this function should match nodes. Any matching node whose span overlaps with the region between *beg* and *end* is captured; it doesn't have to be completely contained in the region.

This function raises the `treesit-query-error` error if *query* is malformed. The signal data contains a description of the specific error. You can use `treesit-query-validate` to validate and debug the query.

For example, suppose *node*'s text is `1 + 2`, and *query* is

```
(setq query
  '((binary_expression
    (number_literal) @number-in-exp) @biexp))
```

Matching that query would return

```
(treesit-query-capture node query)
  ⇒ ((biexp . <node for "1 + 2">)
      (number-in-exp . <node for "1">)
      (number-in-exp . <node for "2">))
```

As mentioned earlier, *query* could contain multiple patterns. For example, it could have two top-level patterns:

```
(setq query
  '((binary_expression) @biexp
    (number_literal) @number @biexp))

treesit-query-string string query language [Function]
This function parses string as language, matches its root node with query, and returns the result.
```

More query syntax

Besides node type and capture name, tree-sitter's pattern syntax can express anonymous node, field name, wildcard, quantification, grouping, alternation, anchor, and predicate.

Anonymous node

An anonymous node is written verbatim, surrounded by quotes. A pattern matching (and capturing) keyword `return` would be

```
"return" @keyword
```

Wild card

In a pattern, ‘(_)’ matches any named node, and ‘_’ matches any named or anonymous node. For example, to capture any named child of a `binary_expression` node, the pattern would be

```
(binary_expression (_ ) @in-biexp)
```

Field name

It is possible to capture child nodes that have specific field names. In the pattern below, `declarator` and `body` are field names, indicated by the colon following them.

```
(function_definition
  declarator: (_ ) @func-declarator
  body: (_ ) @func-body)
```

It is also possible to capture a node that doesn't have a certain field, say, a `function_definition` without a `body` field:

```
(function_definition !body) @func-no-body
```

Quantify node

Tree-sitter recognizes quantification operators ‘`:*`’, ‘`:+`’, and ‘`:?`’. Their meanings are the same as in regular expressions: ‘`:*`’ matches the preceding pattern zero or more times, ‘`:+`’ matches one or more times, and ‘`:?`’ matches zero or one times.

For example, the following pattern matches `type_declaration` nodes that have *zero or more* `long` keywords.

```
(type_declaration "long" :*) @long-type
```

The following pattern matches a type declaration that may or may not have a `long` keyword:

```
(type_declaration "long" :?) @long-type
```

Grouping

Similar to groups in regular expressions, we can bundle patterns into groups and apply quantification operators to them. For example, to express a comma-separated list of identifiers, one could write

```
(identifier) (",") (identifier)) :*
```

Alternation

Again, similar to regular expressions, we can express “match any one of these patterns” in a pattern. The syntax is a vector of patterns. For example, to capture some keywords in C, the pattern would be

```
[  
    "return"  
    "break"  
    "if"  
    "else"  
] @keyword
```

Anchor

The anchor operator `:anchor` can be used to enforce juxtaposition, i.e., to enforce two things to be directly next to each other. The two “things” can be two nodes, or a child and the end of its parent. For example, to capture the first child, the last child, or two adjacent children:

```
; ; Anchor the child with the end of its parent.  
(compound_expression (_) @last-child :anchor)
```

```
; ; Anchor the child with the beginning of its parent.  
(compound_expression :anchor (_) @first-child)
```

```
; ; Anchor two adjacent children.  
(compound_expression  
    (_) @prev-child  
    :anchor  
    (_) @next-child)
```

Note that the enforcement of juxtaposition ignores any anonymous nodes.

Predicate

It is possible to add predicate constraints to a pattern. For example, with the following pattern:

```

(
  (array :anchor (_)
    @first (_)
    @last :anchor)
  (:equal @first @last)
)

```

tree-sitter only matches arrays where the first element is equal to the last element. To attach a predicate to a pattern, we need to group them together. Currently there are three predicates: `:equal`, `:match`, and `:pred`.

:equal arg1 arg2 [Predicate]

Matches if `arg1` is equal to `arg2`. Arguments can be either strings or capture names. Capture names represent the text that the captured node spans in the buffer.

:match regexp capture-name [Predicate]

Matches if the text that `capture-name`'s node spans in the buffer matches regular expression `regexp`, given as a string literal. Matching is case-sensitive.

:pred fn &rest nodes [Predicate]

Matches if function `fn` returns non-`nil` when passed each node in `nodes` as arguments.

Note that a predicate can only refer to capture names that appear in the same pattern. Indeed, it makes little sense to refer to capture names in other patterns.

String patterns

Besides s-expressions, Emacs allows the tree-sitter's native query syntax to be used by writing them as strings. It largely resembles the s-expression syntax. For example, the following query

```

(treesit-query-capture
  node '((addition_expression
    left: (_)
    @left
    "+"
    @plus-sign
    right: (_)
    @right)
    @addition

    ["return" "break"]
    @keyword))

```

is equivalent to

```

(treesit-query-capture
  node "(addition_expression
    left: (_)
    @left
    \"+\"
    @plus-sign
    right: (_)
    @right)
    @addition

    [\\"return\\\" \\"break\\\"]
    @keyword")

```

Most patterns can be written directly as s-expressions inside a string. Only a few of them need modification:

- Anchor `:anchor` is written as `'.'`.
- `'?:'` is written as `'?'`.
- `'_:*'` is written as `'*'`.

- ‘:+’ is written as ‘+’.
- `:equal`, `:match` and `:pred` are written as `#equal`, `#match` and `#pred`, respectively. In general, predicates change their ‘:’ to ‘#’.

For example,

```
'((  
  (compound_expression :anchor (_) @first (_) :* @rest)  
  (:match "love" @first)  
))
```

is written in string form as

```
"(  
  (compound_expression . (_) @first (_)* @rest)  
  (#match \"love\" @first)  
)"
```

Compiling queries

If a query is intended to be used repeatedly, especially in tight loops, it is important to compile that query, because a compiled query is much faster than an uncompiled one. A compiled query can be used anywhere a query is accepted.

treesit-query-compile *language query* [Function]
 This function compiles *query* for *language* into a compiled query object and returns it.
 This function raises the `treesit-query-error` error if *query* is malformed. The signal data contains a description of the specific error. You can use `treesit-query-validate` to validate and debug the query.

treesit-query-language *query* [Function]
 This function returns the language of *query*.

treesit-query-expand *query* [Function]
 This function converts the s-expression *query* into the string format.

treesit-pattern-expand *pattern* [Function]
 This function converts the s-expression *pattern* into the string format.

For more details, read the tree-sitter project’s documentation about pattern-matching, which can be found at <https://tree-sitter.github.io/tree-sitter/using-parsers#pattern-matching-with-queries>.

37.6 Parsing Text in Multiple Languages

Sometimes, the source of a programming language could contain snippets of other languages; HTML + CSS + JavaScript is one example. In that case, text segments written in different languages need to be assigned different parsers. Traditionally, this is achieved by using narrowing. While tree-sitter works with narrowing (see [tree-sitter narrowing], page 1044), the recommended way is instead to specify regions of buffer text (i.e., ranges) in which a parser will operate. This section describes functions for setting and getting ranges for a parser.

Lisp programs should call `treesit-update-ranges` to make sure the ranges for each parser are correct before using parsers in a buffer, and call `treesit-language-at` to figure out the language responsible for the text at some position. These two functions don't work by themselves, they need major modes to set `treesit-range-settings` and `treesit-language-at-point-function`, which do the actual work. These functions and variables are explained in more detail towards the end of the section.

Getting and setting ranges

`treesit-parser-set-included-ranges` *parser ranges* [Function]

This function sets up *parser* to operate on *ranges*. The *parser* will only read the text of the specified ranges. Each range in *ranges* is a pair of the form `(beg . end)`.

The ranges in *ranges* must come in order and must not overlap. That is, in pseudo code:

```
(cl-loop for idx from 1 to (1- (length ranges))
        for prev = (nth (1- idx) ranges)
        for next = (nth idx ranges)
        should (<= (car prev) (cdr prev)
                  (car next) (cdr next)))
```

If *ranges* violates this constraint, or something else went wrong, this function signals the `treesit-range-invalid` error. The signal data contains a specific error message and the ranges we are trying to set.

This function can also be used for disabling ranges. If *ranges* is `nil`, the parser is set to parse the whole buffer.

Example:

```
(treesit-parser-set-included-ranges
  parser '((1 . 9) (16 . 24) (24 . 25)))
```

`treesit-parser-included-ranges` *parser* [Function]

This function returns the ranges set for *parser*. The return value is the same as the *ranges* argument of `treesit-parser-included-ranges`: a list of cons cells of the form `(beg . end)`. If *parser* doesn't have any ranges, the return value is `nil`.

```
(treesit-parser-included-ranges parser)
  ⇒ ((1 . 9) (16 . 24) (24 . 25))
```

`treesit-query-range` *source query &optional beg end* [Function]

This function matches *source* with *query* and returns the ranges of captured nodes. The return value is a list of cons cells of the form `(beg . end)`, where *beg* and *end* specify the beginning and the end of a region of text.

For convenience, *source* can be a language symbol, a parser, or a node. If it's a language symbol, this function matches in the root node of the first parser using that language; if a parser, this function matches in the root node of that parser; if a node, this function matches in that node.

The argument *query* is the query used to capture nodes (see Section 37.5 [Pattern Matching], page 1052). The capture names don't matter. The arguments *beg* and *end*, if both non-`nil`, limit the range in which this function queries.

Like other query functions, this function raises the `treesit-query-error` error if `query` is malformed.

Supporting multiple languages in Lisp programs

It should suffice for general Lisp programs to call the following two functions in order to support program sources that mix multiple languages.

`treesit-update-ranges &optional beg end`

[Function]

This function updates ranges for parsers in the buffer. It makes sure the parsers' ranges are set correctly between `beg` and `end`, according to `treesit-range-settings`. If omitted, `beg` defaults to the beginning of the buffer, and `end` defaults to the end of the buffer.

For example, fontification functions use this function before querying for nodes in a region.

`treesit-language-at pos`

[Function]

This function returns the language of the text at buffer position `pos`. Under the hood it calls `treesit-language-at-point-function` and returns its return value. If `treesit-language-at-point-function` is `nil`, this function returns the language of the first parser in the returned value of `treesit-parser-list`. If there is no parser in the buffer, it returns `nil`.

Supporting multiple languages in major modes

Normally, in a set of languages that can be mixed together, there is a *host language* and one or more *embedded languages*. A Lisp program usually first parses the whole document with the host language's parser, retrieves some information, sets ranges for the embedded languages with that information, and then parses the embedded languages.

Take a buffer containing HTML, CSS, and JavaScript as an example. A Lisp program will first parse the whole buffer with an HTML parser, then query the parser for `style_element` and `script_element` nodes, which correspond to CSS and JavaScript text, respectively. Then it sets the range of the CSS and JavaScript parsers to the range which their corresponding nodes span.

Given a simple HTML document:

```
<html>
  <script>1 + 2</script>
  <style>body { color: "blue"; }</style>
</html>
```

a Lisp program will first parse with a HTML parser, then set ranges for CSS and JavaScript parsers:

```
;; Create parsers.
(setq html (treesit-parser-create 'html))
(setq css (treesit-parser-create 'css))
(setq js (treesit-parser-create 'javascript))
```

```

;; Set CSS ranges.
(setq css-range
  (treesit-query-range
    'html
    '((style_element (raw_text) @capture)))
  (treesit-parser-set-included-ranges css css-range))

;; Set JavaScript ranges.
(setq js-range
  (treesit-query-range
    'html
    '((script_element (raw_text) @capture)))
  (treesit-parser-set-included-ranges js js-range))

```

Emacs automates this process in `treesit-update-ranges`. A multi-language major mode should set `treesit-range-settings` so that `treesit-update-ranges` knows how to perform this process automatically. Major modes should use the helper function `treesit-range-rules` to generate a value that can be assigned to `treesit-range-settings`. The settings in the following example directly translate into operations shown above.

```

(setq treesit-range-settings
  (treesit-range-rules
    :embed 'javascript
    :host 'html
    '((script_element (raw_text) @capture))

    :embed 'css
    :host 'html
    '((style_element (raw_text) @capture)))

```

`treesit-range-rules &rest query-specs` [Function]

This function is used to set `treesit-range-settings`. It takes care of compiling queries and other post-processing, and outputs a value that `treesit-range-settings` can have.

It takes a series of `query-specs`, where each `query-spec` is a `query` preceded by zero or more `keyword/value` pairs. Each `query` is a tree-sitter query in either the string, s-expression, or compiled form, or a function.

If `query` is a tree-sitter query, it should be preceded by two `keyword/value` pairs, where the `:embed` keyword specifies the embedded language, and the `:host` keyword specifies the host language.

`treesit-update-ranges` uses `query` to figure out how to set the ranges for parsers for the embedded language. It queries `query` in a host language parser, computes the ranges which the captured nodes span, and applies these ranges to embedded language parsers.

If `query` is a function, it doesn't need any `keyword` and `value` pair. It should be a function that takes 2 arguments, `start` and `end`, and sets the ranges for parsers in the

current buffer in the region between *start* and *end*. It is fine for this function to set ranges in a larger region that encompasses the region between *start* and *end*.

treesit-range-settings

[Variable]

This variable helps `treesit-update-ranges` in updating the ranges for parsers in the buffer. It is a list of *settings* where the exact format of a *setting* is considered internal. You should use `treesit-range-rules` to generate a value that this variable can have.

treesit-language-at-point-function

[Variable]

This variable's value should be a function that takes a single argument, *pos*, which is a buffer position, and returns the language of the buffer text at *pos*. This variable is used by `treesit-language-at`.

37.7 Developing major modes with tree-sitter

This section covers some general guidelines on developing tree-sitter integration for a major mode.

A major mode supporting tree-sitter features should roughly follow this pattern:

```
(define-derived-mode woomy-mode prog-mode "Woomy"
  "A mode for Woomy programming language."
  (when (treesit-ready-p 'woomy)
    (setq-local treesit-variables ...)
    ...
    (treesit-major-mode-setup)))
```

`treesit-ready-p` automatically emits a warning if conditions for enabling tree-sitter aren't met.

If a tree-sitter major mode shares setup with its “native” counterpart, one can create a “base mode” that contains the common setup, like this:

```
(define-derived-mode woomy--base-mode prog-mode "Woomy"
  "An internal mode for Woomy programming language."
  (common-setup)
  ...)

(define-derived-mode woomy-mode woomy--base-mode "Woomy"
  "A mode for Woomy programming language."
  (native-setup)
  ...)

(define-derived-mode woomy-ts-mode woomy--base-mode "Woomy"
  "A mode for Woomy programming language."
  (when (treesit-ready-p 'woomy)
    (setq-local treesit-variables ...)
    ...
    (treesit-major-mode-setup)))
```

treesit-ready-p *language* &*optional* *quiet*

[Function]

This function checks for conditions for activating tree-sitter. It checks whether Emacs was built with tree-sitter, whether the buffer's size is not too large for tree-sitter

to handle, and whether the grammar for *language* is available on the system (see Section 37.1 [Language Grammar], page 1039).

This function emits a warning if tree-sitter cannot be activated. If *quiet* is `message`, the warning is turned into a message; if *quiet* is `t`, no warning or message is displayed.

If all the necessary conditions are met, this function returns `non-nil`; otherwise it returns `nil`.

`treesit-major-mode-setup` [Function]

This function activates some tree-sitter features for a major mode.

Currently, it sets up the following features:

- If `treesit-font-lock-settings` (see Section 24.6.10 [Parser-based Font Lock], page 578) is `non-nil`, it sets up fontification.
- If `treesit-simple-indent-rules` (see Section 24.7.2 [Parser-based Indentation], page 590) is `non-nil`, it sets up indentation.
- If `treesit-defun-type-regexp` is `non-nil`, it sets up navigation functions for `beginning-of-defun` and `end-of-defun`.
- If `treesit-defun-name-function` is `non-nil`, it sets up add-log functions used by `add-log-current-defun`.
- If `treesit-simple-imenu-settings` (see Section 24.5 [Imenu], page 561) is `non-nil`, it sets up Imenu.

For more information on these built-in tree-sitter features, see Section 24.6.10 [Parser-based Font Lock], page 578, see Section 24.7.2 [Parser-based Indentation], page 590, and see Section 31.2.6 [List Motion], page 861.

For supporting mixing of multiple languages in a major mode, see Section 37.6 [Multiple Languages], page 1057.

Besides `beginning-of-defun` and `end-of-defun`, Emacs provides some additional functions for working with defuns: `treesit-defun-at-point` returns the defun node at point, and `treesit-defun-name` returns the name of a defun node.

`treesit-defun-at-point` [Function]

This function returns the defun node at point, or `nil` if none is found. It respects `treesit-defun-tactic`: if its value is `top-level`, this function returns the top-level defun, and if its value is `nested`, it returns the immediate enclosing defun.

This function requires `treesit-defun-type-regexp` to work. If it is `nil`, this function simply returns `nil`.

`treesit-defun-name node` [Function]

This function returns the defun name of *node*. It returns `nil` if there is no defun name for *node*, or if *node* is not a defun node, or if *node* is `nil`.

Depending on the language and major mode, the defun names are names like function name, class name, struct name, etc.

If `treesit-defun-name-function` is `nil`, this function always returns `nil`.

treesit-defun-name-function

[Variable]

If non-`nil`, this variable's value should be a function that is called with a node as its argument, and returns the defun name of the node. The function should have the same semantics as `treesit-defun-name`: if the node is not a defun node, or the node is a defun node but doesn't have a name, or the node is `nil`, it should return `nil`.

37.8 Tree-sitter C API Correspondence

Emacs' tree-sitter integration doesn't expose every feature provided by tree-sitter's C API. Missing features include:

- Creating a tree cursor and navigating the syntax tree with it.
- Setting timeout and cancellation flag for a parser.
- Setting the logger for a parser.
- Printing a DOT graph of the syntax tree to a file.
- Copying and modifying a syntax tree. (Emacs doesn't expose a tree object.)
- Using (row, column) coordinates as position.
- Updating a node with changes. (In Emacs, retrieve a new node instead of updating the existing one.)
- Querying statics of a language grammar.

In addition, Emacs makes some changes to the C API to make the API more convenient and idiomatic:

- Instead of using byte positions, the Emacs Lisp API uses character positions.
- Null nodes are converted to `nil`.

Below is the correspondence between all C API functions and their ELisp counterparts. Sometimes one ELisp function corresponds to multiple C functions, and many C functions don't have an ELisp counterpart.

38 Abbrevs and Abbrev Expansion

An abbreviation or *abbrev* is a string of characters that may be expanded to a longer string. The user can insert the abbrev string and find it replaced automatically with the expansion of the abbrev. This saves typing.

The set of abbrevs currently in effect is recorded in an *abbrev table*. Each buffer has a local abbrev table, but normally all buffers in the same major mode share one abbrev table. There is also a global abbrev table. Normally both are used.

An abbrev table is represented as an obarray. See Section 9.3 [Creating Symbols], page 135, for information about obarrays. Each abbreviation is represented by a symbol in the obarray. The symbol’s name is the abbreviation; its value is the expansion; its function definition is the hook function for performing the expansion (see Section 38.2 [Defining Abbrevs], page 1067); and its property list cell contains various additional properties, including the use count and the number of times the abbreviation has been expanded (see Section 38.6 [Abbrev Properties], page 1071).

Certain abbrevs, called *system abbrevs*, are defined by a major mode instead of the user. A system abbrev is identified by its non-*nil* `:system` property (see Section 38.6 [Abbrev Properties], page 1071). When abbrevs are saved to an abbrev file, system abbrevs are omitted. See Section 38.3 [Abbrev Files], page 1068.

Because the symbols used for abbrevs are not interned in the usual obarray, they will never appear as the result of reading a Lisp expression; in fact, normally they are never used except by the code that handles abbrevs. Therefore, it is safe to use them in a nonstandard way.

If the minor mode Abbrev mode is enabled, the buffer-local variable `abbrev-mode` is non-*nil*, and abbrevs are automatically expanded in the buffer. For the user-level commands for abbrevs, see Section “Abbrev Mode” in *The GNU Emacs Manual*.

38.1 Abbrev Tables

This section describes how to create and manipulate abbrev tables.

make-abbrev-table &optional props [Function]

This function creates and returns a new, empty abbrev table—an obarray containing no symbols. It is a vector filled with zeros. *props* is a property list that is applied to the new table (see Section 38.7 [Abbrev Table Properties], page 1072).

abbrev-table-p object [Function]

This function returns a non-*nil* value if *object* is an abbrev table.

clear-abbrev-table abbrev-table [Function]

This function undefines all the abbrevs in *abbrev-table*, leaving it empty.

copy-abbrev-table abbrev-table [Function]

This function returns a copy of *abbrev-table*—a new abbrev table containing the same abbrev definitions. It does *not* copy any property lists; only the names, values, and functions.

define-abbrev-table *tabname* *definitions* &optional *docstring* [Function]
 &rest *props*

This function defines *tabname* (a symbol) as an abbrev table name, i.e., as a variable whose value is an abbrev table. It defines abbrevs in the table according to *definitions*, a list of elements of the form (*abbrevname expansion* [*hook*] [*props...*]). These elements are passed as arguments to **define-abbrev**.

The optional string *docstring* is the documentation string of the variable *tabname*. The property list *props* is applied to the abbrev table (see Section 38.7 [Abbrev Table Properties], page 1072).

If this function is called more than once for the same *tabname*, subsequent calls add the definitions in *definitions* to *tabname*, rather than overwriting the entire original contents. (A subsequent call only overrides abbrevs explicitly redefined or undefined in *definitions*.)

abbrev-table-name-list [Variable]

This is a list of symbols whose values are abbrev tables. **define-abbrev-table** adds the new abbrev table name to this list.

insert-abbrev-table-description *name* &optional *human* [Function]

This function inserts before point a description of the abbrev table named *name*. The argument *name* is a symbol whose value is an abbrev table.

If *human* is non-*nil*, the description is human-oriented. System abbrevs are listed and identified as such. Otherwise the description is a Lisp expression—a call to **define-abbrev-table** that would define *name* as it is currently defined, but without the system abbrevs. (The mode or package using *name* is supposed to add these to *name* separately.)

38.2 Defining Abbrevs

define-abbrev is the low-level basic function for defining an abbrev in an abbrev table.

When a major mode defines a system abbrev, it should call **define-abbrev** and specify *t* for the :system property. Be aware that any saved non-system abbrevs are restored at startup, i.e., before some major modes are loaded. Therefore, major modes should not assume that their abbrev tables are empty when they are first loaded.

define-abbrev *abbrev-table* *name* *expansion* &optional *hook* &rest *props* [Function]

This function defines an abbrev named *name*, in *abbrev-table*, to expand to *expansion* and call *hook*, with properties *props* (see Section 38.6 [Abbrev Properties], page 1071). The return value is *name*. The :system property in *props* is treated specially here: if it has the value **force**, then it will overwrite an existing definition even for a non-system abbrev of the same name.

name should be a string. The argument *expansion* is normally the desired expansion (a string), or *nil* to undefine the abbrev. If it is anything but a string or *nil*, then the abbreviation expands solely by running *hook*.

The argument *hook* is a function or *nil*. If *hook* is non-*nil*, then it is called with no arguments after the abbrev is replaced with *expansion*; point is located at the end of *expansion* when *hook* is called.

If `hook` is a non-`nil` symbol whose `no-self-insert` property is non-`nil`, `hook` can explicitly control whether to insert the self-inserting input character that triggered the expansion. If `hook` returns `non-nil` in this case, that inhibits insertion of the character. By contrast, if `hook` returns `nil`, `expand-abbrev` (or `abbrev-insert`) also returns `nil`, as if expansion had not really occurred.

Normally, `define-abbrev` sets the variable `abbrevs-changed` to `t`, if it actually changes the abbrev. This is so that some commands will offer to save the abbrevs. It does not do this for a system abbrev, since those aren't saved anyway.

only-global-abbrevs

[User Option]

If this variable is non-`nil`, it means that the user plans to use global abbrevs only. This tells the commands that define mode-specific abbrevs to define global ones instead. This variable does not alter the behavior of the functions in this section; it is examined by their callers.

38.3 Saving Abbrevs in Files

A file of saved abbrev definitions is actually a file of Lisp code. The abbrevs are saved in the form of a Lisp program to define the same abbrev tables with the same contents. Therefore, you can load the file with `load` (see Section 16.1 [How Programs Do Loading], page 298). However, the function `quietly-read-abbrev-file` is provided as a more convenient interface. Emacs automatically calls this function at startup.

User-level facilities such as `save-some-buffers` can save abbrevs in a file automatically, under the control of variables described here.

abbrev-file-name

[User Option]

This is the default file name for reading and saving abbrevs. By default, Emacs will look for `~/.emacs.d/abbrev_defs`, and, if not found, for `~/.abbrev_defs`; if neither file exists, Emacs will create `~/.emacs.d/abbrev_defs`.

quietly-read-abbrev-file &optional filename

[Function]

This function reads abbrev definitions from a file named `filename`, previously written with `write-abbrev-file`. If `filename` is omitted or `nil`, the file specified in `abbrev-file-name` is used.

As the name implies, this function does not display any messages.

save-abbrevs

[User Option]

A non-`nil` value for `save-abbrevs` means that Emacs should offer to save abbrevs (if any have changed) when files are saved. If the value is `silently`, Emacs saves the abbrevs without asking the user. `abbrev-file-name` specifies the file to save the abbrevs in. The default value is `t`.

abbrevs-changed

[Variable]

This variable is set non-`nil` by defining or altering any abbrevs (except system abbrevs). This serves as a flag for various Emacs commands to offer to save your abbrevs.

write-abbrev-file &optional filename

[Command]

Save all abbrev definitions (except system abbrevs), for all abbrev tables listed in `abbrev-table-name-list`, in the file `filename`, in the form of a Lisp program that

when loaded will define the same abbrevs. Tables that do not have any abbrevs to save are omitted. If *filename* is `nil` or omitted, `abbrev-file-name` is used. This function returns `nil`.

38.4 Looking Up and Expanding Abbreviations

Abbrevs are usually expanded by certain interactive commands, including `self-insert-command`. This section describes the subroutines used in writing such commands, as well as the variables they use for communication.

`abbrev-symbol` *abbrev* &optional *table*

[Function]

This function returns the symbol representing the abbrev named *abbrev*. It returns `nil` if that abbrev is not defined. The optional second argument *table* is the abbrev table in which to look it up. If *table* is `nil`, this function tries first the current buffer's local abbrev table, and second the global abbrev table.

`abbrev-expansion` *abbrev* &optional *table*

[Function]

This function returns the string that *abbrev* would expand into (as defined by the abbrev tables used for the current buffer). It returns `nil` if *abbrev* is not a valid abbrev. The optional argument *table* specifies the abbrev table to use, as in `abbrev-symbol`.

`expand-abbrev`

[Command]

This command expands the abbrev before point, if any. If point does not follow an abbrev, this command does nothing. To do the expansion, it calls the function that is the value of the `abbrev-expand-function` variable, with no arguments, and returns whatever that function does.

The default expansion function returns the abbrev symbol if it did expansion, and `nil` otherwise. If the abbrev symbol has a hook function that is a symbol whose `no-self-insert` property is non-`nil`, and if the hook function returns `nil` as its value, then the default expansion function returns `nil`, even though expansion did occur.

`abbrev-insert` *abbrev* &optional *name start end*

[Function]

This function inserts the abbrev expansion of *abbrev*, replacing the text between *start* and *end*. If *start* is omitted, it defaults to point. *name*, if non-`nil`, should be the name by which this abbrev was found (a string); it is used to figure out whether to adjust the capitalization of the expansion. The function returns *abbrev* if the abbrev was successfully inserted, otherwise it returns `nil`.

`abbrev-prefix-mark` &optional *arg*

[Command]

This command marks the current location of point as the beginning of an abbrev. The next call to `expand-abbrev` will use the text from here to point (where it is then) as the abbrev to expand, rather than using the previous word as usual.

First, this command expands any abbrev before point, unless *arg* is non-`nil`. (Interactively, *arg* is the prefix argument.) Then it inserts a hyphen before point, to indicate the start of the next abbrev to be expanded. The actual expansion removes the hyphen.

abbrev-all-caps

[User Option]

When this is set non-*nil*, an abbrev entered entirely in upper case is expanded using all upper case. Otherwise, an abbrev entered entirely in upper case is expanded by capitalizing each word of the expansion.

abbrev-start-location

[Variable]

The value of this variable is a buffer position (an integer or a marker) for `expand-abbrev` to use as the start of the next abbrev to be expanded. The value can also be *nil*, which means to use the word before point instead. `abbrev-start-location` is set to *nil* each time `expand-abbrev` is called. This variable is also set by `abbrev-prefix-mark`.

abbrev-start-location-buffer

[Variable]

The value of this variable is the buffer for which `abbrev-start-location` has been set. Trying to expand an abbrev in any other buffer clears `abbrev-start-location`. This variable is set by `abbrev-prefix-mark`.

last-abbrev

[Variable]

This is the `abbrev-symbol` of the most recent abbrev expanded. This information is left by `expand-abbrev` for the sake of the `unexpand-abbrev` command (see Section “Expanding Abbrevs” in *The GNU Emacs Manual*).

last-abbrev-location

[Variable]

This is the location of the most recent abbrev expanded. This contains information left by `expand-abbrev` for the sake of the `unexpand-abbrev` command.

last-abbrev-text

[Variable]

This is the exact expansion text of the most recent abbrev expanded, after case conversion (if any). Its value is *nil* if the abbrev has already been unexpanded. This contains information left by `expand-abbrev` for the sake of the `unexpand-abbrev` command.

abbrev-expand-function

[Variable]

The value of this variable is a function that `expand-abbrev` will call with no arguments to do the expansion. The function can do anything it wants before and after performing the expansion. It should return the abbrev symbol if expansion took place.

The following sample code shows a simple use of `abbrev-expand-function`. It assumes that `foo-mode` is a mode for editing certain files in which lines that start with ‘#’ are comments. You want to use Text mode abbrevs for those lines. The regular local abbrev table, `foo-mode-abbrev-table` is appropriate for all other lines. See Section 38.5 [Standard Abbrev Tables], page 1071, for the definitions of `local-abbrev-table` and `text-mode-abbrev-table`. See Section 13.12 [Advising Functions], page 252, for details of `add-function`.

```
(defun foo-mode-abbrev-expand-function (expand)
  (if (not (save-excursion (forward-line 0) (eq (char-after) ?#)))
      ;; Performs normal expansion.
      (funcall expand)
      ;; We're inside a comment: use the text-mode abbrevs.
      (let ((local-abbrev-table text-mode-abbrev-table))
        (funcall expand))))
```

```
(add-hook 'foo-mode-hook
          (lambda ()
            (add-function :around (local 'abbrev-expand-function)
                          #'foo-mode-abbrev-expand-function)))
```

38.5 Standard Abbrev Tables

Here we list the variables that hold the abbrev tables for the preloaded major modes of Emacs.

global-abbrev-table [Variable]

This is the abbrev table for mode-independent abbrevs. The abbrevs defined in it apply to all buffers. Each buffer may also have a local abbrev table, whose abbrev definitions take precedence over those in the global table.

local-abbrev-table [Variable]

The value of this buffer-local variable is the (mode-specific) abbreviation table of the current buffer. It can also be a list of such tables.

abbrev-minor-mode-table-alist [Variable]

The value of this variable is a list of elements of the form (*mode . abbrev-table*) where *mode* is the name of a variable: if the variable is bound to a non-*nil* value, then the *abbrev-table* is active, otherwise it is ignored. *abbrev-table* can also be a list of abbrev tables.

fundamental-mode-abbrev-table [Variable]

This is the local abbrev table used in Fundamental mode; in other words, it is the local abbrev table in all buffers in Fundamental mode.

text-mode-abbrev-table [Variable]

This is the local abbrev table used in Text mode.

lisp-mode-abbrev-table [Variable]

This is the local abbrev table used in Lisp mode. It is the parent of the local abbrev table used in Emacs Lisp mode. See Section 38.7 [Abbrev Table Properties], page 1072.

38.6 Abbrev Properties

Abbrevs have properties, some of which influence the way they work. You can provide them as arguments to `define-abbrev`, and manipulate them with the following functions:

abbrev-put *abbrev prop val* [Function]

Set the property *prop* of *abbrev* to value *val*.

abbrev-get *abbrev prop* [Function]

Return the property *prop* of *abbrev*, or *nil* if the abbrev has no such property.

The following properties have special meanings:

:count This property counts the number of times the abbrev has been expanded. If not explicitly set, it is initialized to 0 by `define-abbrev`.

- :system** If non-`nil`, this property marks the abbrev as a system abbrev. Such abbrevs are not saved (see Section 38.3 [Abbrev Files], page 1068).
- :enable-function**
 - If non-`nil`, this property should be a function of no arguments which returns `nil` if the abbrev should not be used and `t` otherwise.
- :case-fixed**
 - If non-`nil`, this property indicates that the case of the abbrev's name is significant and should only match a text with the same pattern of capitalization. It also disables the code that modifies the capitalization of the expansion.

38.7 Abbrev Table Properties

Like abbrevs, abbrev tables have properties, some of which influence the way they work. You can provide them as arguments to `define-abbrev-table`, and manipulate them with the functions:

abbrev-table-put *table prop val* [Function]

Set the property *prop* of abbrev table *table* to value *val*.

abbrev-table-get *table prop* [Function]

Return the property *prop* of abbrev table *table*, or `nil` if *table* has no such property.

The following properties have special meaning:

- :enable-function**
 - This is like the `:enable-function` abbrev property except that it applies to all abbrevs in the table. It is used before even trying to find the abbrev before point, so it can dynamically modify the abbrev table.
- :case-fixed**
 - This is like the `:case-fixed` abbrev property except that it applies to all abbrevs in the table.
- :regexp**
 - If non-`nil`, this property is a regular expression that indicates how to extract the name of the abbrev before point, before looking it up in the table. When the regular expression matches before point, the abbrev name is expected to be in submatch 1. If this property is `nil`, the default is to use `backward-word` and `forward-word` to find the name. This property allows the use of abbrevs whose name contains characters of non-word syntax.
- :parents**
 - This property holds a list of tables from which to inherit other abbrevs.
- :abbrev-table-modify**
 - This property holds a counter incremented each time a new abbrev is added to the table.

39 Threads

Emacs Lisp provides a limited form of concurrency, called *threads*. All the threads in a given instance of Emacs share the same memory. Concurrency in Emacs Lisp is “mostly cooperative”, meaning that Emacs will only switch execution between threads at well-defined times. However, the Emacs thread support has been designed in a way to later allow more fine-grained concurrency, and correct programs should not rely on cooperative threading.

Currently, thread switching will occur upon explicit request via `thread-yield`, when waiting for keyboard input or for process output from asynchronous processes (e.g., during `accept-process-output`), or during blocking operations relating to threads, such as mutex locking or `thread-join`.

Emacs Lisp provides primitives to create and control threads, and also to create and control mutexes and condition variables, useful for thread synchronization.

While global variables are shared among all Emacs Lisp threads, local variables are not—a dynamic `let` binding is local. Each thread also has its own current buffer (see Section 28.2 [Current Buffer], page 671) and its own match data (see Section 35.6 [Match Data], page 1011).

Note that `let` bindings are treated specially by the Emacs Lisp implementation. There is no way to duplicate this unwinding and rewinding behavior other than by using `let`. For example, a manual implementation of `let` written using `unwind-protect` cannot arrange for variable values to be thread-specific.

In the case of lexical bindings (see Section 12.10 [Variable Scoping], page 201), a closure is an object like any other in Emacs Lisp, and bindings in a closure are shared by any threads invoking the closure.

39.1 Basic Thread Functions

Threads can be created and waited for. A thread cannot be exited directly, but the current thread can be exited implicitly, and other threads can be signaled.

`make-thread function &optional name` [Function]

Create a new thread of execution which invokes *function*. When *function* returns, the thread exits.

The new thread is created with no local variable bindings in effect. The new thread’s current buffer is inherited from the current thread.

name can be supplied to give a name to the thread. The name is used for debugging and informational purposes only; it has no meaning to Emacs. If *name* is provided, it must be a string.

This function returns the new thread.

`threadp object` [Function]

This function returns `t` if *object* represents an Emacs thread, `nil` otherwise.

`thread-join thread` [Function]

Block until *thread* exits, or until the current thread is signaled. It returns the result of the `thread` function. If *thread* has already exited, this returns immediately.

thread-signal *thread error-symbol data* [Function]

Like `signal` (see Section 11.7.3.1 [Signaling Errors], page 180), but the signal is delivered in the thread *thread*. If *thread* is the current thread, then this just calls `signal` immediately. Otherwise, *thread* will receive the signal as soon as it becomes current. If *thread* was blocked by a call to `mutex-lock`, `condition-wait`, or `thread-join`; `thread-signal` will unblock it.

If *thread* is the main thread, the signal is not propagated there. Instead, it is shown as message in the main thread.

thread-yield [Function]

Yield execution to the next runnable thread.

thread-name *thread* [Function]

Return the name of *thread*, as specified to `make-thread`.

thread-live-p *thread* [Function]

Return `t` if *thread* is alive, or `nil` if it is not. A thread is alive as long as its function is still executing.

thread--blocker *thread* [Function]

Return the object that *thread* is waiting on. This function is primarily intended for debugging, and is given a “double hyphen” name to indicate that.

If *thread* is blocked in `thread-join`, this returns the thread for which it is waiting.

If *thread* is blocked in `mutex-lock`, this returns the mutex.

If *thread* is blocked in `condition-wait`, this returns the condition variable.

Otherwise, this returns `nil`.

current-thread [Function]

Return the current thread.

all-threads [Function]

Return a list of all the live thread objects. A new list is returned by each invocation.

main-thread [Variable]

This variable keeps the main thread Emacs is running, or `nil` if Emacs is compiled without thread support.

When code run by a thread signals an error that is unhandled, the thread exits. Other threads can access the error form which caused the thread to exit using the following function.

thread-last-error &optional *cleanup* [Function]

This function returns the last error form recorded when a thread exited due to an error. Each thread that exits abnormally overwrites the form stored by the previous thread’s error with a new value, so only the last one can be accessed. If *cleanup* is non-`nil`, the stored form is reset to `nil`.

39.2 Mutexes

A *mutex* is an exclusive lock. At any moment, zero or one threads may own a mutex. If a thread attempts to acquire a mutex, and the mutex is already owned by some other thread, then the acquiring thread will block until the mutex becomes available.

Emacs Lisp mutexes are of a type called *recursive*, which means that a thread can re-acquire a mutex it owns any number of times. A mutex keeps a count of how many times it has been acquired, and each acquisition of a mutex must be paired with a release. The last release by a thread of a mutex reverts it to the unowned state, potentially allowing another thread to acquire the mutex.

mutexp object [Function]

This function returns `t` if *object* represents an Emacs mutex, `nil` otherwise.

make-mutex &optional name [Function]

Create a new mutex and return it. If *name* is specified, it is a name given to the mutex. It must be a string. The name is for debugging purposes only; it has no meaning to Emacs.

mutex-name mutex [Function]

Return the name of *mutex*, as specified to `make-mutex`.

mutex-lock mutex [Function]

This will block until this thread acquires *mutex*, or until this thread is signaled using `thread-signal`. If *mutex* is already owned by this thread, this simply returns.

mutex-unlock mutex [Function]

Release *mutex*. If *mutex* is not owned by this thread, this will signal an error.

with-mutex mutex body... [Macro]

This macro is the simplest and safest way to evaluate forms while holding a mutex. It acquires *mutex*, invokes *body*, and then releases *mutex*. It returns the result of *body*.

39.3 Condition Variables

A *condition variable* is a way for a thread to block until some event occurs. A thread can wait on a condition variable, to be woken up when some other thread notifies the condition.

A condition variable is associated with a mutex and, conceptually, with some condition. For proper operation, the mutex must be acquired, and then a waiting thread must loop, testing the condition and waiting on the condition variable. For example:

```
(with-mutex mutex
  (while (not global-variable)
    (condition-wait cond-var)))
```

The mutex ensures atomicity, and the loop is for robustness—there may be spurious notifications.

Similarly, the mutex must be held before notifying the condition. The typical, and best, approach is to acquire the mutex, make the changes associated with this condition, and then notify it:

```
(with-mutex mutex
```

```
(setq global-variable (some-computation))
(condition-notify cond-var))
```

make-condition-variable *mutex* &**optional** *name* [Function]

Make a new condition variable associated with *mutex*. If *name* is specified, it is a name given to the condition variable. It must be a string. The name is for debugging purposes only; it has no meaning to Emacs.

condition-variable-p *object* [Function]

This function returns `t` if *object* represents a condition variable, `nil` otherwise.

condition-wait *cond* [Function]

Wait for another thread to notify *cond*, a condition variable. This function will block until the condition is notified, or until a signal is delivered to this thread using **thread-signal**.

It is an error to call **condition-wait** without holding the condition's associated mutex.

condition-wait releases the associated mutex while waiting. This allows other threads to acquire the mutex in order to notify the condition.

condition-notify *cond* &**optional** *all* [Function]

Notify *cond*. The mutex with *cond* must be held before calling this. Ordinarily a single waiting thread is woken by **condition-notify**; but if *all* is not `nil`, then all threads waiting on *cond* are notified.

condition-notify releases the associated mutex while waiting. This allows other threads to acquire the mutex in order to wait on the condition.

condition-name *cond* [Function]

Return the name of *cond*, as passed to **make-condition-variable**.

condition-mutex *cond* [Function]

Return the mutex associated with *cond*. Note that the associated mutex cannot be changed.

39.4 The Thread List

The **list-threads** command lists all the currently alive threads. In the resulting buffer, each thread is identified either by the name passed to **make-thread** (see Section 39.1 [Basic Thread Functions], page 1073), or by its unique internal identifier if it was not created with a name. The status of each thread at the time of the creation or last update of the buffer is shown, in addition to the object the thread was blocked on at the time, if it was blocked.

thread-list-refresh-seconds [Variable]

The ***Threads*** buffer will automatically update twice per second. You can make the refresh rate faster or slower by customizing this variable.

Here are the commands available in the thread list buffer:

- b Show a backtrace of the thread at point. This will show where in its code the thread had yielded or was blocked at the moment you pressed **b**. Be aware that

the backtrace is a snapshot; the thread could have meanwhile resumed execution, and be in a different state, or could have exited.

You may use *g* in the thread's backtrace buffer to get an updated backtrace, as backtrace buffers do not automatically update. See Section 19.1.8 [Backtraces], page 338, for a description of backtraces and the other commands which work on them.

- s* Signal the thread at point. After *s*, type *q* to send a quit signal or *e* to send an error signal. Threads may implement handling of signals, but the default behavior is to exit on any signal. Therefore you should only use this command if you understand how to restart the target thread, because your Emacs session may behave incorrectly if necessary threads are killed.
- g* Update the list of threads and their statuses.

40 Processes

In the terminology of operating systems, a *process* is a space in which a program can execute. Emacs runs in a process. Emacs Lisp programs can invoke other programs in processes of their own. These are called *subprocesses* or *child processes* of the Emacs process, which is their *parent process*.

A subprocess of Emacs may be *synchronous* or *asynchronous*, depending on how it is created. When you create a synchronous subprocess, the Lisp program waits for the subprocess to terminate before continuing execution. When you create an asynchronous subprocess, it can run in parallel with the Lisp program. This kind of subprocess is represented within Emacs by a Lisp object which is also called a “process”. Lisp programs can use this object to communicate with the subprocess or to control it. For example, you can send signals, obtain status information, receive output from the process, or send input to it.

In addition to processes that run programs, Lisp programs can open connections of several types to devices or processes running on the same machine or on other machines. The supported connection types are: TCP and UDP network connections, serial port connections, and pipe connections. Each such connection is also represented by a process object.

processp *object* [Function]

This function returns `t` if *object* represents an Emacs process object, `nil` otherwise. The process object can represent a subprocess running a program or a connection of any supported type.

In addition to subprocesses of the current Emacs session, you can also access other processes running on your machine. See Section 40.12 [System Processes], page 1108.

40.1 Functions that Create Subprocesses

There are three primitives that create a new subprocess in which to run a program. One of them, `make-process`, creates an asynchronous process and returns a process object (see Section 40.4 [Asynchronous Processes], page 1086). The other two, `call-process` and `call-process-region`, create a synchronous process and do not return a process object (see Section 40.3 [Synchronous Processes], page 1081). There are various higher-level functions that make use of these primitives to run particular types of process.

Synchronous and asynchronous processes are explained in the following sections. Since the three functions are all called in a similar fashion, their common arguments are described here.

In all cases, the functions specify the program to be run. An error is signaled if the file is not found or cannot be executed. If the file name is relative, the variable `exec-path` contains a list of directories to search. Emacs initializes `exec-path` when it starts up, based on the value of the environment variable `PATH`. The standard file name constructs, ‘~’, ‘.’, and ‘..’, are interpreted as usual in `exec-path`, but environment variable substitutions (`$HOME`, etc.) are not recognized; use `substitute-in-file-name` to perform them (see Section 26.9.4 [File Name Expansion], page 639). `nil` in this list refers to `default-directory`.

Executing a program can also try adding suffixes to the specified name:

exec-suffixes

[User Option]

This variable is a list of suffixes (strings) to try adding to the specified program file name. The list should include "" if you want the name to be tried exactly as specified. The default value is system-dependent.

Please note: The argument *program* contains only the name of the program file; it may not contain any command-line arguments. You must use a separate argument, *args*, to provide those, as described below.

Each of the subprocess-creating functions has a *buffer-or-name* argument that specifies where the output from the program will go. It should be a buffer or a buffer name; if it is a buffer name, that will create the buffer if it does not already exist. It can also be *nil*, which says to discard the output, unless a custom filter function handles it. (See Section 40.9.2 [Filter Functions], page 1101, and Chapter 20 [Read and Print], page 371.) Normally, you should avoid having multiple processes send output to the same buffer because their output would be intermixed randomly. For synchronous processes, you can send the output to a file instead of a buffer (and the corresponding argument is therefore more appropriately called *destination*). By default, both standard output and standard error streams go to the same destination, but all the 3 primitives allow optionally to direct the standard error stream to a different destination.

All three of the subprocess-creating functions allow to specify command-line arguments for the process to run. For *call-process* and *call-process-region*, these come in the form of a *&rest* argument, *args*. For *make-process*, both the program to run and its command-line arguments are specified as a list of strings. The command-line arguments must all be strings, and they are supplied to the program as separate argument strings. Wildcard characters and other shell constructs have no special meanings in these strings, since the strings are passed directly to the specified program.

The subprocess inherits its environment from Emacs, but you can specify overrides for it with *process-environment*. See Section 42.3 [System Environment], page 1265. The subprocess gets its current directory from the value of *default-directory*.

exec-directory

[Variable]

The value of this variable is a string, the name of a directory that contains programs that come with GNU Emacs and are intended for Emacs to invoke. The program *movemail* is an example of such a program; Rmail uses it to fetch new mail from an inbox.

exec-path

[User Option]

The value of this variable is a list of directories to search for programs to run in subprocesses. Each element is either the name of a directory (i.e., a string), or *nil*, which stands for the default directory (which is the value of *default-directory*). See Section 26.6.6 [Locating Files], page 628, for the details of this search.

The value of *exec-path* is used by *call-process* and *start-process* when the *program* argument is not an absolute file name.

Generally, you should not modify *exec-path* directly. Instead, ensure that your PATH environment variable is set appropriately before starting Emacs. Trying to modify *exec-path* independently of PATH can lead to confusing results.

exec-path

[Function]

This function is an extension of the variable `exec-path`. If `default-directory` indicates a remote directory, this function returns a list of directories used for searching programs on the respective remote host. In case of a local `default-directory`, the function returns just the value of the variable `exec-path`.

40.2 Shell Arguments

Lisp programs sometimes need to run a shell and give it a command that contains file names that were specified by the user. These programs ought to be able to support any valid file name. But the shell gives special treatment to certain characters, and if these characters occur in the file name, they will confuse the shell. To handle these characters, use the function `shell-quote-argument`:

shell-quote-argument argument &optional posix

[Function]

This function returns a string that represents, in shell syntax, an argument whose actual contents are `argument`. It should work reliably to concatenate the return value into a shell command and then pass it to a shell for execution.

Precisely what this function does depends on your operating system. The function is designed to work with the syntax of your system's standard shell; if you use an unusual shell, you will need to redefine this function. See Section 42.22 [Security Considerations], page 1300.

; ; This example shows the behavior on GNU and Unix systems.

```
(shell-quote-argument "foo > bar")
⇒ "foo\\ \\>\\ bar"
```

; ; This example shows the behavior on MS-DOS and MS-Windows.

```
(shell-quote-argument "foo > bar")
⇒ "\\foo > bar\\\"
```

Here's an example of using `shell-quote-argument` to construct a shell command:

```
(concat "diff -u "
       (shell-quote-argument oldfile)
       " "
       (shell-quote-argument newfile))
```

If the optional `posix` argument is non-`nil`, `argument` is quoted according to POSIX shell quoting rules, regardless of the system's shell. This is useful when your shell could run on a remote host, which requires a POSIX shell in general.

```
(shell-quote-argument "foo > bar" (file-remote-p default-directory))■
```

The following two functions are useful for combining a list of individual command-line argument strings into a single string, and taking a string apart into a list of individual command-line arguments. These functions are mainly intended for converting user input in the minibuffer, a Lisp string, into a list of string arguments to be passed to `make-process`, `call-process` or `start-process`, or for converting such lists of arguments into a single Lisp string to be presented in the minibuffer or echo area. Note that if a shell is involved (e.g., if

using `call-process-shell-command`), arguments should still be protected by `shell-quote-argument`; `combine-and-quote-strings` is *not* intended to protect special characters from shell evaluation.

split-string-shell-command *string* [Function]

This function splits *string* into substrings, respecting double and single quotes, as well as backslash quoting.

```
(split-string-shell-command "ls /tmp/'foo bar'")
⇒ ("ls" "/tmp/foo bar")
```

split-string-and-unquote *string* &**optional** *separators* [Function]

This function splits *string* into substrings at matches for the regular expression *separators*, like `split-string` does (see Section 4.3 [Creating Strings], page 55); in addition, it removes quoting from the substrings. It then makes a list of the substrings and returns it.

If *separators* is omitted or `nil`, it defaults to "`\s-+`", which is a regular expression that matches one or more characters with whitespace syntax (see Section 36.2.1 [Syntax Class Table], page 1023).

This function supports two types of quoting: enclosing a whole string in double quotes "...", and quoting individual characters with a backslash escape '\'. The latter is also used in Lisp strings, so this function can handle those as well.

combine-and-quote-strings *list-of-strings* &**optional** *separator* [Function]

This function concatenates *list-of-strings* into a single string, quoting each string as necessary. It also sticks the *separator* string between each pair of strings; if *separator* is omitted or `nil`, it defaults to " ". The return value is the resulting string.

The strings in *list-of-strings* that need quoting are those that include *separator* as their substring. Quoting a string encloses it in double quotes "...". In the simplest case, if you are consing a command from the individual command-line arguments, every argument that includes embedded blanks will be quoted.

40.3 Creating a Synchronous Process

After a *synchronous process* is created, Emacs waits for the process to terminate before continuing. Starting `Dired` on GNU or Unix¹ is an example of this: it runs `ls` in a synchronous process, then modifies the output slightly. Because the process is synchronous, the entire directory listing arrives in the buffer before Emacs tries to do anything with it.

While Emacs waits for the synchronous subprocess to terminate, the user can quit by typing `C-g`. The first `C-g` tries to kill the subprocess with a `SIGINT` signal; but it waits until the subprocess actually terminates before quitting. If during that time the user types another `C-g`, that kills the subprocess instantly with `SIGKILL` and quits immediately (except on MS-DOS, where killing other processes doesn't work). See Section 22.11 [Quitting], page 471.

The synchronous subprocess functions return an indication of how the process terminated.

¹ On other systems, Emacs uses a Lisp emulation of `ls`; see Section 26.10 [Contents of Directories], page 645.

The output from a synchronous subprocess is generally decoded using a coding system, much like text read from a file. The input sent to a subprocess by `call-process-region` is encoded using a coding system, much like text written into a file. See Section 34.10 [Coding Systems], page 976.

`call-process` *program &optional infile destination display &rest args* [Function]

This function calls *program* and waits for it to finish.

The current working directory of the subprocess is set to the current buffer's value of `default-directory` if that is local (as determined by `unhandled-file-name-directory`), or "`~`" otherwise. If you want to run a process in a remote directory use `process-file`.

The standard input for the new process comes from file *infile* if *infile* is not `nil`, and from the null device otherwise. The argument *destination* says where to put the process output. Here are the possibilities:

a buffer Insert the output in that buffer, before point. This includes both the standard output stream and the standard error stream of the process.

a buffer name (a string)

Insert the output in a buffer with that name, before point.

`t` Insert the output in the current buffer, before point.

`nil` Discard the output.

`0` Discard the output, and return `nil` immediately without waiting for the subprocess to finish.

In this case, the process is not truly synchronous, since it can run in parallel with Emacs; but you can think of it as synchronous in that Emacs is essentially finished with the subprocess as soon as this function returns.

MS-DOS doesn't support asynchronous subprocesses, so this option doesn't work there.

(`:file file-name`)

Send the output to the file name specified, overwriting it if it already exists.

(`real-destination error-destination`)

Keep the standard output stream separate from the standard error stream; deal with the ordinary output as specified by *real-destination*, and dispose of the error output according to *error-destination*. If *error-destination* is `nil`, that means to discard the error output, `t` means mix it with the ordinary output, and a string specifies a file name to redirect error output into.

You can't directly specify a buffer to put the error output in; that is too difficult to implement. But you can achieve this result by sending the error output to a temporary file and then inserting the file into a buffer when the subprocess finishes.

If `display` is non-`nil`, then `call-process` redisplays the buffer as output is inserted. (However, if the coding system chosen for decoding output is `undecided`, meaning deduce the encoding from the actual data, then redisplay sometimes cannot continue once non-ASCII characters are encountered. There are fundamental reasons why it is hard to fix this; see Section 40.9 [Output from Processes], page 1099.)

Otherwise the function `call-process` does no redisplay, and the results become visible on the screen only when Emacs redisperses that buffer in the normal course of events. The remaining arguments, `args`, are strings that specify command line arguments for the program. Each string is passed to `program` as a separate argument.

The value returned by `call-process` (unless you told it not to wait) indicates the reason for process termination. A number gives the exit status of the subprocess; 0 means success, and any other value means failure. If the process terminated with a signal, `call-process` returns a string describing the signal. If you told `call-process` not to wait, it returns `nil`.

In the examples below, the buffer ‘`foo`’ is current.

```
(call-process "pwd" nil t)
⇒ 0

----- Buffer: foo -----
/home/lewis/manual
----- Buffer: foo -----

(call-process "grep" nil "bar" nil "lewis" "/etc/passwd")
⇒ 0

----- Buffer: bar -----
lewis:x:1001:1001:Bil Lewis,,,,:/home/lewis:/bin/bash

----- Buffer: bar -----
```

Here is an example of the use of `call-process`, as used to be found in the definition of the `insert-directory` function:

```
(call-process insert-directory-program nil t nil switches
  (if full-directory-p
      (concat (file-name-as-directory file) "."))
  file))
```

`process-file` `program` &`optional` `infile` `buffer` `display` &`rest` `args` [Function]

This function processes files synchronously in a separate process. It is similar to `call-process`, but may invoke a file name handler based on the value of the variable `default-directory`, which specifies the current working directory of the subprocess.

The arguments are handled in almost the same way as for `call-process`, with the following differences:

Some file name handlers may not support all combinations and forms of the arguments `infile`, `buffer`, and `display`. For example, some file name handlers might behave as if `display` were `nil`, regardless of the value actually passed. As another example, some file name handlers might not support separating standard output and error output by way of the `buffer` argument.

If a file name handler is invoked, it determines the program to run based on the first argument `program`. For instance, suppose that a handler for remote files is invoked.

Then the path that is used for searching for the program might be different from `exec-path`.

The second argument `infile` may invoke a file name handler. The file name handler could be different from the handler chosen for the `process-file` function itself. (For example, `default-directory` could be on one remote host, and `infile` on a different remote host. Or `default-directory` could be non-special, whereas `infile` is on a remote host.)

If `buffer` is a list of the form `(real-destination error-destination)`, and `error-destination` names a file, then the same remarks as for `infile` apply.

The remaining arguments (`args`) will be passed to the process verbatim. Emacs is not involved in processing file names that are present in `args`. To avoid confusion, it may be best to avoid absolute file names in `args`, but rather to specify all file names as relative to `default-directory`. The function `file-relative-name` is useful for constructing such relative file names. Alternatively, you can use `file-local-name` (see Section 26.12 [Magic File Names], page 649) to obtain an absolute file name as seen from the remote host's perspective.

`process-file-side-effects`

[Variable]

This variable indicates whether a call of `process-file` changes remote files.

By default, this variable is always set to `t`, meaning that a call of `process-file` could potentially change any file on a remote host. When set to `nil`, a file name handler could optimize its behavior with respect to remote file attribute caching.

You should only ever change this variable with a let-binding; never with `setq`.

`process-file-return-signal-string`

[User Option]

This user option indicates whether a call of `process-file` returns a string describing the signal interrupting a remote process.

When a process returns an exit code greater than 128, it is interpreted as a signal. `process-file` requires to return a string describing this signal.

Since there are processes violating this rule, returning exit codes greater than 128 which are not bound to a signal, `process-file` returns always the exit code as natural number for remote processes. Setting this user option to `non-nil` forces `process-file` to interpret such exit codes as signals, and to return a corresponding string.

`call-process-region start end program &optional delete destination display &rest args`

[Function]

This function sends the text from `start` to `end` as standard input to a process running `program`. It deletes the text sent if `delete` is non-`nil`; this is useful when `destination` is `t`, to insert the output in the current buffer in place of the input.

The arguments `destination` and `display` control what to do with the output from the subprocess, and whether to update the display as it comes in. For details, see the description of `call-process`, above. If `destination` is the integer 0, `call-process-region` discards the output and returns `nil` immediately, without waiting for the subprocess to finish (this only works if asynchronous subprocesses are supported; i.e., not on MS-DOS).

The remaining arguments, `args`, are strings that specify command line arguments for the program.

The return value of `call-process-region` is just like that of `call-process`: `nil` if you told it to return without waiting; otherwise, a number or string which indicates how the subprocess terminated.

In the following example, we use `call-process-region` to run the `cat` utility, with standard input being the first five characters in buffer ‘`foo`’ (the word ‘`input`’). `cat` copies its standard input into its standard output. Since the argument `destination` is `t`, this output is inserted in the current buffer.

```
----- Buffer: foo -----
input*
----- Buffer: foo -----  

(call-process-region 1 6 "cat" nil t)
⇒ 0  

----- Buffer: foo -----
inputinput*
----- Buffer: foo -----
```

For example, the `shell-command-on-region` command uses `call-shell-region` in a manner similar to this:

```
(call-shell-region
  start end
  command          ; shell command
  nil              ; do not delete region
  buffer)          ; send output to buffer
```

call-process-shell-command *command* &**optional** *infile* *destination* [Function]
display

This function executes the shell command *command* synchronously. The other arguments are handled as in `call-process`. An old calling convention allowed passing any number of additional arguments after *display*, which were concatenated to *command*; this is still supported, but strongly discouraged.

process-file-shell-command *command* &**optional** *infile* *destination* [Function]
display

This function is like `call-process-shell-command`, but uses `process-file` internally. Depending on `default-directory`, *command* can be executed also on remote hosts. An old calling convention allowed passing any number of additional arguments after *display*, which were concatenated to *command*; this is still supported, but strongly discouraged.

call-shell-region *start* *end* *command* &**optional** *delete* *destination* [Function]

This function sends the text from *start* to *end* as standard input to an inferior shell running *command*. This function is similar than `call-process-region`, with `process` being a shell. The arguments `delete`, `destination` and the return value are like in `call-process-region`. Note that this function doesn’t accept additional arguments.

shell-command-to-string *command* [Function]

This function executes *command* (a string) as a shell command, then returns the command’s output as a string.

process-lines program &rest args [Function]

This function runs *program*, waits for it to finish, and returns its output as a list of strings. Each string in the list holds a single line of text output by the program; the end-of-line characters are stripped from each line. The arguments beyond *program*, *args*, are strings that specify command-line arguments with which to run the program.

If *program* exits with a non-zero exit status, this function signals an error.

This function works by calling `call-process`, so program output is decoded in the same way as for `call-process`.

process-lines-ignore-status program &rest args [Function]

This function is just like `process-lines`, but does not signal an error if *program* exits with a non-zero exit status.

40.4 Creating an Asynchronous Process

In this section, we describe how to create an asynchronous process. After an asynchronous process is created, it runs in parallel with Emacs, and Emacs can communicate with it using the functions described in the following sections (see Section 40.7 [Input to Processes], page 1096, and see Section 40.9 [Output from Processes], page 1099). Note that process communication is only partially asynchronous: Emacs sends and receives data to and from a process only when those functions are called.

An asynchronous process is controlled either via a *pty* (pseudo-terminal) or a *pipe*. The choice of pty or pipe is made when creating the process, by default based on the value of the variable `process-connection-type` (see below). If available, ptys are usually preferable for processes visible to the user, as in Shell mode, because they allow for job control (*C-c*, *C-z*, etc.) between the process and its children, and because interactive programs treat ptys as terminal devices, whereas pipes don't support these features. However, for subprocesses used by Lisp programs for internal purposes (i.e., no user interaction with the subprocess is required), where significant amounts of data need to be exchanged between the subprocess and the Lisp program, it is often better to use a pipe, because pipes are more efficient. Also, the total number of ptys is limited on many systems, and it is good not to waste them unnecessarily.

make-process &rest args [Function]

This function is the basic low-level primitive for starting asynchronous subprocesses. It returns a process object representing the subprocess. Compared to the more high-level `start-process`, described below, it takes keyword arguments, is more flexible, and allows to specify process filters and sentinels in a single call.

The arguments *args* are a list of keyword/argument pairs. Omitting a keyword is always equivalent to specifying it with value `nil`. Here are the meaningful keywords:

:name name

Use the string *name* as the process name; if a process with this name already exists, then *name* is modified (by appending '*<1>*', etc.) to be unique.

:buffer buffer

Use *buffer* as the process buffer. If the value is `nil`, the subprocess is not associated with any buffer.

:command *command*

Use *command* as the command line of the process. The value should be a list starting with the program's executable file name, followed by strings to give to the program as its arguments. If the first element of the list is **nil**, Emacs opens a new pseudoterminal (pty) and associates its input and output with *buffer*, without actually running any program; the rest of the list elements are ignored in that case.

:coding *coding*

If *coding* is a symbol, it specifies the coding system to be used for both reading and writing of data from and to the connection. If *coding* is a cons cell (*decoding* . *encoding*), then *decoding* will be used for reading and *encoding* for writing. The coding system used for encoding the data written to the program is also used for encoding the command-line arguments (but not the program itself, whose file name is encoded as any other file name; see Section 34.10.2 [Encoding and I/O], page 978).

If *coding* is **nil**, the default rules for finding the coding system will apply. See Section 34.10.5 [Default Coding Systems], page 983.

:connection-type *type*

Initialize the type of device used to communicate with the subprocess. Possible values are **pty** to use a pty, **pipe** to use a pipe, or **nil** to use the default derived from the value of the **process-connection-type** variable. If *type* is a cons cell (*input* . *output*), then *input* will be used for standard input and *output* for standard output (and standard error if **:stderr** is **nil**).

On systems where ptys are not available (MS-Windows), this parameter is ignored, and pipes are used unconditionally.

:noquery *query-flag*

Initialize the process query flag to *query-flag*. See Section 40.11 [Query Before Exit], page 1107.

:stop *stopped*

If provided, *stopped* must be **nil**; it is an error to use any non-**nil** value. The **:stop** key is ignored otherwise and is retained for compatibility with other process types such as pipe processes. Asynchronous subprocesses never start in the stopped state.

:filter *filter*

Initialize the process filter to *filter*. If not specified, a default filter will be provided, which can be overridden later. See Section 40.9.2 [Filter Functions], page 1101.

:sentinel *sentinel*

Initialize the process sentinel to *sentinel*. If not specified, a default sentinel will be used, which can be overridden later. See Section 40.10 [Sentinels], page 1105.

:stderr *stderr*

Associate *stderr* with the standard error of the process. A non-*nil* value should be either a buffer or a pipe process created with **make-pipe-process**, described below. If *stderr* is *nil*, standard error is mixed with standard output, and both are sent to *buffer* or *filter*.

If *stderr* is a buffer, Emacs will create a pipe process, the *standard error process*. This process will have the default filter (see Section 40.9.2 [Filter Functions], page 1101), sentinel (see Section 40.10 [Sentinels], page 1105), and coding systems (see Section 34.10.5 [Default Coding Systems], page 983). On the other hand, it will use *query-flag* as its query-on-exit flag (see Section 40.11 [Query Before Exit], page 1107). It will be associated with the *stderr* buffer (see Section 40.9.1 [Process Buffers], page 1099) and send its output (which is the standard error of the main process) there. To get the process object for the standard error process, pass the *stderr* buffer to **get-buffer-process**.

If *stderr* is a pipe process, Emacs will use it as standard error process for the new process.

:file-handler *file-handler*

If *file-handler* is non-*nil*, then look for a file name handler for the current buffer's **default-directory**, and invoke that file name handler to make the process. If there is no such handler, proceed as if *file-handler* were *nil*.

The original argument list, modified with the actual connection information, is available via the **process-contact** function.

The current working directory of the subprocess is set to the current buffer's value of **default-directory** if that is local (as determined by **unhandled-file-name-directory**), or `~` otherwise. If you want to run a process in a remote directory, pass **:file-handler** *t* to **make-process**. In that case, the current working directory is the local name component of **default-directory** (as determined by **file-local-name**).

Depending on the implementation of the file name handler, it might not be possible to apply *filter* or *sentinel* to the resulting process object. The **:stderr** argument cannot be a pipe process, file name handlers do not support pipe processes for this. A buffer as **:stderr** argument is accepted, its contents is shown without the use of pipe processes. See Section 40.9.2 [Filter Functions], page 1101, Section 40.10 [Sentinels], page 1105, and Section 40.9.4 [Accepting Output], page 1104.

Some file name handlers may not support **make-process**. In such cases, this function does nothing and returns *nil*.

make-pipe-process &*rest args*

[Function]

This function creates a bidirectional pipe which can be attached to a child process. This is useful with the **:stderr** keyword of **make-process**. The function returns a process object.

The arguments *args* are a list of keyword/argument pairs. Omitting a keyword is always equivalent to specifying it with value *nil*.

Here are the meaningful keywords:

`:name name`

Use the string *name* as the process name. As with `make-process`, it is modified if necessary to make it unique.

`:buffer buffer`

Use *buffer* as the process buffer.

`:coding coding`

If *coding* is a symbol, it specifies the coding system to be used for both reading and writing of data from and to the connection. If *coding* is a cons cell (*decoding* . *encoding*), then *decoding* will be used for reading and *encoding* for writing.

If *coding* is `nil`, the default rules for finding the coding system will apply. See Section 34.10.5 [Default Coding Systems], page 983.

`:noquery query-flag`

Initialize the process query flag to *query-flag*. See Section 40.11 [Query Before Exit], page 1107.

`:stop stopped`

If *stopped* is non-`nil`, start the process in the stopped state. In the stopped state, a pipe process does not accept incoming data, but you can send outgoing data. The stopped state is set by `stop-process` and cleared by `continue-process` (see Section 40.8 [Signals to Processes], page 1097).

`:filter filter`

Initialize the process filter to *filter*. If not specified, a default filter will be provided, which can be changed later. See Section 40.9.2 [Filter Functions], page 1101.

`:sentinel sentinel`

Initialize the process sentinel to *sentinel*. If not specified, a default sentinel will be used, which can be changed later. See Section 40.10 [Sentinels], page 1105.

The original argument list, modified with the actual connection information, is available via the `process-contact` function.

`start-process name buffer-or-name program &rest args` [Function]

This function is a higher-level wrapper around `make-process`, exposing an interface that is similar to `call-process`. It creates a new asynchronous subprocess and starts the specified *program* running in it. It returns a process object that stands for the new subprocess in Lisp. The argument *name* specifies the name for the process object; as with `make-process`, it is modified if necessary to make it unique. The buffer *buffer-or-name* is the buffer to associate with the process.

If *program* is `nil`, Emacs opens a new pseudoterminal (pty) and associates its input and output with *buffer-or-name*, without creating a subprocess. In that case, the remaining arguments *args* are ignored.

The rest of *args* are strings that specify command line arguments for the subprocess. In the example below, the first process is started and runs (rather, sleeps) for 100 seconds (the output buffer ‘*foo*’ is created immediately). Meanwhile, the second process is started, and given the name ‘*my-process<1>*’ for the sake of uniqueness. It inserts the directory listing at the end of the buffer ‘*foo*’, before the first process finishes. Then it finishes, and a message to that effect is inserted in the buffer. Much later, the first process finishes, and another message is inserted in the buffer for it.

```
(start-process "my-process" "foo" "sleep" "100")
⇒ #<process my-process>

(start-process "my-process" "foo" "ls" "-l" "/bin")
⇒ #<process my-process<1>>

----- Buffer: foo -----
total 8336
-rwxr-xr-x 1 root root 971384 Mar 30 10:14 bash
-rwxr-xr-x 1 root root 146920 Jul 5 2011 bsd-csh
...
-rwxr-xr-x 1 root root 696880 Feb 28 15:55 zsh4

Process my-process<1> finished

Process my-process finished
----- Buffer: foo -----
```

start-file-process *name buffer-or-name program &rest args* [Function]

Like **start-process**, this function starts a new asynchronous subprocess running *program* in it, and returns its process object.

The difference from **start-process** is that this function may invoke a file name handler based on the value of **default-directory**. This handler ought to run *program*, perhaps on the local host, perhaps on a remote host that corresponds to **default-directory**. In the latter case, the local part of **default-directory** becomes the working directory of the process.

This function does not try to invoke file name handlers for *program* or for the rest of *args*. For that reason, if *program* or any of *args* use the remote-file syntax (see Section 26.12 [Magic File Names], page 649), they must be converted either to file names relative to **default-directory**, or to names that identify the files locally on the remote host, by running them through **file-local-name**.

Depending on the implementation of the file name handler, it might not be possible to apply **process-filter** or **process-sentinel** to the resulting process object. See Section 40.9.2 [Filter Functions], page 1101, and Section 40.10 [Sentinels], page 1105.

Some file name handlers may not support **start-file-process** (for example the function **ange-ftp-hook-function**). In such cases, this function does nothing and returns **nil**.

start-process-shell-command *name buffer-or-name command* [Function]

This function is like **start-process**, except that it uses a shell to execute the specified *command*. The argument *command* is a shell command string. The variable **shell-file-name** specifies which shell to use.

The point of running a program through the shell, rather than directly with `make-process` or `start-process`, is so that you can employ shell features such as wildcards in the arguments. It follows that if you include any arbitrary user-specified arguments in the command, you should quote them with `shell-quote-argument` first, so that any special shell characters do *not* have their special shell meanings. See Section 40.2 [Shell Arguments], page 1080. Of course, when executing commands based on user input you should also consider the security implications.

start-file-process-shell-command *name buffer-or-name* [Function]
command

This function is like `start-process-shell-command`, but uses `start-file-process` internally. Because of this, *command* can also be executed on remote hosts, depending on `default-directory`.

process-connection-type [Variable]

This variable controls the type of device used to communicate with asynchronous subprocesses. If it is `non-nil`, then ptys are used, when available. Otherwise, pipes are used.

The value of `process-connection-type` takes effect when `make-process` or `start-process` is called. So you can specify how to communicate with one subprocess by binding the variable around the call to these functions.

Note that the value of this variable is ignored when `make-process` is called with a `non-nil` value of the `:stderr` parameter; in that case, Emacs will communicate with the process using pipes. It is also ignored if ptys are unavailable (MS-Windows).

```
(let ((process-connection-type nil)) ; use a pipe
     (start-process ...))
```

To determine whether a given subprocess actually got a pipe or a pty, use the function `process-tty-name` (see Section 40.6 [Process Information], page 1092).

process-error-pause-time [Variable]

If a process sentinel/filter function has an error, Emacs will (by default) pause Emacs for `process-error-pause-time` seconds after displaying this error, so that users will see the error in question. However, this can lead to situations where Emacs becomes unresponsive (if there's a lot of these errors happening), so this can be disabled by setting `process-error-pause-time` to 0.

40.5 Deleting Processes

Deleting a process disconnects Emacs immediately from the subprocess. Processes are deleted automatically after they terminate, but not necessarily right away. You can delete a process explicitly at any time. If you explicitly delete a terminated process before it is deleted automatically, no harm results. Deleting a running process sends a signal to terminate it (and its child processes, if any), and calls the process sentinel. See Section 40.10 [Sentinels], page 1105.

When a process is deleted, the process object itself continues to exist as long as other Lisp objects point to it. All the Lisp primitives that work on process objects accept deleted processes, but those that do I/O or send signals will report an error. The process mark

continues to point to the same place as before, usually into a buffer where output from the process was being inserted.

delete-exited-processes

[User Option]

This variable controls automatic deletion of processes that have terminated (due to calling `exit` or to a signal). If it is `nil`, then they continue to exist until the user runs `list-processes`. Otherwise, they are deleted immediately after they exit.

delete-process &optional process

[Function]

This function deletes a process, killing it with a `SIGKILL` signal if the process was running a program. The argument may be a process, the name of a process, a buffer, or the name of a buffer. (A buffer or buffer-name stands for the process that `get-buffer-process` returns, and a missing or `nil` process means that the current buffer's process should be killed.) Calling `delete-process` on a running process terminates it, updates the process status, and runs the sentinel immediately. If the process has already terminated, calling `delete-process` has no effect on its status, or on the running of its sentinel (which will happen sooner or later).

If the process object represents a network, serial, or pipe connection, its status changes to `closed`; otherwise, it changes to `signal`, unless the process already exited. See Section 40.6 [Process Information], page 1092.

```
(delete-process "*shell*")
⇒ nil
```

40.6 Process Information

Several functions return information about processes.

list-processes &optional query-only buffer

[Command]

This command displays a listing of all living processes. In addition, it finally deletes any process whose status was ‘Exited’ or ‘Signaled’. It returns `nil`.

The processes are shown in a buffer named `*Process List*` (unless you specify otherwise using the optional argument `buffer`), whose major mode is Process Menu mode.

If `query-only` is non-`nil`, it only lists processes whose query flag is non-`nil`. See Section 40.11 [Query Before Exit], page 1107.

process-list

[Function]

This function returns a list of all processes that have not been deleted.

```
(process-list)
⇒ (#<process display-time> #<process shell>)
```

num-processors &optional query

[Function]

This function returns the number of processors, a positive integer. Each usable thread execution unit counts as a processor. By default, the count includes the number of available processors, which you can override by setting the `OMP_NUM_THREADS` environment variable of OpenMP (<https://www.openmp.org/spec-html/5.1/openmpse59.html>). If the optional argument `query` is `current`, this function ignores `OMP_NUM_THREADS`; if `query` is `all`, this function also counts processors that are on the system but are not available to the current process.

get-process name [Function]

This function returns the process named *name* (a string), or `nil` if there is none. The argument *name* can also be a process object, in which case it is returned.

```
(get-process "shell")
⇒ #<process shell>
```

process-command process [Function]

This function returns the command that was executed to start *process*. This is a list of strings, the first string being the program executed and the rest of the strings being the arguments that were given to the program. For a network, serial, or pipe connection, this is either `nil`, which means the process is running or `t` (process is stopped).

```
(process-command (get-process "shell"))
⇒ ("bash" "-i")
```

process-contact process &optional key no-block [Function]

This function returns information about how a network, a serial, or a pipe connection was set up. When *key* is `nil`, it returns (*hostname service*) for a network connection, (*port speed*) for a serial connection, and `t` for a pipe connection. For an ordinary child process, this function always returns `t` when called with a `nil` key.

If *key* is `t`, the value is the complete status information for the connection, server, serial port, or pipe; that is, the list of keywords and values specified in `make-network-process`, `make-serial-process`, or `make-pipe-process`, except that some of the values represent the current status instead of what you specified.

For a network process, the values include (see `make-network-process` for a complete list):

- :buffer** The associated value is the process buffer.
 - :filter** The associated value is the process filter function. See Section 40.9.2 [Filter Functions], page 1101.
 - :sentinel** The associated value is the process sentinel function. See Section 40.10 [Sentinels], page 1105.
 - :remote** In a connection, the address in internal format of the remote peer.
 - :local** The local address, in internal format.
 - :service** In a server, if you specified `t` for *service*, this value is the actual port number.
- `:local` and `:remote` are included even if they were not specified explicitly in `make-network-process`.

For a serial connection, see `make-serial-process` and `serial-process-configure` for the list of keys. For a pipe connection, see `make-pipe-process` for the list of keys.

If *key* is a keyword, the function returns the value corresponding to that keyword.

If *process* is a non-blocking network stream that hasn't been fully set up yet, then this function will block until that has happened. If given the optional *no-block* parameter, this function will return `nil` instead of blocking.

process-id *process*

[Function]

This function returns the PID of *process*. This is an integral number that distinguishes the process *process* from all other processes running on the same computer at the current time. The PID of a process is chosen by the operating system kernel when the process is started and remains constant as long as the process exists. For network, serial, and pipe connections, this function returns **nil**.

process-name *process*

[Function]

This function returns the name of *process*, as a string.

process-status *process-name*

[Function]

This function returns the status of *process-name* as a symbol. The argument *process-name* must be a process, a buffer, or a process name (a string).

The possible values for an actual subprocess are:

- run** for a process that is running.
 - stop** for a process that is stopped but continuable.
 - exit** for a process that has exited.
 - signal** for a process that has received a fatal signal.
 - open** for a network, serial, or pipe connection that is open.
 - closed** for a network, serial, or pipe connection that is closed. Once a connection is closed, you cannot reopen it, though you might be able to open a new connection to the same place.
 - connect** for a non-blocking connection that is waiting to complete.
 - failed** for a non-blocking connection that has failed to complete.
 - listen** for a network server that is listening.
 - nil** if *process-name* is not the name of an existing process.
- ```
(process-status (get-buffer "*shell*"))
 ⇒ run
```

For a network, serial, or pipe connection, **process-status** returns one of the symbols **open**, **stop**, or **closed**. The latter means that the other side closed the connection, or Emacs did **delete-process**. The value **stop** means that **stop-process** was called on the connection.

**process-live-p** *process*

[Function]

This function returns non-**nil** if *process* is alive. A process is considered alive if its status is **run**, **open**, **listen**, **connect** or **stop**.

**process-type** *process*

[Function]

This function returns the symbol **network** for a network connection or server, **serial** for a serial port connection, **pipe** for a pipe connection, or **real** for a subprocess created for running a program.

**process-exit-status** process [Function]

This function returns the exit status of *process* or the signal number that killed it. (Use the result of **process-status** to determine which of those it is.) If *process* has not yet terminated, the value is 0. For network, serial, and pipe connections that are already closed, the value is either 0 or 256, depending on whether the connection was closed normally or abnormally.

**process-tty-name** process &optional stream [Function]

This function returns the terminal name that *process* is using for its communication with Emacs—or **nil** if it is using pipes instead of a pty (see **process-connection-type** in Section 40.4 [Asynchronous Processes], page 1086). By default, this function returns the terminal name if any of *process*'s standard streams use a terminal. If *stream* is one of **stdin**, **stdout**, or **stderr**, this function returns the terminal name (or **nil**, as above) that *process* uses for that stream specifically. You can use this to determine whether a particular stream uses a pipe or a pty.

If *process* represents a program running on a remote host, this function returns the *local* terminal name that communicates with *process*; you can get the terminal name used by that program on the remote host with the *process* property **remote-tty**. If *process* represents a network, serial, or pipe connection, this function always returns **nil**.

**process-coding-system** process [Function]

This function returns a cons cell (**decode** . **encode**), describing the coding systems in use for decoding output from, and encoding input to, *process* (see Section 34.10 [Coding Systems], page 976).

**set-process-coding-system** process &optional decoding-system [Function]  
encoding-system

This function specifies the coding systems to use for subsequent output from and input to *process*. It will use *decoding-system* to decode subprocess output, and *encoding-system* to encode subprocess input.

Every process also has a property list that you can use to store miscellaneous values associated with the process.

**process-get** process propname [Function]

This function returns the value of the *propname* property of *process*.

**process-put** process propname value [Function]

This function sets the value of the *propname* property of *process* to *value*.

**process-plist** process [Function]

This function returns the process plist of *process*.

**set-process-plist** process plist [Function]

This function sets the process plist of *process* to *plist*.

## 40.7 Sending Input to Processes

Asynchronous subprocesses receive input when it is sent to them by Emacs, which is done with the functions in this section. You must specify the process to send input to, and the input data to send. If the subprocess runs a program, the data appears on the standard input of that program; for connections, the data is sent to the connected device or program.

Some operating systems have limited space for buffered input in a pty. On these systems, Emacs sends an EOF periodically amidst the other characters, to force them through. For most programs, these EOFs do no harm.

Subprocess input is normally encoded using a coding system before the subprocess receives it, much like text written into a file. You can use `set-process-coding-system` to specify which coding system to use (see Section 40.6 [Process Information], page 1092). Otherwise, the coding system comes from `coding-system-for-write`, if that is non-`nil`; or else from the defaulting mechanism (see Section 34.10.5 [Default Coding Systems], page 983).

Sometimes the system is unable to accept input for that process, because the input buffer is full. When this happens, the send functions wait a short while, accepting output from subprocesses, and then try again. This gives the subprocess a chance to read more of its pending input and make space in the buffer. It also allows filters (including the one currently running), sentinels and timers to run—so take account of that in writing your code.

In these functions, the `process` argument can be a process or the name of a process, or a buffer or buffer name (which stands for a process via `get-buffer-process`). `nil` means the current buffer's process.

### `process-send-string` `process string`

[Function]

This function sends `process` the contents of `string` as standard input. It returns `nil`.

For example, to make a Shell buffer list files:

```
(process-send-string "shell<1>" "ls\n")
⇒ nil
```

### `process-send-region` `process start end`

[Function]

This function sends the text in the region defined by `start` and `end` as standard input to `process`.

An error is signaled unless both `start` and `end` are integers or markers that indicate positions in the current buffer. (It is unimportant which number is larger.)

### `process-send-eof` `&optional process`

[Function]

This function makes `process` see an end-of-file in its input. The EOF comes after any text already sent to it. The function returns `process`.

```
(process-send-eof "shell")
⇒ "shell"
```

### `process-running-child-p` `&optional process`

[Function]

This function will tell you whether a `process`, which must not be a connection but a real subprocess, has given control of its terminal to a child process of its own. If this is true, the function returns the numeric ID of the foreground process group of `process`; it returns `nil` if Emacs can be certain that this is not so. The value is `t` if Emacs cannot tell whether this is true. This function signals an error if `process` is a network, serial, or pipe connection, or if the subprocess is not active.

## 40.8 Sending Signals to Processes

Sending a signal to a subprocess is a way of interrupting its activities. There are several different signals, each with its own meaning. The set of signals and their names is defined by the operating system. For example, the signal **SIGINT** means that the user has typed **C-c**, or that some analogous thing has happened.

Each signal has a standard effect on the subprocess. Most signals kill the subprocess, but some stop (or resume) execution instead. Most signals can optionally be handled by programs; if the program handles the signal, then we can say nothing in general about its effects.

You can send signals explicitly by calling the functions in this section. Emacs also sends signals automatically at certain times: killing a buffer sends a **SIGHUP** signal to all its associated processes; killing Emacs sends a **SIGHUP** signal to all remaining processes. (**SIGHUP** is a signal that usually indicates that the user “hung up the phone”, i.e., disconnected.)

Each of the signal-sending functions takes two optional arguments: *process* and *current-group*.

The argument *process* must be either a process, a process name, a buffer, a buffer name, or **nil**. A buffer or buffer name stands for a process through **get-buffer-process**. **nil** stands for the process associated with the current buffer. Except with **stop-process** and **continue-process**, an error is signaled if *process* does not identify an active process, or if it represents a network, serial, or pipe connection.

The argument *current-group* is a flag that makes a difference when you are running a job-control shell as an Emacs subprocess. If it is **non-nil**, then the signal is sent to the current process-group of the terminal that Emacs uses to communicate with the subprocess. If the process is a job-control shell, this means the shell’s current subjob. If *current-group* is **nil**, the signal is sent to the process group of the immediate subprocess of Emacs. If the subprocess is a job-control shell, this is the shell itself. If *current-group* is **lambda**, the signal is sent to the process-group that owns the terminal, but only if it is not the shell itself.

The flag *current-group* has no effect when a pipe is used to communicate with the subprocess, because the operating system does not support the distinction in the case of pipes. For the same reason, job-control shells won’t work when a pipe is used. See **process-connection-type** in Section 40.4 [Asynchronous Processes], page 1086.

**interrupt-process** &**optional** *process* *current-group* [Function]

This function interrupts the process *process* by sending the signal **SIGINT**. Outside of Emacs, typing the interrupt character (normally **C-c** on some systems, and **DEL** on others) sends this signal. When the argument *current-group* is **non-nil**, you can think of this function as typing **C-c** on the terminal by which Emacs talks to the subprocess.

**kill-process** &**optional** *process* *current-group* [Command]

This command kills the process *process* by sending the signal **SIGKILL**. This signal kills the subprocess immediately, and cannot be handled by the subprocess. Interactively, it’ll prompt the user for a process name, defaulting to the process (if any) in the current buffer.

**quit-process** &**optional** *process* *current-group* [Function]

This function sends the signal **SIGQUIT** to the process *process*. This signal is the one sent by the quit character (usually **C-\**) when you are not inside Emacs.

**stop-process** &optional process current-group [Function]

This function stops the specified process. If it is a real subprocess running a program, it sends the signal SIGTSTP to that subprocess. If *process* represents a network, serial, or pipe connection, this function inhibits handling of the incoming data from the connection; for a network server, this means not accepting new connections. Use **continue-process** to resume normal execution.

Outside of Emacs, on systems with job control, the stop character (usually *C-z*) normally sends the SIGTSTP signal to a subprocess. When *current-group* is non-nil, you can think of this function as typing *C-z* on the terminal Emacs uses to communicate with the subprocess.

**continue-process** &optional process current-group [Function]

This function resumes execution of the process *process*. If it is a real subprocess running a program, it sends the signal SIGCONT to that subprocess; this presumes that *process* was stopped previously. If *process* represents a network, serial, or pipe connection, this function resumes handling of the incoming data from the connection. For serial connections, data that arrived during the time the process was stopped might be lost.

**signal-process** process signal &optional remote [Command]

This function sends a signal to process *process*. The argument *signal* specifies which signal to send; it should be an integer, or a symbol whose name is a signal.

The *process* argument can be a system process ID (an integer); that allows you to send signals to processes that are not children of Emacs. See Section 40.12 [System Processes], page 1108.

If *process* is a process object which contains the property **remote-pid**, or *process* is a number and *remote* is a remote file name, *process* is interpreted as process on the respective remote host, which will be the process to signal.

If *process* is a string, it is interpreted as process object with the respective process name, or as a number.

Sometimes, it is necessary to send a signal to a non-local asynchronous process. This is possible by writing an own **interrupt-process** or **signal-process** implementation. This function must be added then to **interrupt-process-functions** or **signal-process-functions**, respectively.

**interrupt-process-functions** [Variable]

This variable is a list of functions to be called for **interrupt-process**. The arguments of the functions are the same as for **interrupt-process**. These functions are called in the order of the list, until one of them returns non-nil. The default function, which shall always be the last in this list, is **internal-default-interrupt-process**.

This is the mechanism, how Tramp implements **interrupt-process**.

**signal-process-functions** [Variable]

This variable is a list of functions to be called for **signal-process**. The arguments of the functions are the same as for **signal-process**. These functions are called in the order of the list, until one of them returns non-nil. The default function, which shall always be the last in this list, is **internal-default-signal-process**.

This is the mechanism, how Tramp implements `signal-process`.

## 40.9 Receiving Output from Processes

The output that an asynchronous subprocess writes to its standard output stream is passed to a function called the *filter function*. The default filter function simply inserts the output into a buffer, which is called the associated buffer of the process (see Section 40.9.1 [Process Buffers], page 1099). If the process has no buffer then the default filter discards the output.

If the subprocess writes to its standard error stream, by default the error output is also passed to the process filter function. Alternatively, you could use the `:stderr` parameter with a non-`nil` value in a call to `make-process` (see Section 40.4 [Asynchronous Processes], page 1086) to make the destination of the error output separate from the standard output.

When a subprocess terminates, Emacs reads any pending output, then stops reading output from that subprocess. Therefore, if the subprocess has children that are still live and still producing output, Emacs won't receive that output.

Output from a subprocess can arrive only while Emacs is waiting: when reading terminal input (see the function `waiting-for-user-input-p`), in `sit-for` and `sleep-for` (see Section 22.10 [Waiting], page 470), in `accept-process-output` (see Section 40.9.4 [Accepting Output], page 1104), and in functions which send data to processes (see Section 40.7 [Input to Processes], page 1096). This minimizes the problem of timing errors that usually plague parallel programming. For example, you can safely create a process and only then specify its buffer or filter function; no output can arrive before you finish, if the code in between does not call any primitive that waits.

### process-adaptive-read-buffering

[Variable]

On some systems, when Emacs reads the output from a subprocess, the output data is read in very small blocks, potentially resulting in very poor performance. This behavior can be remedied to some extent by setting the variable `process-adaptive-read-buffering` to a non-`nil` value (the default), as it will automatically delay reading from such processes, thus allowing them to produce more output before Emacs tries to read it.

### 40.9.1 Process Buffers

A process can (and usually does) have an *associated buffer*, which is an ordinary Emacs buffer that is used for two purposes: storing the output from the process, and deciding when to kill the process. You can also use the buffer to identify a process to operate on, since in normal practice only one process is associated with any given buffer. Many applications of processes also use the buffer for editing input to be sent to the process, but this is not built into Emacs Lisp.

By default, process output is inserted in the associated buffer. (You can change this by defining a custom filter function, see Section 40.9.2 [Filter Functions], page 1101.) The position to insert the output is determined by the `process-mark`, which is then updated to point to the end of the text just inserted. Usually, but not always, the `process-mark` is at the end of the buffer.

Killing the associated buffer of a process also kills the process. Emacs asks for confirmation first, if the process's `process-query-on-exit-flag` is non-`nil` (see Section 40.11 [Query

Before Exit], page 1107). This confirmation is done by the function `process-kill-buffer-query-function`, which is run from `kill-buffer-query-functions` (see Section 28.10 [Killing Buffers], page 685).

### `process-buffer process`

[Function]

This function returns the associated buffer of the specified *process*.

```
(process-buffer (get-process "shell"))
 ⇒ #<buffer *shell*>
```

### `process-mark process`

[Function]

This function returns the process marker for *process*, which is the marker that says where to insert output from the process.

If *process* does not have a buffer, `process-mark` returns a marker that points nowhere.

The default filter function uses this marker to decide where to insert process output, and updates it to point after the inserted text. That is why successive batches of output are inserted consecutively.

Custom filter functions normally should use this marker in the same fashion. For an example of a filter function that uses `process-mark`, see [Process Filter Example], page 1102.

When the user is expected to enter input in the process buffer for transmission to the process, the process marker separates the new input from previous output.

### `set-process-buffer process buffer`

[Function]

This function sets the buffer associated with *process* to *buffer*. If *buffer* is `nil`, the process becomes associated with no buffer; if non-`nil` and different from the buffer associated with the process, the process mark will be set to point to the end of *buffer* (unless the process mark is already associated with *buffer*).

### `get-buffer-process buffer-or-name`

[Function]

This function returns a nondeleted process associated with the buffer specified by *buffer-or-name*. If there are several processes associated with it, this function chooses one (currently, the one most recently created, but don't count on that). Deletion of a process (see `delete-process`) makes it ineligible for this function to return.

It is usually a bad idea to have more than one process associated with the same buffer.

```
(get-buffer-process "*shell*")
 ⇒ #<process shell>
```

Killing the process's buffer deletes the process, which kills the subprocess with a `SIGHUP` signal (see Section 40.8 [Signals to Processes], page 1097).

If the process's buffer is displayed in a window, your Lisp program may wish to tell the process the dimensions of that window, so that the process could adapt its output to those dimensions, much as it adapts to the screen dimensions. The following functions allow communicating this kind of information to processes; however, not all systems support the underlying functionality, so it is best to provide fallbacks, e.g., via command-line arguments or environment variables.

**set-process-window-size** *process height width* [Function]

Tell *process* that its logical window size has dimensions *width* by *height*, in character units. If this function succeeds in communicating this information to the process, it returns `t`; otherwise it returns `nil`.

When windows that display buffers associated with process change their dimensions, the affected processes should be told about these changes. By default, when the window configuration changes, Emacs will automatically call `set-process-window-size` on behalf of every process whose buffer is displayed in a window, passing it the smallest dimensions of all the windows displaying the process's buffer. This works via `window-configuration-change-hook` (see Section 29.28 [Window Hooks], page 779), which is told to invoke the function that is the value of the variable `window-adjust-process-window-size-function` for each process whose buffer is displayed in at least one window. You can customize this behavior by setting the value of that variable.

**window-adjust-process-window-size-function** [User Option]

The value of this variable should be a function of two arguments: a process and the list of windows displaying the process's buffer. When the function is called, the process's buffer is the current buffer. The function should return a cons cell (`(width . height)`) that describes the dimensions of the logical process window to be passed via a call to `set-process-window-size`. The function can also return `nil`, in which case Emacs will not call `set-process-window-size` for this process.

Emacs supplies two predefined values for this variable: `window-adjust-process-window-size-smallest`, which returns the smallest of all the dimensions of the windows that display a process's buffer; and `window-adjust-process-window-size-largest`, which returns the largest dimensions. For more complex strategies, write your own function.

This variable can be buffer-local.

If the process has the `adjust-window-size-function` property (see Section 40.6 [Process Information], page 1092), its value overrides the global and buffer-local values of `window-adjust-process-window-size-function`.

### 40.9.2 Process Filter Functions

A process *filter function* is a function that receives the standard output from the associated process. *All* output from that process is passed to the filter. The default filter simply outputs directly to the process buffer.

By default, the error output from the process, if any, is also passed to the filter function, unless the destination for the standard error stream of the process was separated from the standard output when the process was created. Emacs will only call the filter function during certain function calls. See Section 40.9 [Output from Processes], page 1099. Note that if any of those functions are called by the filter, the filter may be called recursively.

A filter function must accept two arguments: the associated process and a string, which is output just received from it. The function is then free to do whatever it chooses with the output.

Quitting is normally inhibited within a filter function—otherwise, the effect of typing `C-g` at command level or to quit a user command would be unpredictable. If you want to

permit quitting inside a filter function, bind `inhibit-quit` to `nil`. In most cases, the right way to do this is with the macro `with-local-quit`. See Section 22.11 [Quitting], page 471.

If an error happens during execution of a filter function, it is caught automatically, so that it doesn't stop the execution of whatever program was running when the filter function was started. However, if `debug-on-error` is non-`nil`, errors are not caught. This makes it possible to use the Lisp debugger to debug filter functions. See Section 19.1 [Debugger], page 333. If an error is caught, Emacs pauses for `process-error-pause-time` seconds so that the user sees the error. See Section 40.4 [Asynchronous Processes], page 1086.

Many filter functions sometimes (or always) insert the output in the process's buffer, mimicking the actions of the default filter. Such filter functions need to make sure that they save the current buffer, select the correct buffer (if different) before inserting output, and then restore the original buffer. They should also check whether the buffer is still alive, update the process marker, and in some cases update the value of point. Here is how to do these things:

```
(defun ordinary-insertion-filter (proc string)
 (when (buffer-live-p (process-buffer proc))
 (with-current-buffer (process-buffer proc)
 (let ((moving (= (point) (process-mark proc))))
 (save-excursion
 ; Insert the text, advancing the process marker.
 (goto-char (process-mark proc))
 (insert string)
 (set-marker (process-mark proc) (point)))
 (if moving (goto-char (process-mark proc)))))))
```

To make the filter force the process buffer to be visible whenever new text arrives, you could insert a line like the following just before the `with-current-buffer` construct:

```
(display-buffer (process-buffer proc))
```

To force point to the end of the new output, no matter where it was previously, eliminate the variable `moving` from the example and call `goto-char` unconditionally. Note that this doesn't necessarily move the window point. The default filter actually uses `insert-before-markers` which moves all markers, including the window point. This may move unrelated markers, so it's generally better to move the window point explicitly, or set its insertion type to `t` (see Section 29.19 [Window Point], page 758).

Note that Emacs automatically saves and restores the match data while executing filter functions. See Section 35.6 [Match Data], page 1011.

The output to the filter may come in chunks of any size. A program that produces the same output twice in a row may send it as one batch of 200 characters one time, and five batches of 40 characters the next. If the filter looks for certain text strings in the subprocess output, make sure to handle the case where one of these strings is split across two or more batches of output; one way to do this is to insert the received text into a temporary buffer, which can then be searched.

### `set-process-filter` *process filter*

[Function]

This function gives *process* the filter function *filter*. If *filter* is `nil`, it gives the process the default filter, which inserts the process output into the process buffer. If *filter* is `t`, Emacs stops accepting output from the process, unless it's a network server process that listens for incoming connections.

**process-filter** *process* [Function]

This function returns the filter function of *process*.

In case the process's output needs to be passed to several filters, you can use **add-function** to combine an existing filter with a new one. See Section 13.12 [Advising Functions], page 252.

Here is an example of the use of a filter function:

```
(defun keep-output (process output)
 (setq kept (cons output kept)))
 ⇒ keep-output
 (setq kept nil)
 ⇒ nil
 (set-process-filter (get-process "shell") 'keep-output)
 ⇒ keep-output
 (process-send-string "shell" "ls ~/other\n")
 ⇒ nil
 kept
 ⇒ ("lewis@slug:$ "
"FINAL-W87-SHORT.MSS backup.ctl kolstad.mss~"
"address.txt backup.psf kolstad.psf"
"backup.bib~ david.mss resume-Dec-86.mss~"
"backup.err david.psf resume-Dec.psf"
"backup.mss dland syllabus.mss"
"
"#backups.mss# backup.mss~ kolstad.mss"
")
```

### 40.9.3 Decoding Process Output

When Emacs writes process output directly into a multibyte buffer, it decodes the output according to the process output coding system. If the coding system is **raw-text** or **no-conversion**, Emacs converts the unibyte output to multibyte using **string-to-multibyte**, and inserts the resulting multibyte text.

You can use **set-process-coding-system** to specify which coding system to use (see Section 40.6 [Process Information], page 1092). Otherwise, the coding system comes from **coding-system-for-read**, if that is non-nil; or else from the defaulting mechanism (see Section 34.10.5 [Default Coding Systems], page 983). If the text output by a process contains null bytes, Emacs by default uses **no-conversion** for it; see Section 34.10.3 [Lisp and Coding Systems], page 979, for how to control this behavior.

**Warning:** Coding systems such as **undecided**, which determine the coding system from the data, do not work entirely reliably with asynchronous subprocess output. This is because Emacs has to process asynchronous subprocess output in batches, as it arrives. Emacs must try to detect the proper coding system from one batch at a time, and this does not always work. Therefore, if at all possible, specify a coding system that determines both the character code conversion and the end of line conversion—that is, one like **latin-1-unix**, rather than **undecided** or **latin-1**.

When Emacs calls a process filter function, it provides the process output as a multibyte string or as a unibyte string according to the process's filter coding system. Emacs decodes the output according to the process output coding system, which usually produces a multibyte string, except for coding systems such as **binary** and **raw-text**.

#### 40.9.4 Accepting Output from Processes

Output from asynchronous subprocesses normally arrives only while Emacs is waiting for some sort of external event, such as elapsed time or terminal input. Occasionally it is useful in a Lisp program to explicitly permit output to arrive at a specific point, or even to wait until output arrives from a process.

`accept-process-output &optional process seconds millisec  
just-this-one` [Function]

This function allows Emacs to read pending output from processes. The output is given to their filter functions. If *process* is `non-nil` then this function does not return until some output has been received from *process* or *process* has closed the connection.

The arguments *seconds* and *millisec* let you specify timeout periods. The former specifies a period measured in seconds and the latter specifies one measured in milliseconds. The two time periods thus specified are added together, and `accept-process-output` returns after that much time, even if there is no subprocess output.

The argument *millisec* is obsolete (and should not be used), because *seconds* can be floating point to specify waiting a fractional number of seconds. If *seconds* is 0, the function accepts whatever output is pending but does not wait.

If *process* is a process, and the argument *just-this-one* is `non-nil`, only output from that process is handled, suspending output from other processes until some output has been received from that process or the timeout expires. If *just-this-one* is an integer, also inhibit running timers. This feature is generally not recommended, but may be necessary for specific applications, such as speech synthesis.

The function `accept-process-output` returns `non-nil` if it got output from *process*, or from any process if *process* is `nil`; this can occur even after a process has exited if the corresponding connection contains buffered data. The function returns `nil` if the timeout expired or the connection was closed before output arrived.

If a connection from a process contains buffered data, `accept-process-output` can return `non-nil` even after the process has exited. Therefore, although the following loop:

```
;; This loop contains a bug.
(while (process-live-p process)
 (accept-process-output process))
```

will often read all output from *process*, it has a race condition and can miss some output if `process-live-p` returns `nil` while the connection still contains data. Better is to write the loop like this:

```
(while (accept-process-output process))
```

If you have passed a non-`nil` `stderr` to `make-process`, it will have a standard error process. See Section 40.4 [Asynchronous Processes], page 1086. In that case, waiting for process output from the main process doesn't wait for output from the standard error process. To make sure you have received both all of standard output and all of standard error from a process, use the following code:

```
(while (accept-process-output process))
(while (accept-process-output stderr-process))
```

If you passed a buffer to the `stderr` argument of `make-process`, you still have to wait for the standard error process, like so:

```
(let* ((stdout (generate-new-buffer "stdout"))
 (stderr (generate-new-buffer "stderr")))
 (process (make-process :name "test"
 :command '("my-program")
 :buffer stdout
 :stderr stderr))
 (stderr-process (get-buffer-process stderr)))
 (unless (and process stderr-process)
 (error "Process unexpectedly nil"))
 (while (accept-process-output process))
 (while (accept-process-output stderr-process)))
```

Only when both `accept-process-output` forms return `nil`, you can be sure that the process has exited and Emacs has read all its output.

Reading pending standard error from a process running on a remote host is not possible this way.

#### 40.9.5 Processes and Threads

Because threads were a relatively late addition to Emacs Lisp, and due to the way dynamic binding was sometimes used in conjunction with `accept-process-output`, by default a process is locked to the thread that created it. When a process is locked to a thread, output from the process can only be accepted by that thread.

A Lisp program can specify to which thread a process is to be locked, or instruct Emacs to unlock a process, in which case its output can be processed by any thread. Only a single thread will wait for output from a given process at one time—once one thread begins waiting for output, the process is temporarily locked until `accept-process-output` or `sit-for` returns.

If the thread exits, all the processes locked to it are unlocked.

`process-thread process` [Function]

Return the thread to which `process` is locked. If `process` is unlocked, return `nil`.

`set-process-thread process thread` [Function]

Set the locking thread of `process` to `thread`. `thread` may be `nil`, in which case the process is unlocked.

#### 40.10 Sentinels: Detecting Process Status Changes

A process sentinel is a function that is called whenever the associated process changes status for any reason, including signals (whether sent by Emacs or caused by the process's own actions) that terminate, stop, or continue the process. The process sentinel is also called if the process exits. The sentinel receives two arguments: the process for which the event occurred, and a string describing the type of event.

If no sentinel function was specified for a process, it will use the default sentinel function, which inserts a message in the process's buffer with the process name and the string describing the event.

The string describing the event looks like one of the following (but this is not an exhaustive list of event strings):

- `"finished\n".`
- `"deleted\n".`
- `"exited abnormally with code exitcode (core dumped)\n".` The “core dumped” part is optional, and only appears if the process dumped core.
- `"failed with code fail-code\n".`
- `"signal-description (core dumped)\n".` The *signal-description* is a system-dependent textual description of a signal, e.g., `"killed"` for SIGKILL. The “core dumped” part is optional, and only appears if the process dumped core.
- `"open from host-name\n".`
- `"open\n".`
- `"run\n".`
- `"connection broken by remote peer\n".`

A sentinel runs only while Emacs is waiting (e.g., for terminal input, or for time to elapse, or for process output). This avoids the timing errors that could result from running sentinels at random places in the middle of other Lisp programs. A program can wait, so that sentinels will run, by calling `sit-for` or `sleep-for` (see Section 22.10 [Waiting], page 470), or `accept-process-output` (see Section 40.9.4 [Accepting Output], page 1104). Emacs also allows sentinels to run when the command loop is reading input. `delete-process` calls the sentinel when it terminates a running process.

Emacs does not keep a queue of multiple reasons to call the sentinel of one process; it records just the current status and the fact that there has been a change. Therefore two changes in status, coming in quick succession, can call the sentinel just once. However, process termination will always run the sentinel exactly once. This is because the process status can't change again after termination.

Emacs explicitly checks for output from the process before running the process sentinel. Once the sentinel runs due to process termination, no further output can arrive from the process.

A sentinel that writes the output into the buffer of the process should check whether the buffer is still alive. If it tries to insert into a dead buffer, it will get an error. If the buffer is dead, `(buffer-name (process-buffer process))` returns `nil`.

Quitting is normally inhibited within a sentinel—otherwise, the effect of typing `C-g` at command level or to quit a user command would be unpredictable. If you want to permit quitting inside a sentinel, bind `inhibit-quit` to `nil`. In most cases, the right way to do this is with the macro `with-local-quit`. See Section 22.11 [Quitting], page 471.

If an error happens during execution of a sentinel, it is caught automatically, so that it doesn't stop the execution of whatever programs was running when the sentinel was started. However, if `debug-on-error` is non-`nil`, errors are not caught. This makes it possible to use the Lisp debugger to debug the sentinel. See Section 19.1 [Debugger], page 333. If an error is caught, Emacs pauses for `process-error-pause-time` seconds so that the user sees the error. See Section 40.4 [Asynchronous Processes], page 1086.

While a sentinel is running, the process sentinel is temporarily set to `nil` so that the sentinel won't run recursively. For this reason it is not possible for a sentinel to specify a new sentinel.

Note that Emacs automatically saves and restores the match data while executing sentinels. See Section 35.6 [Match Data], page 1011.

**set-process-sentinel** *process sentinel* [Function]

This function associates *sentinel* with *process*. If *sentinel* is `nil`, then the process will have the default sentinel, which inserts a message in the process's buffer when the process status changes.

Changes in process sentinels take effect immediately—if the sentinel is slated to be run but has not been called yet, and you specify a new sentinel, the eventual call to the sentinel will use the new one.

```
(defun msg-me (process event)
 (princ
 (format "Process: %s had the event '%s'" process event)))
(set-process-sentinel (get-process "shell") 'msg-me)
⇒ msg-me
(kill-process (get-process "shell"))
⇒ Process: #<process shell> had the event 'killed'
⇒ #<process shell>
```

**process-sentinel** *process* [Function]

This function returns the sentinel of *process*.

In case a process status changes need to be passed to several sentinels, you can use `add-function` to combine an existing sentinel with a new one. See Section 13.12 [Advising Functions], page 252.

**waiting-for-user-input-p** [Function]

While a sentinel or filter function is running, this function returns non-`nil` if Emacs was waiting for keyboard input from the user at the time the sentinel or filter function was called, or `nil` if it was not.

## 40.11 Querying Before Exit

When Emacs exits, it terminates all its subprocesses. For subprocesses that run a program, it sends them the `SIGHUP` signal; connections are simply closed. Because subprocesses may be doing valuable work, Emacs normally asks the user to confirm that it is ok to terminate them. Each process has a query flag, which, if non-`nil`, says that Emacs should ask for confirmation before exiting and thus killing that process. The default for the query flag is `t`, meaning *do* query.

**process-query-on-exit-flag** *process* [Function]

This returns the query flag of *process*.

**set-process-query-on-exit-flag** *process flag* [Function]

This function sets the query flag of *process* to *flag*. It returns *flag*.

Here is an example of using `set-process-query-on-exit-flag` on a shell process to avoid querying:

```
(set-process-query-on-exit-flag (get-process "shell") nil)
⇒ nil
```

**confirm-kill-processes** [User Option]

If this user option is set to `t` (the default), then Emacs asks for confirmation before killing processes on exit. If it is `nil`, Emacs kills processes without confirmation, i.e., the query flag of all processes is ignored.

## 40.12 Accessing Other Processes

In addition to accessing and manipulating processes that are subprocesses of the current Emacs session, Emacs Lisp programs can also access other processes. We call these *system processes*, to distinguish them from Emacs subprocesses.

Emacs provides several primitives for accessing system processes. Not all platforms support these primitives; on those which don't, these primitives return `nil`.

**list-system-processes** [Function]

This function returns a list of all the processes running on the system. Each process is identified by its PID, a numerical process ID that is assigned by the OS and distinguishes the process from all the other processes running on the same machine at the same time.

If `default-directory` points to a remote host, processes of that host are returned.

**process-attributes pid** [Function]

This function returns an alist of attributes for the process specified by its process ID `pid`. Each association in the alist is of the form `(key . value)`, where `key` designates the attribute and `value` is the value of that attribute. The various attribute `keys` that this function can return are listed below. Not all platforms support all of these attributes; if an attribute is not supported, its association will not appear in the returned alist.

If `default-directory` points to a remote host, `pid` is regarded as process of that host.

|                    |                                                                                                                                                                                                                                                                                                                |
|--------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>euid</code>  | The effective user ID of the user who invoked the process. The corresponding <code>value</code> is a number. If the process was invoked by the same user who runs the current Emacs session, the value is identical to what <code>user-uid</code> returns (see Section 42.4 [User Identification], page 1269). |
| <code>user</code>  | User name corresponding to the process's effective user ID, a string.                                                                                                                                                                                                                                          |
| <code>egid</code>  | The group ID of the effective user ID, a number.                                                                                                                                                                                                                                                               |
| <code>group</code> | Group name corresponding to the effective user's group ID, a string.                                                                                                                                                                                                                                           |
| <code>comm</code>  | The name of the command that runs in the process. This is a string that usually specifies the name of the executable file of the process, without the leading directories. However, some special system processes can report strings that do not correspond to an executable file of a program.                |
| <code>state</code> | The state code of the process. This is a short string that encodes the scheduling state of the process. Here's a list of the most frequently seen codes:                                                                                                                                                       |
| "D"                | uninterruptible sleep (usually I/O)                                                                                                                                                                                                                                                                            |
| "R"                | running                                                                                                                                                                                                                                                                                                        |

|                      |                                                                                                                                                                                                  |
|----------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| "S"                  | interruptible sleep (waiting for some event)                                                                                                                                                     |
| "T"                  | stopped, e.g., by a job control signal                                                                                                                                                           |
| "Z"                  | zombie: a process that terminated, but was not reaped by its parent                                                                                                                              |
|                      | For the full list of the possible states, see the manual page of the <code>ps</code> command.                                                                                                    |
| <code>ppid</code>    | The process ID of the parent process, a number.                                                                                                                                                  |
| <code>pgrp</code>    | The process group ID of the process, a number.                                                                                                                                                   |
| <code>sess</code>    | The session ID of the process. This is a number that is the process ID of the process's <i>session leader</i> .                                                                                  |
| <code>ttname</code>  | A string that is the name of the process's controlling terminal. On Unix and GNU systems, this is normally the file name of the corresponding terminal device, such as <code>/dev/pts65</code> . |
| <code>tpgid</code>   | The numerical process group ID of the foreground process group that uses the process's terminal.                                                                                                 |
| <code>minflt</code>  | The number of minor page faults caused by the process since its beginning. (Minor page faults are those that don't involve reading from disk.)                                                   |
| <code>majflt</code>  | The number of major page faults caused by the process since its beginning. (Major page faults require a disk to be read, and are thus more expensive than minor page faults.)                    |
| <code>cminflt</code> |                                                                                                                                                                                                  |
| <code>cmajflt</code> | Like <code>minflt</code> and <code>majflt</code> , but include the number of page faults for all the child processes of the given process.                                                       |
| <code>utime</code>   | Time spent by the process in the user context, for running the application's code. The corresponding <i>value</i> is a Lisp timestamp (see Section 42.5 [Time of Day], page 1270).               |
| <code>stime</code>   | Time spent by the process in the system (kernel) context, for processing system calls. The corresponding <i>value</i> is a Lisp timestamp.                                                       |
| <code>time</code>    | The sum of <code>utime</code> and <code>stime</code> . The corresponding <i>value</i> is a Lisp timestamp.                                                                                       |
| <code>cutime</code>  |                                                                                                                                                                                                  |
| <code>cstime</code>  |                                                                                                                                                                                                  |
| <code>ctime</code>   | Like <code>utime</code> , <code>stime</code> , and <code>time</code> , but include the times of all the child processes of the given process.                                                    |
| <code>pri</code>     | The numerical priority of the process.                                                                                                                                                           |
| <code>nice</code>    | The <i>nice value</i> of the process, a number. (Processes with smaller nice values get scheduled more favorably.)                                                                               |
| <code>thcount</code> | The number of threads in the process.                                                                                                                                                            |
| <code>start</code>   | The time when the process was started, as a Lisp timestamp.                                                                                                                                      |

|                    |                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
|--------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>etime</code> | The time elapsed since the process started, as a Lisp timestamp.                                                                                                                                                                                                                                                                                                                                                                                                 |
| <code>vsize</code> | The virtual memory size of the process, measured in kilobytes.                                                                                                                                                                                                                                                                                                                                                                                                   |
| <code>rss</code>   | The size of the process's <i>resident set</i> , the number of kilobytes occupied by the process in the machine's physical memory.                                                                                                                                                                                                                                                                                                                                |
| <code>pcpu</code>  | The percentage of the CPU time used by the process since it started. The corresponding <i>value</i> is a nonnegative floating-point number. Although in theory the number can exceed 100 on a multicore platform, it is usually less than 100 because Emacs is typically single-threaded.                                                                                                                                                                        |
| <code>pmem</code>  | The percentage of the total physical memory installed on the machine used by the process's resident set. The value is a floating-point number between 0 and 100.                                                                                                                                                                                                                                                                                                 |
| <code>args</code>  | The command-line with which the process was invoked. This is a string in which individual command-line arguments are separated by blanks; whitespace characters that are embedded in the arguments are quoted as appropriate for the system's shell: escaped by backslash characters on GNU and Unix, and enclosed in double quote characters on Windows. Thus, this command-line string can be directly used in primitives such as <code>shell-command</code> . |

## 40.13 Transaction Queues

You can use a *transaction queue* to communicate with a subprocess using transactions. First use `tq-create` to create a transaction queue communicating with a specified process. Then you can call `tq-enqueue` to send a transaction.

**`tq-create process`** [Function]

This function creates and returns a transaction queue communicating with *process*. The argument *process* should be a subprocess capable of sending and receiving streams of bytes. It may be a child process, or it may be a TCP connection to a server, possibly on another machine.

**`tq-enqueue queue question regexp closure fn &optional delay-question`** [Function]

This function sends a transaction to queue *queue*. Specifying the queue has the effect of specifying the subprocess to talk to.

The argument *question* is the outgoing message that starts the transaction. The argument *fn* is the function to call when the corresponding answer comes back; it is called with two arguments: *closure*, and the answer received.

The argument *regexp* is a regular expression that should match text at the end of the entire answer, but nothing before; that's how `tq-enqueue` determines where the answer ends.

If the argument *delay-question* is non-`nil`, delay sending this question until the process has finished replying to any previous questions. This produces more reliable results with some processes.

**tq-close queue** [Function]

Shut down transaction queue *queue*, waiting for all pending transactions to complete, and then terminate the connection or child process.

Transaction queues are implemented by means of a filter function. See Section 40.9.2 [Filter Functions], page 1101.

## 40.14 Network Connections

Emacs Lisp programs can open stream (TCP) and datagram (UDP) network connections (see Section 40.16 [Datagrams], page 1114) to other processes on the same machine or other machines. A network connection is handled by Lisp much like a subprocess, and is represented by a process object. However, the process you are communicating with is not a child of the Emacs process, has no process ID, and you can't kill it or send it signals. All you can do is send and receive data. `delete-process` closes the connection, but does not kill the program at the other end; that program must decide what to do about closure of the connection.

Lisp programs can listen for connections by creating network servers. A network server is also represented by a kind of process object, but unlike a network connection, the network server never transfers data itself. When it receives a connection request, it creates a new network connection to represent the connection just made. (The network connection inherits certain information, including the process plist, from the server.) The network server then goes back to listening for more connection requests.

Network connections and servers are created by calling `make-network-process` with an argument list consisting of keyword/argument pairs, for example `:server t` to create a server process, or `:type 'datagram` to create a datagram connection. See Section 40.17 [Low-Level Network], page 1115, for details. You can also use the `open-network-stream` function described below.

To distinguish the different types of processes, the `process-type` function returns the symbol `network` for a network connection or server, `serial` for a serial port connection, `pipe` for a pipe connection, or `real` for a real subprocess.

The `process-status` function returns `open`, `closed`, `connect`, `stop`, or `failed` for network connections. For a network server, the status is always `listen`. Except for `stop`, none of those values is possible for a real subprocess. See Section 40.6 [Process Information], page 1092.

You can stop and resume operation of a network process by calling `stop-process` and `continue-process`. For a server process, being stopped means not accepting new connections. (Up to 5 connection requests will be queued for when you resume the server; you can increase this limit, unless it is imposed by the operating system—see the `:server` keyword of `make-network-process`, Section 40.17.1 [Network Processes], page 1115.) For a network stream connection, being stopped means not processing input (any arriving input waits until you resume the connection). For a datagram connection, some number of packets may be queued but input may be lost. You can use the function `process-command` to determine whether a network connection or server is stopped; a non-`nil` value means yes.

Emacs can create encrypted network connections, using the built-in support for the GnuTLS Transport Layer Security Library; see the GnuTLS project page (<https://www.gnutls.org/>.

[gnu.org/software/gnutls/](http://gnu.org/software/gnutls/)). If your Emacs was compiled with GnuTLS support, the function `gnutls-available-p` is defined and returns non-`nil`. For more details, see Section “Overview” in *The Emacs-GnuTLS manual*. The `open-network-stream` function can transparently handle the details of creating encrypted connections for you, using whatever support is available.

`open-network-stream name buffer host service &rest parameters` [Function]

This function opens a TCP connection, with optional encryption, and returns a process object that represents the connection.

The `name` argument specifies the name for the process object. It is modified as necessary to make it unique.

The `buffer` argument is the buffer to associate with the connection. Output from the connection is inserted in the buffer, unless you specify your own filter function to handle the output. If `buffer` is `nil`, it means that the connection is not associated with any buffer.

The arguments `host` and `service` specify where to connect to; `host` is the host name (a string), and `service` is the name of a defined network service (a string) or a port number (an integer like `80` or an integer string like `"80"`).

The remaining arguments `parameters` are keyword/argument pairs that are mainly relevant to encrypted connections:

`:nowait boolean`

If non-`nil`, try to make an asynchronous connection.

`:noquery query-flag`

Initialize the process query flag to `query-flag`. See Section 40.11 [Query Before Exit], page 1107.

`:coding coding`

Use this to set the coding systems used by the network process, in preference to binding `coding-system-for-read` or `coding-system-for-write`. See Section 40.17.1 [Network Processes], page 1115, for details.

`:type type`

The type of connection. Options are:

`plain` An ordinary, unencrypted connection.

`tls`

`ssl` A TLS (Transport Layer Security) connection.

`nil`

`network` Start with a plain connection, and if parameters ‘`:success`’ and ‘`:capability-command`’ are supplied, try to upgrade to an encrypted connection via STARTTLS. If that fails, retain the unencrypted connection.

`starttls` As for `nil`, but if STARTTLS fails, drop the connection.

`shell` A shell connection.

**:always-query-capabilities boolean**  
 If non-nil, always ask for the server's capabilities, even when doing a 'plain' connection.

**:capability-command capability-command**  
 Command to query the host capabilities. This can either be a string (which will then be sent verbatim to the server) or a function (called with a single parameter: the "greeting" from the server when connecting) that should return a string.

**:end-of-command regexp**  
**:end-of-capability regexp**  
 Regular expression matching the end of a command, or the end of the command *capability-command*. The latter defaults to the former.

**:starttls-function function**  
 Function of one argument (the response to *capability-command*), which returns either `nil` or the command to activate STARTTLS, if supported.

**:success regexp**  
 Regular expression matching a successful STARTTLS negotiation.

**:use-starttls-if-possible boolean**  
 If non-nil, do opportunistic STARTTLS upgrades even if Emacs doesn't have built-in TLS support.

**:warn-unless-encrypted boolean**  
 If non-nil, and `:return-value` is also non-nil, Emacs will warn if the connection isn't encrypted. This is useful for protocols like IMAP and the like, where most users would expect the network traffic to be encrypted.

**:client-certificate list-or-t**  
 Either a list of the form (*key-file cert-file*), naming the certificate key file and certificate file itself, or t, meaning to query `auth-source` for this information (see Section "auth-source" in *Emacs auth-source Library*). Only used for TLS or STARTTLS. To enable automatic queries of `auth-source` when `:client-certificate` is not specified customize `network-stream-use-client-certificates` to t.

**:return-list cons-or-nil**  
 The return value of this function. If omitted or `nil`, return a process object. Otherwise, a cons of the form (*process-object . plist*), where *plist* can include the following keywords:

- :greeting string-or-nil**  
 If non-nil, the greeting string returned by the host.
- :capabilities string-or-nil**  
 If non-nil, the host's capability string.
- :type symbol**  
 The connection type: 'plain' or 'tls'.

**:shell-command *string-or-nil***

If the connection type is `shell`, this parameter will be interpreted as a format-spec string (see Section 4.8 [Custom Format Strings], page 70) that will be executed to make the connection. The specs available are ‘%s’ for the host name and ‘%p’ for the port number. For instance, if you want to first ssh to ‘gateway’ before making a plain connection, then this parameter’s value could be something like ‘`ssh gateway nc %s %p`’.

## 40.15 Network Servers

You create a server by calling `make-network-process` (see Section 40.17.1 [Network Processes], page 1115) with `:server t`. The server will listen for connection requests from clients. When it accepts a client connection request, that creates a new network connection, itself a process object, with the following parameters:

- The connection’s process name is constructed by concatenating the server process’s name with a client identification string. The client identification string for an IPv4 connection looks like ‘`<a.b.c.d:p>`’, which represents an address and port number. Otherwise, it is a unique number in brackets, as in ‘`<nnn>`’. The number is unique for each connection in the Emacs session.
- If the server has a non-default filter, the connection process does not get a separate process buffer; otherwise, Emacs creates a new buffer for the purpose. The buffer name is the server’s buffer name or process name, concatenated with the client identification string.

The server’s process buffer value is never used directly, but the log function can retrieve it and use it to log connections by inserting text there.

- The communication type and the process filter and sentinel are inherited from those of the server. The server never directly uses its filter and sentinel; their sole purpose is to initialize connections made to the server.
- The connection’s process contact information is set according to the client’s addressing information (typically an IP address and a port number). This information is associated with the `process-contact` keywords `:host`, `:service`, `:remote`.
- The connection’s local address is set up according to the port number used for the connection.
- The client process’s plist is initialized from the server’s plist.

## 40.16 Datagrams

A `datagram` connection communicates with individual packets rather than streams of data. Each call to `process-send` sends one datagram packet (see Section 40.7 [Input to Processes], page 1096), and each datagram received results in one call to the filter function.

The datagram connection doesn’t have to talk with the same remote peer all the time. It has a `remote-peer-address` which specifies where to send datagrams to. Each time an incoming datagram is passed to the filter function, the peer address is set to the address that datagram came from; that way, if the filter function sends a datagram, it will go back to that place. You can specify the remote peer address when you create the datagram connection using the `:remote` keyword. You can change it later on by calling `set-process-datagram-address`.

**process-datagram-address** process [Function]

If *process* is a datagram connection or server, this function returns its remote peer address.

**set-process-datagram-address** process *address* [Function]

If *process* is a datagram connection or server, this function sets its remote peer address to *address*.

## 40.17 Low-Level Network Access

You can also create network connections by operating at a lower level than that of `open-network-stream`, using `make-network-process`.

### 40.17.1 make-network-process

The basic function for creating network connections and network servers is `make-network-process`. It can do either of those jobs, depending on the arguments you give it.

**make-network-process** &rest *args* [Function]

This function creates a network connection or server and returns the process object that represents it. The arguments *args* are a list of keyword/argument pairs. Omitting a keyword is always equivalent to specifying it with value `nil`, except for `:coding`, `:filter-multibyte`, and `:reuseaddr`. Here are the meaningful keywords (those corresponding to network options are listed in the following section):

`:name name`

Use the string *name* as the process name. It is modified if necessary to make it unique.

`:type type`

Specify the communication type. A value of `nil` specifies a stream connection (the default); `datagram` specifies a datagram connection; `seqpacket` specifies a sequenced packet stream connection. Both connections and servers can be of these types.

`:server server-flag`

If *server-flag* is non-`nil`, create a server. Otherwise, create a connection. For a stream type server, *server-flag* may be an integer, which then specifies the length of the queue of pending connections to the server. The default queue length is 5.

`:host host`

Specify the host to connect to. *host* should be a host name or Internet address, as a string, or the symbol `local` to specify the local host. If you specify *host* for a server, it must specify a valid address for the local host, and only clients connecting to that address will be accepted. When using `local`, by default IPv4 will be used, specify a *family* of `ipv6` to override this. To listen on all interfaces, specify an address of `"0.0.0.0"` for IPv4 or `"::"` for IPv6. Note that on some operating systems, listening on `"::"` will also listen on IPv4, so attempting to then listen separately on IPv4 will result in `EADDRINUSE` errors (`"Address already in use"`).

`:service service`

*service* specifies a port number to connect to; or, for a server, the port number to listen on. It should be a service name like `"https"` that

translates to a port number, or an integer like ‘443’ or an integer string like “443” that specifies the port number directly. For a server, it can also be `t`, which means to let the system select an unused port number.

`:family family`

`family` specifies the address (and protocol) family for communication. `nil` means determine the proper address family automatically for the given `host` and `service`. `local` specifies a Unix socket, in which case `host` is ignored. `ipv4` and `ipv6` specify to use IPv4 and IPv6, respectively.

`:use-external-socket use-external-socket`

If `use-external-socket` is non-`nil` use any sockets passed to Emacs on invocation instead of allocating one. This is used by the Emacs server code to allow on-demand socket activation. If Emacs wasn’t passed a socket, this option is silently ignored.

`:local local-address`

For a server process, `local-address` is the address to listen on. It overrides `family`, `host` and `service`, so you might as well not specify them.

`:remote remote-address`

For a connection, `remote-address` is the address to connect to. It overrides `family`, `host` and `service`, so you might as well not specify them.

For a datagram server, `remote-address` specifies the initial setting of the remote datagram address.

The format of `local-address` or `remote-address` depends on the address family:

- An IPv4 address is represented as a five-element vector of four 8-bit integers and one 16-bit integer [`a b c d p`] corresponding to numeric IPv4 address `a.b.c.d` and port number `p`.
- An IPv6 address is represented as a nine-element vector of 16-bit integers [`a b c d e f g h p`] corresponding to numeric IPv6 address `a:b:c:d:e:f:g:h` and port number `p`.
- A local address is represented as a string, which specifies the address in the local address space.
- An unsupported-family address is represented by a cons (`f . av`), where `f` is the family number and `av` is a vector specifying the socket address using one element per address data byte. Do not rely on this format in portable code, as it may depend on implementation defined constants, data sizes, and data structure alignment.

`:nowait bool`

If `bool` is non-`nil` for a stream connection, return without waiting for the connection to complete. When the connection succeeds or fails, Emacs will call the sentinel function, with a second argument matching “`open`” (if successful) or “`failed`”. The default is to block, so that `make-network-process` does not return until the connection has succeeded or failed.

If you’re setting up an asynchronous TLS connection, you have to also provide the `:tls-parameters` parameter (see below).

Depending on the capabilities of Emacs, how asynchronous `:nowait` is may vary. The three elements that may (or may not) be done asynchronously are domain name resolution, socket setup, and (for TLS connections) TLS negotiation.

Many functions that interact with process objects, (for instance, `process-datagram-address`) rely on them at least having a socket before they can return a useful value. These functions will block until the socket has achieved the desired status. The recommended way of interacting with asynchronous sockets is to place a sentinel on the process, and not try to interact with it before it has changed status to ‘“`run`”’. That way, none of these functions will block.

`:tls-parameters`

When opening a TLS connection, this should be where the first element is the TLS type (which should either be `gnutls-x509pki` or `gnutls-anon`, and the remaining elements should form a keyword list acceptable for `gnutls-boot`. (This keyword list can be obtained from the `gnutls-boot-parameters` function.) The TLS connection will then be negotiated after completing the connection to the host.

`:stop stopped`

If `stopped` is non-`nil`, start the network connection or server in the stopped state.

`:buffer buffer`

Use `buffer` as the process buffer.

`:coding coding`

Use `coding` as the coding system for this process. To specify different coding systems for decoding data from the connection and for encoding data sent to it, specify `(decoding . encoding)` for `coding`.

If you don’t specify this keyword at all, the default is to determine the coding systems from the data.

`:noquery query-flag`

Initialize the process query flag to `query-flag`. See Section 40.11 [Query Before Exit], page 1107.

`:filter filter`

Initialize the process filter to `filter`.

`:filter-multibyte multibyte`

If `multibyte` is non-`nil`, strings given to the process filter are multibyte, otherwise they are unibyte. The default is `t`.

`:sentinel sentinel`

Initialize the process sentinel to `sentinel`.

`:log log`

Initialize the log function of a server process to `log`. The log function is called each time the server accepts a network connection from a client. The arguments passed to the log function are `server`, `connection`, and

message; where server is the server process, connection is the new process for the connection, and message is a string describing what has happened.

:plist *plist* Initialize the process plist to *plist*.

The original argument list, modified with the actual connection information, is available via the `process-contact` function.

### 40.17.2 Network Options

The following network options can be specified when you create a network process. Except for `:reuseaddr`, you can also set or modify these options later, using `set-network-process-option`.

For a server process, the options specified with `make-network-process` are not inherited by the client connections, so you will need to set the necessary options for each child connection as it is created.

:bindtodevice *device-name*

If *device-name* is a non-empty string identifying a network interface name (see `network-interface-list`), only handle packets received on that interface. If *device-name* is `nil` (the default), handle packets received on any interface.

Using this option may require special privileges on some systems.

:broadcast *broadcast-flag*

If *broadcast-flag* is non-`nil` for a datagram process, the process will receive datagram packet sent to a broadcast address, and be able to send packets to a broadcast address. This is ignored for a stream connection.

:dontroute *dontroute-flag*

If *dontroute-flag* is non-`nil`, the process can only send to hosts on the same network as the local host.

:keepalive *keepalive-flag*

If *keepalive-flag* is non-`nil` for a stream connection, enable exchange of low-level keep-alive messages.

:linger *linger-arg*

If *linger-arg* is non-`nil`, wait for successful transmission of all queued packets on the connection before it is deleted (see `delete-process`). If *linger-arg* is an integer, it specifies the maximum time in seconds to wait for queued packets to be sent before closing the connection. The default is `nil`, which means to discard unsent queued packets when the process is deleted.

:oobinline *oobinline-flag*

If *oobinline-flag* is non-`nil` for a stream connection, receive out-of-band data in the normal data stream. Otherwise, ignore out-of-band data.

:priority *priority*

Set the priority for packets sent on this connection to the integer *priority*. The interpretation of this number is protocol specific; such as setting the TOS (type of service) field on IP packets sent on this connection. It may also have system dependent effects, such as selecting a specific output queue on the network interface.

`:reuseaddr reuseaddr-flag`

If `reuseaddr-flag` is non-`nil` (the default) for a stream server process, allow this server to reuse a specific port number (see `:service`), unless another process on this host is already listening on that port. If `reuseaddr-flag` is `nil`, there may be a period of time after the last use of that port (by any process on the host) where it is not possible to make a new server on that port.

**set-network-process-option** *process option value &optional no-error* [Function]

This function sets or modifies a network option for network process *process*. The accepted options and values are as for `make-network-process`. If *no-error* is non-`nil`, this function returns `nil` instead of signaling an error if *option* is not a supported option. If the function successfully completes, it returns `t`.

The current setting of an option is available via the `process-contact` function.

### 40.17.3 Testing Availability of Network Features

To test for the availability of a given network feature, use `featurep` like this:

```
(featurep 'make-network-process '(keyword value))
```

The result of this form is `t` if it works to specify *keyword* with value *value* in `make-network-process`. Here are some of the *keyword*—*value* pairs you can test in this way.

`(:nowait t)`

Non-`nil` if non-blocking connect is supported.

`(:type datagram)`

Non-`nil` if datagrams are supported.

`(:family local)`

Non-`nil` if local (a.k.a. “UNIX domain”) sockets are supported.

`(:family ipv6)`

Non-`nil` if IPv6 is supported.

`(:service t)`

Non-`nil` if the system can select the port for a server.

To test for the availability of a given network option, use `featurep` like this:

```
(featurep 'make-network-process 'keyword)
```

The accepted *keyword* values are `:bindtodevice`, etc. For the complete list, see Section 40.17.2 [Network Options], page 1118. This form returns non-`nil` if that particular network option is supported by `make-network-process` (or `set-network-process-option`).

## 40.18 Misc Network Facilities

These additional functions are useful for creating and operating on network connections. Note that they are supported only on some systems.

**network-interface-list &optional full family** [Function]

This function returns a list describing the network interfaces of the machine you are using. The value is an alist whose elements have the form (`ifname . address`).

*ifname* is a string naming the interface, *address* has the same form as the *local-address* and *remote-address* arguments to `make-network-process`, i.e. a vector of integers. By default both IPv4 and IPv6 addresses are returned if possible.

Optional argument *full* non-*nil* means to instead return a list of one or more elements of the form `(ifname addr bcast netmask)`. *ifname* is a non-unique string naming the interface. *addr*, *bcast*, and *netmask* are vectors of integers detailing the IP address, broadcast address, and network mask.

Optional argument *family* specified as symbol `ipv4` or `ipv6` restricts the returned information to IPv4 and IPv6 addresses respectively, independently of the value of *full*. Specifying `ipv6` when IPv6 support is not available will result in an error being signaled.

Some examples:

```
(network-interface-list) ⇒
(("vmnet8" .
 [172 16 76 1 0])
("vmnet1" .
 [172 16 206 1 0])
("lo0" .
 [65152 0 0 0 0 0 0 1 0])
("lo0" .
 [0 0 0 0 0 0 0 1 0])
("lo0" .
 [127 0 0 1 0)))

(network-interface-list t) ⇒
(("vmnet8"
 [172 16 76 1 0]
 [172 16 76 255 0]
 [255 255 255 0 0])
("vmnet1"
 [172 16 206 1 0]
 [172 16 206 255 0]
 [255 255 255 0 0])
("lo0"
 [65152 0 0 0 0 0 0 1 0]
 [65152 0 0 0 65535 65535 65535 65535 0]
 [65535 65535 65535 65535 0 0 0 0 0])
("lo0"
 [0 0 0 0 0 0 0 1 0]
 [0 0 0 0 0 0 1 0]
 [65535 65535 65535 65535 65535 65535 65535 65535 0])
("lo0"
 [127 0 0 1 0]
 [127 255 255 255 0]
 [255 0 0 0 0]))
```

**network-interface-info** *ifname* [Function]

This function returns information about the network interface named *ifname*. The value is a list of the form (*addr bcast netmask hwaddr flags*).

*addr* The Internet protocol address.

*bcast* The broadcast address.

*netmask* The network mask.

*hwaddr* The layer 2 address (Ethernet MAC address, for instance).

*flags* The current flags of the interface.

Note that this function returns only IPv4 information.

**format-network-address** *address &optional omit-port* [Function]

This function converts the Lisp representation of a network address to a string.

A five-element vector [*a b c d p*] represents an IPv4 address *a.b.c.d* and port number *p*. **format-network-address** converts that to the string "*a.b.c.d:p*".

A nine-element vector [*a b c d e f g h p*] represents an IPv6 address along with a port number. **format-network-address** converts that to the string "[*a:b:c:d:e:f:g:h*]:*p*".

If the vector does not include the port number, *p*, or if *omit-port* is non-*nil*, the result does not include the :*p* suffix.

**network-lookup-address-info** *name &optional family hints* [Function]

This function performs hostname lookups on *name*, which is expected to be an ASCII-only string, otherwise it signals an error. Call **puny-encode-domain** on *name* first if you wish to lookup internationalized hostnames.

If successful, this function returns a list of Lisp representations of network addresses (see Section 40.17.1 [Network Processes], page 1115, for a description of the format), otherwise return *nil*. In the latter case, it also logs an error message hopefully explaining what went wrong.

By default, this function attempts both IPv4 and IPv6 lookups. The optional argument *family* controls this behavior, specifying the symbol **ipv4** or **ipv6** restricts lookups to IPv4 and IPv6 respectively.

If optional argument *hints* is **numeric**, the function treats the *name* as a numerical IP address (and does not perform DNS lookups). This can be used to check whether a string is a valid numerical representation of an IP address, or to convert a numerical string to its canonical representation. e.g.

```
(network-lookup-address-info "127.1" 'ipv4 'numeric)
⇒ ([127 0 0 1 0])
```

```
(network-lookup-address-info "::1" nil 'numeric)
⇒ ([0 0 0 0 0 0 1 0])
```

Be warned that there are some surprising valid forms, especially for IPv4, e.g ‘0xe3010203’ and ‘0343.1.2.3’ are both valid, as are ‘0’ and ‘1’ (but they are invalid for IPv6).

## 40.19 Communicating with Serial Ports

Emacs can communicate with serial ports. For interactive use, `M-x serial-term` opens a terminal window. In a Lisp program, `make-serial-process` creates a process object.

The serial port can be configured at run-time, without having to close and re-open it. The function `serial-process-configure` lets you change the speed, bytesize, and other parameters. In a terminal window created by `serial-term`, you can click on the mode line for configuration.

A serial connection is represented by a process object, which can be used in a similar way to a subprocess or network process. You can send and receive data, and configure the serial port. A serial process object has no process ID, however, and you can't send signals to it, and the status codes are different from other types of processes. `delete-process` on the process object or `kill-buffer` on the process buffer close the connection, but this does not affect the device connected to the serial port.

The function `process-type` returns the symbol `serial` for a process object representing a serial port connection.

Serial ports are available on GNU/Linux, Unix, and MS Windows systems.

**serial-term** *port* *speed* &**optional** *line-mode* [Command]

Start a terminal-emulator for a serial port in a new buffer. *port* is the name of the serial port to connect to. For example, this could be `/dev/ttyS0` on Unix. On MS Windows, this could be `COM1`, or `\.\COM10` (double the backslashes in Lisp strings).

*speed* is the speed of the serial port in bits per second. 9600 is a common value. The buffer is in Term mode; see Section “Term Mode” in *The GNU Emacs Manual*, for the commands to use in that buffer. You can change the speed and the configuration in the mode line menu. If *line-mode* is non-`nil`, `term-line-mode` is used; otherwise `term-raw-mode` is used.

**make-serial-process** &**rest** *args* [Function]

This function creates a process and a buffer. Arguments are specified as keyword/argument pairs. Here's the list of the meaningful keywords, with the first two (*port* and *speed*) being mandatory:

**:port** *port*

This is the name of the serial port. On Unix and GNU systems, this is a file name such as `/dev/ttyS0`. On Windows, this could be `COM1`, or `\.\COM10` for ports higher than `COM9` (double the backslashes in Lisp strings).

**:speed** *speed*

The speed of the serial port in bits per second. This function calls `serial-process-configure` to handle the speed; see the following documentation of that function for more details.

**:name** *name*

The name of the process. If *name* is not given, *port* will serve as the process name as well.

**:buffer buffer**

The buffer to associate with the process. The value can be either a buffer or a string that names a buffer. Process output goes at the end of that buffer, unless you specify an output stream or filter function to handle the output. If *buffer* is not given, the process buffer's name is taken from the value of the **:name** keyword.

**:coding coding**

If *coding* is a symbol, it specifies the coding system used for both reading and writing for this process. If *coding* is a cons (*decoding* . *encoding*), *decoding* is used for reading, and *encoding* is used for writing. If not specified, the default is to determine the coding systems from the data itself.

**:noquery query-flag**

Initialize the process query flag to *query-flag*. See Section 40.11 [Query Before Exit], page 1107. The flags defaults to **nil** if unspecified.

**:stop bool**

Start process in the stopped state if *bool* is non-**nil**. In the stopped state, a serial process does not accept incoming data, but you can send outgoing data. The stopped state is cleared by **continue-process** and set by **stop-process**.

**:filter filter**

Install *filter* as the process filter.

**:sentinel sentinel**

Install *sentinel* as the process sentinel.

**:plist plist**

Install *plist* as the initial plist of the process.

**:bytesize****:parity****:stopbits****:flowcontrol**

These are handled by **serial-process-configure**, which is called by **make-serial-process**.

The original argument list, possibly modified by later configuration, is available via the function **process-contact**.

Here is an example:

```
(make-serial-process :port "/dev/ttyS0" :speed 9600)
```

**serial-process-configure &rest args** [Function]

This function configures a serial port connection. Arguments are specified as keyword/argument pairs. Attributes that are not given are re-initialized from the process's current configuration (available via the function **process-contact**), or set to reasonable default values. The following arguments are defined:

```
:process process
:name name
:buffer buffer
:port port
```

Any of these arguments can be given to identify the process that is to be configured. If none of these arguments is given, the current buffer's process is used.

```
:speed speed
```

The speed of the serial port in bits per second, a.k.a. *baud rate*. The value can be any number, but most serial ports work only at a few defined values between 1200 and 115200, with 9600 being the most common value. If *speed* is `nil`, the function ignores all other arguments and does not configure the port. This may be useful for special serial ports such as Bluetooth-to-serial converters, which can only be configured through ‘AT’ commands sent through the connection. The value of `nil` for *speed* is valid only for connections that were already opened by a previous call to `make-serial-process` or `serial-term`.

```
:bytesize bytesize
```

The number of bits per byte, which can be 7 or 8. If *bytesize* is not given or `nil`, it defaults to 8.

```
:parity parity
```

The value can be `nil` (don't use parity), the symbol `odd` (use odd parity), or the symbol `even` (use even parity). If *parity* is not given, it defaults to no parity.

```
:stopbits stopbits
```

The number of stopbits used to terminate a transmission of each byte. *stopbits* can be 1 or 2. If *stopbits* is not given or `nil`, it defaults to 1.

```
:flowcontrol flowcontrol
```

The type of flow control to use for this connection, which is either `nil` (don't use flow control), the symbol `hw` (use RTS/CTS hardware flow control), or the symbol `sw` (use XON/XOFF software flow control). If *flowcontrol* is not given, it defaults to no flow control.

Internally, `make-serial-process` calls `serial-process-configure` for the initial configuration of the serial port.

## 40.20 Packing and Unpacking Byte Arrays

This section describes how to pack and unpack arrays of bytes, usually for binary network protocols. These functions convert byte arrays to alists, and vice versa. The byte array can be represented as a unibyte string or as a vector of integers, while the alist associates symbols either with fixed-size objects or with recursive sub-alists. To use the functions referred to in this section, load the `bindat` library.

Conversion from byte arrays to nested alists is also known as *deserializing* or *unpacking*, while going in the opposite direction is also known as *serializing* or *packing*.

### 40.20.1 Describing Data Layout

To control unpacking and packing, you write a *data layout specification*, also called a *Bindat type expression*. This can be a *base type* or a *composite type* made of several fields, where the specification controls the length of each field to be processed, and how to pack or unpack it. We normally keep bindat type values in variables whose names end in `-bindat-spec`; that kind of name is automatically recognized as risky (see Section 12.12 [File Local Variables], page 213).

**bindat-type &rest type** [Macro]

Creates a Bindat type *value* object according to the Bindat type *expression type*.

A field’s *type* describes the size (in bytes) of the object that the field represents and, in the case of multibyte fields, how the bytes are ordered within the field. The two possible orderings are *big endian* (also known as “network byte ordering”) and *little endian*. For instance, the number `#x23cd` (decimal 9165) in big endian would be the two bytes `#x23` `#xcd`; and in little endian, `#xcd #x23`. Here are the possible type values:

**u8**

**byte** Unsigned byte, with length 1.

**uint bitlen &optional le**

Unsigned integer in network byte order (big-endian), with *bitlen* bits. *bitlen* has to be a multiple of 8. If *le* is non-`nil`, then use little-endian byte order.

**sint bitlen le**

Signed integer in network byte order (big-endian), with *bitlen* bits. *bitlen* has to be a multiple of 8. If *le* is non-`nil`, then use little-endian byte order.

**str len**

Unibyte string (see Section 34.1 [Text Representations], page 963) of length *len* bytes. When packing, the first *len* bytes of the input string are copied to the packed output. If the input string is shorter than *len*, the remaining bytes will be null (zero) unless a pre-allocated string was provided to `bindat-pack`, in which case the remaining bytes are left unmodified. If the input string is multibyte with only ASCII and `eight-bit` characters, it is converted to unibyte before it is packed; other multibyte strings signal an error. When unpacking, any null bytes in the packed input string will appear in the unpacked output.

**strz &optional len**

If *len* is not provided, this is a variable-length null-terminated unibyte string (see Section 34.1 [Text Representations], page 963). When packing into `strz`, the entire input string is copied to the packed output followed by a null (zero) byte. (If pre-allocated string is provided for packing into `strz`, that pre-allocated string should have enough space for the additional null byte appended to the output string contents, see Section 40.20.2 [Bindat Functions], page 1127). The length of the packed output is the length of the input string plus one (for the null terminator). The input string must not contain any null bytes. If the input string is multibyte with only ASCII and `eight-bit` characters, it is converted to unibyte before it is packed; other multibyte strings signal an error. When unpacking a `strz`, the resulting output string will contain all bytes up to (but excluding) the null byte that terminated the input string.

If *len* is provided, **strz** behaves the same as **str**, but with a couple of differences:

- When packing, a null terminator is written after the packed input string if the number of characters in the input string is less than *len*.
- When unpacking, the first null byte encountered in the packed string is interpreted as the terminating byte, and it and all subsequent bytes are excluded from the result of the unpacking.

**Caution:** The packed output will not be null-terminated unless the input string is shorter than *len* bytes or it contains a null byte within the first *len* bytes.

#### **vec** *len* [*type*]

Vector of *len* elements. The type of the elements is given by *type*, defaulting to bytes. The *type* can be any Bindat type expression.

#### **repeat** *len* [*type*]

Like **vec**, but it unpacks to and packs from lists, whereas **vec** unpacks to vectors.

**bits** *len* List of bits that are set to 1 in *len* bytes. The bytes are taken in big-endian order, and the bits are numbered starting with  $8 * \text{len} - 1$  and ending with zero. For example: **bits** 2 unpacks `#x28 #x1c` to (2 3 4 11 13) and `#x1c #x28` to (3 5 10 11 12).

**fill** *len* *len* bytes used as a mere filler. In packing, these bytes are left unchanged, which normally means they remain zero. When unpacking, this just returns **nil**.

**align** *len* Same as **fill** except the number of bytes is that needed to skip to the next multiple of *len* bytes.

**type** *exp* This lets you refer to a type indirectly: *exp* is a Lisp expression which should return a Bindat type *value*.

**unit** *exp* This is a trivial type which uses up 0 bits of space. *exp* describes the value returned when we try to “unpack” such a field.

#### **struct** *fields...*

Composite type made of several fields. Every field is of the form `(name type)` where *type* can be any Bindat type expression. *name* can be `_` when the field’s value does not deserve to be named, as is often the case for **align** and **fill** fields. When the context makes it clear that this is a Bindat type expression, the symbol **struct** can be omitted.

In the types above, *len* and *bitlen* are given as an integer specifying the number of bytes (or bits) in the field. When the length of a field is not fixed, it typically depends on the value of preceding fields. For this reason, the length *len* does not have to be a constant but can be any Lisp expression and it can refer to the value of previous fields via their name.

For example, the specification of a data layout where a leading byte gives the size of a subsequent vector of 16 bit integers could be:

```
(bindat-type
 (len u8)
 (payload vec (1+ len) uint 16))
```

### 40.20.2 Functions to Unpack and Pack Bytes

In the following documentation, *type* refers to a Bindat type value as returned from `bindat-type`, *raw* to a byte array, and *struct* to an alist representing unpacked field data.

**bindat-unpack** *type raw &optional idx* [Function]

This function unpacks data from the unibyte string or byte array *raw* according to *type*. Normally, this starts unpacking at the beginning of the byte array, but if *idx* is non-*nil*, it specifies a zero-based starting position to use instead.

The value is an alist or nested alist in which each element describes one unpacked field.

**bindat-get-field** *struct &rest name* [Function]

This function selects a field's data from the nested alist *struct*. Usually *struct* was returned by `bindat-unpack`. If *name* corresponds to just one argument, that means to extract a top-level field value. Multiple *name* arguments specify repeated lookup of sub-structures. An integer *name* acts as an array index.

For example, `(bindat-get-field struct a b 2 c)` means to find field *c* in the third element of subfield *b* of field *a*. (This corresponds to `struct.a.b[2].c` in the C programming language syntax.)

Although packing and unpacking operations change the organization of data (in memory), they preserve the data's *total length*, which is the sum of all the fields' lengths, in bytes. This value is not generally inherent in either the specification or alist alone; instead, both pieces of information contribute to its calculation. Likewise, the length of a string or array being unpacked may be longer than the data's total length as described by the specification.

**bindat-length** *type struct* [Function]

This function returns the total length of the data in *struct*, according to *type*.

**bindat-pack** *type struct &optional raw idx* [Function]

This function returns a byte array packed according to *type* from the data in the alist *struct*. It normally creates and fills a new byte array starting at the beginning. However, if *raw* is non-*nil*, it specifies a pre-allocated unibyte string or vector to pack into. If *idx* is non-*nil*, it specifies the starting offset for packing into *raw*.

When pre-allocating, you should make sure (`length raw`) meets or exceeds the total length to avoid an out-of-range error.

**bindat-ip-to-string** *ip* [Function]

Convert the Internet address vector *ip* to a string in the usual dotted notation.

```
(bindat-ip-to-string [127 0 0 1])
⇒ "127.0.0.1"
```

### 40.20.3 Advanced data layout specifications

Bindat type expressions are not limited to the types described earlier. They can also be arbitrary Lisp forms returning Bindat type expressions. For example, the type below describes data which can either contain a 24-bit error code or a vector of bytes:

```
(bindat-type
```

```
(len u8)
(payload . (if (zerop len) (uint 24) (vec (1- len)))))
```

Furthermore, while composite types are normally unpacked to (and packed from) association lists, this can be changed via the use of the following special keyword arguments:

**:unpack-val exp**

When the list of fields ends with this keyword argument, then the value returned when unpacking is the value of *exp* instead of the standard alist. *exp* can refer to all the previous fields by their name.

**:pack-val exp**

If a field's type is followed by this keyword argument, then the value packed into this field is returned by *exp* instead of being extracted from the alist.

**:pack-var name**

If the list of fields is preceded by this keyword argument, then all the subsequent **:pack-val** arguments can refer to the overall value to pack into this composite type via the variable named *name*.

For example, one could describe a 16-bit signed integer as follows:

```
(defconst sint16-bindat-spec
 (let* ((max (ash 1 15))
 (wrap (+ max max)))
 (bindat-type :pack-var v
 (n uint 16 :pack-val (if (< v 0) (+ v wrap) v))
 :unpack-val (if (>= n max) (- n wrap) n))))
```

Which would then behave as follows:

```
(bindat-pack sint16-bindat-spec -8)
⇒ "\377\370"

(bindat-unpack sint16-bindat-spec "\300\100")
⇒ -16320
```

Finally, you can define new Bindat type forms to use in Bindat type expressions with **bindat-defmacro**:

**bindat-defmacro name args &rest body**

[Macro]

Define a new Bindat type expression named *name* and taking arguments *args*. Its behavior follows that of **defmacro**, which the important difference that the new forms can only be used within Bindat type expressions.

## 41 Emacs Display

This chapter describes a number of features related to the display that Emacs presents to the user.

### 41.1 Refreshing the Screen

The function `redraw-frame` clears and redisplays the entire contents of a given frame (see Chapter 30 [Frames], page 785). This is useful if the screen is corrupted.

**redraw-frame &optional frame** [Function]

This function clears and redisplays frame *frame*. If *frame* is omitted or `nil`, it redraws the selected frame.

Even more powerful is `redraw-display`:

**redraw-display** [Command]

This function clears and redisplays all visible frames.

In Emacs, processing user input takes priority over redisplay. If you call these functions when input is available, they don't redisplay immediately, but the requested redisplay does happen eventually—after all the input has been processed.

On text terminals, suspending and resuming Emacs normally also refreshes the screen. Some terminal emulators record separate contents for display-oriented programs such as Emacs and for ordinary sequential display. If you are using such a terminal, you might want to inhibit the redisplay on resumption.

**no-redraw-on-reenter** [User Option]

This variable controls whether Emacs redraws the entire screen after it has been suspended and resumed. `Non-nil` means there is no need to redraw, `nil` means redrawing is needed. The default is `nil`.

### 41.2 Forcing Redisplay

Emacs normally tries to redisplay the screen whenever it waits for input. With the following function, you can request an immediate attempt to redisplay, in the middle of Lisp code, without actually waiting for input.

**redisplay &optional force** [Function]

This function tries immediately to redisplay. The optional argument *force*, if `non-nil`, forces the redisplay to be performed, instead of being preempted if input is pending.

The function returns `t` if it actually tried to redisplay, and `nil` otherwise. A value of `t` does not mean that redisplay proceeded to completion; it could have been preempted by newly arriving input.

Although `redisplay` tries immediately to redisplay, it does not change how Emacs decides which parts of its frame(s) to redisplay. By contrast, the following function adds certain windows to the pending redisplay work (as if their contents had completely changed), but does not immediately try to perform redisplay.

**force-window-update &optional object** [Function]

This function forces some or all windows to be updated the next time Emacs does a redisplay. If *object* is a window, that window is to be updated. If *object* is a buffer or buffer name, all windows displaying that buffer are to be updated. If *object* is `nil` (or omitted), all windows are to be updated.

This function does not do a redisplay immediately; Emacs does that as it waits for input, or when the function `redisplay` is called.

**pre-redisplay-function** [Variable]

A function run just before redisplay. It is called with one argument, the set of windows to be redisplayed. The set can be `nil`, meaning only the selected window, or `t`, meaning all the windows.

**pre-redisplay-functions** [Variable]

This hook is run just before redisplay. It is called once in each window that is about to be redisplayed, with `current-buffer` set to the buffer displayed in that window.

### 41.3 Truncation

When a line of text extends beyond the right edge of a window, Emacs can *continue* the line (make it wrap to the next screen line), or *truncate* the line (limit it to one screen line). The additional screen lines used to display a long text line are called *continuation* lines. Continuation is not the same as filling; continuation happens on the screen only, not in the buffer contents, and it breaks a line precisely at the right margin, not at a word boundary. See Section 33.11 [Filling], page 899.

On a graphical display, tiny arrow images in the window fringes indicate truncated and continued lines (see Section 41.13 [Fringes], page 1189). On a text terminal, and on a graphical display when `fringe-mode` was turned off, a ‘\$’ in the rightmost column of the window indicates truncation; a ‘\’ on the rightmost column indicates a line that wraps. (The display table can specify alternate characters to use for this; see Section 41.23.2 [Display Tables], page 1243).

Since wrapping and truncation of text contradict each other, Emacs turns off line truncation when wrapping is requested, and vice versa.

**truncate-lines** [User Option]

If this buffer-local variable is non-`nil`, lines that extend beyond the right edge of the window are truncated; otherwise, they are continued. As a special exception, the variable `truncate-partial-width-windows` takes precedence in *partial-width* windows (i.e., windows that do not occupy the entire frame width).

**truncate-partial-width-windows** [User Option]

This variable controls line truncation in *partial-width* windows. A *partial-width* window is one that does not occupy the entire frame width (see Section 29.7 [Splitting Windows], page 708). If the value is `nil`, line truncation is determined by the variable `truncate-lines` (see above). If the value is an integer *n*, lines are truncated if the *partial-width* window has fewer than *n* columns, regardless of the value of `truncate-lines`; if the *partial-width* window has *n* or more columns, line truncation is determined by `truncate-lines`. For any other non-`nil` value, lines are truncated in every *partial-width* window, regardless of the value of `truncate-lines`.

When horizontal scrolling (see Section 29.23 [Horizontal Scrolling], page 767) is in use in a window, that forces truncation.

**wrap-prefix**

[Variable]

If this buffer-local variable is non-`nil`, it defines a *wrap prefix* which Emacs displays at the start of every continuation line. (If lines are truncated, `wrap-prefix` is never used.) Its value may be a string or an image (see Section 41.16.4 [Other Display Specs], page 1203), or a stretch of whitespace such as specified by the `:width` or `:align-to` display properties (see Section 41.16.2 [Specified Space], page 1200). The value is interpreted in the same way as a `display` text property. See Section 41.16 [Display Property], page 1198.

A wrap prefix may also be specified for regions of text, using the `wrap-prefix` text or overlay property. This takes precedence over the `wrap-prefix` variable. See Section 33.19.4 [Special Properties], page 924.

**line-prefix**

[Variable]

If this buffer-local variable is non-`nil`, it defines a *line prefix* which Emacs displays at the start of every non-continuation line. Its value may be a string or an image (see Section 41.16.4 [Other Display Specs], page 1203), or a stretch of whitespace such as specified by the `:width` or `:align-to` display properties (see Section 41.16.2 [Specified Space], page 1200). The value is interpreted in the same way as a `display` text property. See Section 41.16 [Display Property], page 1198.

A line prefix may also be specified for regions of text using the `line-prefix` text or overlay property. This takes precedence over the `line-prefix` variable. See Section 33.19.4 [Special Properties], page 924.

## 41.4 The Echo Area

The *echo area* is used for displaying error messages (see Section 11.7.3 [Errors], page 179), for messages made with the `message` primitive, and for echoing keystrokes. It is not the same as the minibuffer, despite the fact that the minibuffer appears (when active) in the same place on the screen as the echo area. See Section “The Minibuffer” in *The GNU Emacs Manual*.

Apart from the functions documented in this section, you can print Lisp objects to the echo area by specifying `t` as the output stream. See Section 20.4 [Output Streams], page 375.

### 41.4.1 Displaying Messages in the Echo Area

This section describes the standard functions for displaying messages in the echo area.

**message format-string &rest arguments**

[Function]

This function displays a message in the echo area. `format-string` is a format string, and `arguments` are the objects for its format specifications, like in the `format-message` function (see Section 4.7 [Formatting Strings], page 66). The resulting formatted string is displayed in the echo area; if it contains `face` text properties, it is displayed with the specified faces (see Section 41.12 [Faces], page 1164). The string is also added to the `*Messages*` buffer, but without text properties (see Section 41.4.3 [Logging Messages], page 1137).

Typically grave accent and apostrophe in the format translate to matching curved quotes, e.g., "Missing ‘%s’" might result in "Missing ‘foo’". See Section 25.4 [Text Quoting Style], page 600, for how to influence or inhibit this translation.

In batch mode, the message is printed to the standard error stream, followed by a newline.

When `inhibit-message` is non-`nil`, no message will be displayed in the echo area, it will only be logged to ‘\*Messages\*’.

If `format-string` is `nil` or the empty string, `message` clears the echo area; if the echo area has been expanded automatically, this brings it back to its normal size. If the minibuffer is active, this brings the minibuffer contents back onto the screen immediately.

```
(message "Reverting `~%s'..." (buffer-name))
 → Reverting 'subr.el'...
 ⇒ "Reverting 'subr.el'..."

----- Echo Area -----
Reverting 'subr.el'...
----- Echo Area -----
```

To automatically display a message in the echo area or in a pop-buffer, depending on its size, use `display-message-or-buffer` (see below).

**Warning:** If you want to use your own string as a message verbatim, don’t just write `(message string)`. If `string` contains ‘%’, ‘`’, or ‘’ it may be reformatted, with undesirable results. Instead, use `(message "%s" string)`.

The following facilities allow users and Lisp programs to control how echo-area messages are displayed.

#### `set-message-function`

[Variable]

If this variable is non-`nil`, it should be a function of one argument, the text of a message to display in the echo area. That function will be called by `message` and related functions. If the function returns `nil`, the message is displayed in the echo area as usual. If the function returns a string, that string is displayed in the echo area instead of the original message. If the function returns any other non-`nil` value, that means the message was already handled, so `message` will not display anything in the echo area.

The default value calls `set-minibuffer-message`, described below.

#### `clear-message-function`

[Variable]

If this variable is non-`nil`, it should be a function of no arguments; `message` and related functions call it when their argument message is `nil` or the empty string, to clear the echo area.

Usually this function is called when the next input event arrives after displaying an echo-area message. The function is expected to clear the message displayed by its counterpart function specified by `set-message-function`, but doesn’t have to. If the function wants the echo area to remain uncleared, it should return the symbol `dont-clear-message`; any other value will result in the echo area being cleared.

The default value is the function that clears the message displayed in an active minibuffer.

**set-message-functions**

[User Option]

The value of this user option is a list of functions to be called for handling display of echo-area messages. Each function is called with one argument, the text of the message to display. If the function returns a string, that string replaces the original message, and the next function in the list is called with the new message text. If the function returns `nil`, the next function in the list is called with the same text; if the last function in the list returns `nil`, the message text is displayed in the echo area. If the function returns a non-`nil` value that is not a string, the message is considered to be handled, and no further functions in the list are called.

The three useful functions to be put in the list that is the value of this option are described below.

**set-minibuffer-message message**

[Function]

This function displays `message` in the echo-area when the minibuffer is not active, and at the end of the minibuffer when the minibuffer is active. However, if the text shown in the active minibuffer has the `minibuffer-message` text property (see Section 33.19.4 [Special Properties], page 924) on some character, the message will be displayed before the first character having that property.

This function is by default the only member of the list in `set-message-functions`.

**inhibit-message message**

[Function]

If an echo-area `message` matches any regexp in the list that is the value of the user option `inhibit-message-regexp`s, this function suppresses the display of that message and returns a non-`nil` value that is not a string. Thus, if this function is in the list `set-message-functions`, the rest of the functions in the list will not be called when `message` matches the regexps in `inhibit-message-regexp`s. To ensure a matching `message` will never be displayed, make this function be the first element of the list in `set-message-functions`.

**set-multi-message message**

[Function]

This function accumulates several echo-area messages emitted one after another, and returns them as a single string in which individual messages are separated by newlines. Up to `multi-message-max` recent messages can be accumulated. The accumulated messages are discarded when more than `multi-message-timeout` seconds have elapsed since the time the first message was emitted.

**inhibit-message**

[Variable]

When this variable is non-`nil`, `message` and related functions will not display any messages in the Echo Area. Echo-area messages are still logged in the `*Messages*` buffer, though.

**with-temp-message message &rest body**

[Macro]

This construct displays a message in the echo area temporarily, during the execution of `body`. It displays `message`, executes `body`, then returns the value of the last `body` form while restoring the previous echo area contents.

**message-or-box** *format-string &rest arguments* [Function]

This function displays a message like `message`, but may display it in a dialog box instead of the echo area. If this function is called in a command that was invoked using the mouse—more precisely, if `last-nonmenu-event` (see Section 22.5 [Command Loop Info], page 436) is either `nil` or a list—then it uses a dialog box or pop-up menu to display the message. Otherwise, it uses the echo area. (This is the same criterion that `y-or-n-p` uses to make a similar decision; see Section 21.7 [Yes-or-No Queries], page 413.)

You can force use of the mouse or of the echo area by binding `last-nonmenu-event` to a suitable value around the call.

**message-box** *format-string &rest arguments* [Function]

This function displays a message like `message`, but uses a dialog box (or a pop-up menu) whenever that is possible. If it is impossible to use a dialog box or pop-up menu, because the terminal does not support them, then `message-box` uses the echo area, like `message`.

**display-message-or-buffer** *message &optional buffer-name action frame* [Function]

This function displays the message `message`, which may be either a string or a buffer. If it is shorter than the maximum height of the echo area, as defined by `max-mini-window-height`, it is displayed in the echo area, using `message`. Otherwise, `display-buffer` is used to show it in a pop-up buffer.

Returns either the string shown in the echo area, or when a pop-up buffer is used, the window used to display it.

If `message` is a string, then the optional argument `buffer-name` is the name of the buffer used to display it when a pop-up buffer is used, defaulting to `*Message*`. In the case where `message` is a string and displayed in the echo area, it is not specified whether the contents are inserted into the buffer anyway.

The optional arguments `action` and `frame` are as for `display-buffer`, and only used if a buffer is displayed.

**current-message** [Function]

This function returns the message currently being displayed in the echo area, or `nil` if there is none.

#### 41.4.2 Reporting Operation Progress

When an operation can take a while to finish, you should inform the user about the progress it makes. This way the user can estimate remaining time and clearly see that Emacs is busy working, not hung. A convenient way to do this is to use a *progress reporter*.

Here is a working example that does nothing useful:

```
(let ((progress-reporter
 (make-progress-reporter "Collecting mana for Emacs..."'
 0 500)))
 (dotimes (k 500)
 (sit-for 0.01)
 (progress-reporter-update progress-reporter k))
 (progress-reporter-done progress-reporter))
```

**make-progress-reporter** *message* &optional *min-value* *max-value* [Function]  
*current-value* *min-change* *min-time*

This function creates and returns a progress reporter object, which you will use as an argument for the other functions listed below. The idea is to precompute as much data as possible to make progress reporting very fast.

When this progress reporter is subsequently used, it will display *message* in the echo area, followed by progress percentage. *message* is treated as a simple string. If you need it to depend on a filename, for instance, use **format-message** before calling this function.

The arguments *min-value* and *max-value* should be numbers standing for the starting and final states of the operation. For instance, an operation that scans a buffer should set these to the results of **point-min** and **point-max** correspondingly. *max-value* should be greater than *min-value*.

Alternatively, you can set *min-value* and *max-value* to **nil**. In that case, the progress reporter does not report process percentages; it instead displays a “spinner” that rotates a notch each time you update the progress reporter.

If *min-value* and *max-value* are numbers, you can give the argument *current-value* a numerical value specifying the initial progress; if omitted, this defaults to *min-value*.

The remaining arguments control the rate of echo area updates. The progress reporter will wait for at least *min-change* more percents of the operation to be completed before printing next message; the default is one percent. *min-time* specifies the minimum time in seconds to pass between successive prints; the default is 0.2 seconds. (On some operating systems, the progress reporter may handle fractions of seconds with varying precision).

This function calls **progress-reporter-update**, so the first message is printed immediately.

**progress-reporter-update** *reporter* &optional *value* *suffix* [Function]

This function does the main work of reporting progress of your operation. It displays the message of *reporter*, followed by progress percentage determined by *value*. If percentage is zero, or close enough according to the *min-change* and *min-time* arguments, then it is omitted from the output.

*reporter* must be the result of a call to **make-progress-reporter**. *value* specifies the current state of your operation and must be between *min-value* and *max-value* (inclusive) as passed to **make-progress-reporter**. For instance, if you scan a buffer, then *value* should be the result of a call to **point**.

Optional argument *suffix* is a string to be displayed after *reporter*'s main message and progress text. If *reporter* is a non-numerical reporter, then *value* should be **nil**, or a string to use instead of *suffix*.

This function respects *min-change* and *min-time* as passed to **make-progress-reporter** and so does not output new messages on every invocation. It is thus very fast and normally you should not try to reduce the number of calls to it: resulting overhead will most likely negate your effort.

**progress-reporter-force-update** *reporter* &*optional value* [Function]  
*new-message suffix*

This function is similar to **progress-reporter-update** except that it prints a message in the echo area unconditionally.

*reporter*, *value*, and *suffix* have the same meaning as for **progress-reporter-update**. Optional *new-message* allows you to change the message of the *reporter*. Since this function always updates the echo area, such a change will be immediately presented to the user.

**progress-reporter-done** *reporter* [Function]

This function should be called when the operation is finished. It prints the message of *reporter* followed by word ‘done’ in the echo area.

You should always call this function and not hope for **progress-reporter-update** to print ‘100%’. Firstly, it may never print it, there are many good reasons for this not to happen. Secondly, ‘done’ is more explicit.

**dotimes-with-progress-reporter** (*var count [result]*) [Macro]  
*reporter-or-message body...*

This is a convenience macro that works the same way as **dotimes** does, but also reports loop progress using the functions described above. It allows you to save some typing. The argument *reporter-or-message* can be either a string or a progress reporter object.

You can rewrite the example in the beginning of this subsection using this macro as follows:

```
(dotimes-with-progress-reporter
 (k 500)
 "Collecting some mana for Emacs..."
 (sit-for 0.01))
```

Using a reporter object as the *reporter-or-message* argument is useful if you want to specify the optional arguments in **make-progress-reporter**. For instance, you can write the previous example as follows:

```
(dotimes-with-progress-reporter
 (k 500)
 (make-progress-reporter "Collecting some mana for Emacs..." 0 500 0 1 1.5)■
 (sit-for 0.01))
```

**dolist-with-progress-reporter** (*var list [result]*) [Macro]  
*reporter-or-message body...*

This is another convenience macro that works the same way as **dolist** does, but also reports loop progress using the functions described above. As in **dotimes-with-progress-reporter**, *reporter-or-message* can be a progress reporter or a string. You can rewrite the previous example with this macro as follows:

```
(dolist-with-progress-reporter
 (k (number-sequence 0 500))
 "Collecting some mana for Emacs..."
 (sit-for 0.01))
```

**with-delayed-message** (*timeout message*) *body...* [Macro]

Sometimes it's unclear whether an operation will take a long time to execute or not, or it can be inconvenient to implement a progress reporter. This macro can be used in those situations.

```
(with-delayed-message (2 (format "Gathering data for %s" entry))
 (setq data (gather-data entry)))
```

In this example, if the body takes more than two seconds to execute, the message will be displayed. If it takes a shorter time than that, the message won't be displayed. In either case, the body is evaluated as normally, and the return value of the final element in the body is the return value of the macro.

The *message* element is evaluated before *body*, and is always evaluated, whether the message is displayed or not.

#### 41.4.3 Logging Messages in \*Messages\*

Almost all the messages displayed in the echo area are also recorded in the **\*Messages\*** buffer so that the user can refer back to them. This includes all the messages that are output with **message**. By default, this buffer is read-only and uses the major mode **messages-buffer-mode**. Nothing prevents the user from killing the **\*Messages\*** buffer, but the next display of a message recreates it. Any Lisp code that needs to access the **\*Messages\*** buffer directly and wants to ensure that it exists should use the function **messages-buffer**.

**messages-buffer** [Function]

This function returns the **\*Messages\*** buffer. If it does not exist, it creates it, and switches it to **messages-buffer-mode**.

**message-log-max** [User Option]

This variable specifies how many lines to keep in the **\*Messages\*** buffer. The value **t** means there is no limit on how many lines to keep. The value **nil** disables message logging entirely. Here's how to display a message and prevent it from being logged:

```
(let (message-log-max)
 (message ...))
```

**messages-buffer-name** [Variable]

This variable has the name of the buffer where messages should be logged to, and defaults to **\*Messages\***. Some packages may find it useful to temporarily redirect the output to a different buffer (perhaps to write the buffer out to a log file later), and they can bind this variable to a different buffer name. (Note that this buffer (if it doesn't exist already), will be created and put into **messages-buffer-mode**.)

To make **\*Messages\*** more convenient for the user, the logging facility combines successive identical messages. It also combines successive related messages for the sake of two cases: question followed by answer, and a series of progress messages.

A question followed by an answer has two messages like the ones produced by **y-or-n-p**: the first is '**question**', and the second is '**question...answer**'. The first message conveys no additional information beyond what's in the second, so logging the second message discards the first from the log.

A series of progress messages has successive messages like those produced by `make-progress-reporter`. They have the form ‘`base...how-far`’, where `base` is the same each time, while `how-far` varies. Logging each message in the series discards the previous one, provided they are consecutive.

The functions `make-progress-reporter` and `y-or-n-p` don’t have to do anything special to activate the message log combination feature. It operates whenever two consecutive messages are logged that share a common prefix ending in ‘`...`’.

#### 41.4.4 Echo Area Customization

These variables control details of how the echo area works.

##### `cursor-in-echo-area`

[Variable]

This variable controls where the cursor appears when a message is displayed in the echo area. If it is `non-nil`, then the cursor appears at the end of the message. Otherwise, the cursor appears at point—not in the echo area at all.

The value is normally `nil`; Lisp programs bind it to `t` for brief periods of time.

##### `echo-area-clear-hook`

[Variable]

This normal hook is run whenever the echo area is cleared—either by (`(message nil)`) or for any other reason.

##### `echo-keystrokes`

[User Option]

This variable determines how much time should elapse before command characters echo. Its value must be a number, and specifies the number of seconds to wait before echoing. If the user types a prefix key (such as `C-x`) and then delays this many seconds before continuing, the prefix key is echoed in the echo area. (Once echoing begins in a key sequence, all subsequent characters in the same key sequence are echoed immediately.)

If the value is zero, then command input is not echoed.

##### `message-truncate-lines`

[Variable]

Normally, displaying a long message resizes the echo area to display the entire message, wrapping long line as needed. But if the variable `message-truncate-lines` is `non-nil`, long lines of echo-area message are instead truncated to fit the mini-window width.

The variable `max-mini-window-height`, which specifies the maximum height for resizing minibuffer windows, also applies to the echo area (which is really a special use of the minibuffer window; see Section 21.11 [Minibuffer Windows], page 418).

### 41.5 Reporting Warnings

*Warnings* are a facility for a program to inform the user of a possible problem, but continue running (as opposed to signaling an error, see Section 11.7.3 [Errors], page 179).

#### 41.5.1 Warning Basics

Every warning is a textual message, which explains the problem for the user, with the associated *severity level* which is a symbol. Here are the supported severity levels, in order of decreasing severity, and their meanings:

- :emergency** A problem that will seriously impair Emacs operation soon if the user does not attend to it promptly.
- :error** A report about data or circumstances that are inherently wrong.
- :warning** A report about data or circumstances that are not inherently wrong, but raise suspicion of a possible problem.
- :debug** A report of information that may be useful if the user is currently debugging the Lisp program which issues the warning.

When your program encounters invalid input data, it can either signal a Lisp error by calling `error` or `signal` (see Section 11.7.3.1 [Signaling Errors], page 180) or report a warning with severity `:error`. Signaling a Lisp error is the easiest thing to do, but it means the signaling program cannot continue execution. If you want to take the trouble of implementing a way to continue processing despite the invalid data, then reporting a warning of severity `:error` is the right way of informing the user of the problem. For instance, the Emacs Lisp byte compiler can report an error that way and continue compiling other functions. (If the program signals a Lisp error and then handles it with `condition-case`, the user won't see the error message; reporting that as a warning instead avoids that problem.)

In addition to severity level, each warning has a `warning type` to classify it. The warning type is either a symbol or a list of symbols. If it is a symbol, it should be the custom group that you use for the program's user options; if it is a list, the first element of the list should be that custom group. For example, byte compiler warnings use the warning type (`bytecomp`). If the warning type is a list, the elements of the list after the first one, which should be arbitrary symbols, represent subcategories of the warning: they will be displayed to the user to better explain the nature of the warning.

**display-warning** *type message &optional level buffer-name* [Function]

This function reports a warning, using the string *message* as the warning text and *type* as the warning type. *level* should be the severity level, and defaults to `:warning` if omitted or `nil`.

*buffer-name*, if non-`nil`, specifies the name of the buffer for logging the warning message. By default, it is `*Warnings*`.

**lwarn** *type level message &rest args* [Function]

This function reports a warning using the value returned by `(format-message message args...)` as the message text in the `*Warnings*` buffer. In other respects it is equivalent to `display-warning`.

**warn** *message &rest args* [Function]

This function reports a warning using the value returned by `(format-message message args...)` as the message text, `emacs` as the warning type, and `:warning` as the severity level. It exists for compatibility only; we recommend not using it, because you should specify a specific warning type.

## 41.5.2 Warning Variables

Programs can customize how their warnings appear by binding the variables described in this section.

**warning-levels**

[Variable]

This list defines the meaning and severity order of the warning severity levels. Each element defines one severity level, and they are arranged in order of decreasing severity.

Each element has the form (*level string [function]*), where *level* is the severity level it defines. *string* specifies the textual description of this level. *string* should use ‘%s’ to specify where to put the warning type information, or it can omit the ‘%s’ so as not to include that information.

The optional *function*, if non-*nil*, is a function to call with no arguments, to get the user’s attention. A notable example is *ding* (see Section 41.24 [Beeping], page 1247).

Normally you should not change the value of this variable.

**warning-prefix-function**

[Variable]

If non-*nil*, the value is a function to generate prefix text for warnings. Programs can bind the variable to a suitable function. *display-warning* calls this function with the warnings buffer the current buffer, and the function can insert text into it. That text becomes the beginning of the warning message.

The function is called with two arguments, the severity level and its entry in *warning-levels*. It should return a list to use instead of that entry (the value need not be an actual member of *warning-levels*, but it must have the same structure). By constructing this value, the function can change the severity of the warning, or specify different handling for a given severity level.

If the variable’s value is *nil*, there’s no prefix text, before the warning is displayed, starting with the *string* part of the entry in *warning-levels* corresponding to the warning’s level.

**warning-series**

[Variable]

Programs can bind this variable to *t* to say that the next warning should begin a series. When several warnings form a series, that means to leave point on the first warning of the series, rather than keep moving it for each warning so that it appears on the last one. The series ends when the local binding of this variable is unbound and *warning-series* becomes *nil* again.

The value can also be a symbol with a function definition. That is equivalent to *t*, except that the next warning will also call the function with no arguments with the warnings buffer the current buffer. The function can, for example, insert text which will serve as a header for the series of warnings.

Once a series has begun, the value of this variable is a marker which points to the buffer position in the warnings buffer of the start of the series.

The variable’s normal value is *nil*, which means to handle each warning separately.

**warning-fill-prefix**

[Variable]

When this variable is non-*nil*, it specifies a fill prefix to use for filling the text of each warning.

**warning-fill-column**

[Variable]

The column at which to fill warnings.

**warning-type-format**

[Variable]

This variable specifies the format for displaying the warning type in the warning text. The result of formatting the type this way gets included in the message under the control of the string in the entry in `warning-levels`. The default value is "`(%s)`". If you bind it to the empty string "" then the warning type won't appear at all.

### 41.5.3 Warning Options

These variables are used by users to control what happens when a Lisp program reports a warning.

**warning-minimum-level**

[User Option]

This user option specifies the minimum severity level that should be shown immediately to the user, by popping the warnings buffer in some window. The default is `:warning`, which means to show the warning buffer for any warning severity except `:debug`. The warnings of lower severity levels will still be written into the warnings buffer, but the buffer will not be forced onto display.

**warning-minimum-log-level**

[User Option]

This user option specifies the minimum severity level that should be logged in the warnings buffer. Warnings of lower severity will be completely ignored: not written to the warnings buffer and not displayed. The default is `:warning`, which means to log warnings of any severity except `:debug`.

**warning-suppress-types**

[User Option]

This list specifies which warning types should not be displayed immediately when they occur. Each element of the list should be a list of symbols. If an element of this list has the same elements as the first elements in a warning type, then the warning of that type will not be shown on display by popping the warnings buffer in some window (the warning will still be logged in the warnings buffer).

For example, if the value of this variable is a list like this:

```
((foo) (bar subtype))
```

then warnings whose types are `foo` or `(foo)` or `(foo something)` or `(bar subtype other)` will not be shown to the user.

**warning-suppress-log-types**

[User Option]

This list specifies which warning types should be ignored: not logged in the warnings buffer and not shown to the user. The structure and the matching of warning types are the same as for `warning-suppress-types` above.

During startup, Emacs delays showing any warnings until after it loads and processes the site-wide and user's init files (see Section 42.1.1 [Startup Summary], page 1255). Let-binding (see Section 12.3 [Local Variables], page 190) the values of these options around some code in your init files which might emit a warning will therefore not work, because it will not be in effect by the time the warning is actually processed. Thus, if you want to suppress some warnings during startup, change the values of the above options in your init file early enough, or put those let-binding forms in your `after-init-hook` or `emacs-startup-hook` functions. See Section 42.1.2 [Init File], page 1258.

#### 41.5.4 Delayed Warnings

Sometimes, you may wish to avoid showing a warning while a command is running, and only show it only after the end of the command. You can use the function `delay-warning` for this. Emacs automatically delays any warnings emitted during the early stages of startup, and shows them only after the init files are processed.

**delay-warning** *type message &optional level buffer-name* [Function]

This function is the delayed counterpart to `display-warning` (see Section 41.5.1 [Warning Basics], page 1138), and it is called with the same arguments. The warning message is queued into `delayed-warnings-list`.

**delayed-warnings-list** [Variable]

The value of this variable is a list of warnings to be displayed after the current command has finished. Each element must be a list

`(type message [level [buffer-name]])`

with the same form, and the same meanings, as the argument list of `display-warning`. Immediately after running `post-command-hook` (see Section 22.1 [Command Overview], page 423), the Emacs command loop displays all the warnings specified by this variable, then resets the variable to `nil`.

Programs which need to further customize the delayed warnings mechanism can change the variable `delayed-warnings-hook`:

**delayed-warnings-hook** [Variable]

This is a normal hook which is run by the Emacs command loop, after `post-command-hook`, in order to process and display delayed warnings. Emacs also runs this hook during startup, after loading the site-start and user init files (see Section 42.1.1 [Startup Summary], page 1255), because warnings emitted before that are automatically delayed.

Its default value is a list of two functions:

`(collapse-delayed-warnings display-delayed-warnings)`

The function `collapse-delayed-warnings` removes repeated entries from `delayed-warnings-list`. The function `display-delayed-warnings` calls `display-warning` on each of the entries in `delayed-warnings-list`, in turn, and then sets `delayed-warnings-list` to `nil`.

#### 41.6 Invisible Text

You can make characters *invisible*, so that they do not appear on the screen, with the `invisible` property. This can be either a text property (see Section 33.19 [Text Properties], page 917) or an overlay property (see Section 41.9 [Overlays], page 1150). Cursor motion also partly ignores these characters; if the command loop finds that point is inside a range of invisible text after a command, it relocates point to the other side of the text.

In the simplest case, any non-`nil` `invisible` property makes a character invisible. This is the default case—if you don’t alter the default value of `buffer-invisibility-spec`, this is how the `invisible` property works. You should normally use `t` as the value of the `invisible` property if you don’t plan to set `buffer-invisibility-spec` yourself.

More generally, you can use the variable `buffer-invisibility-spec` to control which values of the `invisible` property make text invisible. This permits you to classify the text

into different subsets in advance, by giving them different `invisible` values, and subsequently make various subsets visible or invisible by changing the value of `buffer-invisibility-spec`.

Controlling visibility with `buffer-invisibility-spec` is especially useful in a program to display the list of entries in a database. It permits the implementation of convenient filtering commands to view just a part of the entries in the database. Setting this variable is very fast, much faster than scanning all the text in the buffer looking for properties to change.

**buffer-invisibility-spec** [Variable]

This variable specifies which kinds of `invisible` properties actually make a character invisible. Setting this variable makes it buffer-local.

**t** A character is invisible if its `invisible` property is non-`nil`. This is the default.

**a list** Each element of the list specifies a criterion for invisibility; if a character's `invisible` property fits any one of these criteria, the character is invisible. The list can have two kinds of elements:

**atom** A character is invisible if its `invisible` property value is `atom` or if it is a list with `atom` as a member; comparison is done with `eq`.

**(atom . t)**

A character is invisible if its `invisible` property value is `atom` or if it is a list with `atom` as a member; comparison is done with `eq`. Moreover, a sequence of such characters displays as an ellipsis.

Two functions are specifically provided for adding elements to `buffer-invisibility-spec` and removing elements from it.

**add-to-invisibility-spec element** [Function]

This function adds the element `element` to `buffer-invisibility-spec`. If `buffer-invisibility-spec` was `t`, it changes to a list, `(t)`, so that text whose `invisible` property is `t` remains invisible.

**remove-from-invisibility-spec element** [Function]

This removes the element `element` from `buffer-invisibility-spec`. This does nothing if `element` is not in the list.

A convention for use of `buffer-invisibility-spec` is that a major mode should use the mode's own name as an element of `buffer-invisibility-spec` and as the value of the `invisible` property:

```
;; If you want to display an ellipsis:
(add-to-invisibility-spec '(my-symbol . t))
;; If you don't want ellipsis:
(add-to-invisibility-spec 'my-symbol)
```

```
(overlay-put (make-overlay beginning end)
 'invisible 'my-symbol)

;; When done with the invisibility:
(remove-from-invisibility-spec '(my-symbol . t))
;; Or respectively:
(remove-from-invisibility-spec 'my-symbol)
```

You can check for invisibility using the following function:

**invisible-p pos-or-prop** [Function]

If *pos-or-prop* is a marker or number, this function returns a non-nil value if the text at that position is currently invisible.

If *pos-or-prop* is any other kind of Lisp object, that is taken to mean a possible value of the **invisible** text or overlay property. In that case, this function returns a non-nil value if that value would cause text to become invisible, based on the current value of **buffer-invisibility-spec**.

The return value of this function is *t* if the text would be completely hidden on display, or a non-nil, non-*t* value if the text would be replaced by an ellipsis.

Ordinarily, functions that operate on text or move point do not care whether the text is invisible, they process invisible characters and visible characters alike. The user-level line motion commands, such as **next-line**, **previous-line**, ignore invisible newlines if **line-move-ignore-invisible** is non-nil (the default), i.e., behave like these invisible newlines didn't exist in the buffer, but only because they are explicitly programmed to do so.

If a command ends with point inside or at the boundary of invisible text, the main editing loop relocates point to one of the two ends of the invisible text. Emacs chooses the direction of relocation so that it is the same as the overall movement direction of the command; if in doubt, it prefers a position where an inserted char would not inherit the **invisible** property. Additionally, if the text is not replaced by an ellipsis and the command only moved within the invisible text, then point is moved one extra character so as to try and reflect the command's movement by a visible movement of the cursor.

Thus, if the command moved point back to an invisible range (with the usual stickiness), Emacs moves point back to the beginning of that range. If the command moved point forward into an invisible range, Emacs moves point forward to the first visible character that follows the invisible text and then forward one more character.

These *adjustments* of point that ended up in the middle of invisible text can be disabled by setting **disable-point-adjustment** to a non-nil value. See Section 22.6 [Adjusting Point], page 439.

Incremental search can make invisible overlays visible temporarily and/or permanently when a match includes invisible text. To enable this, the overlay should have a non-nil **isearch-open-invisible** property. The property value should be a function to be called with the overlay as an argument. This function should make the overlay visible permanently; it is used when the match overlaps the overlay on exit from the search.

During the search, such overlays are made temporarily visible by temporarily modifying their invisible and intangible properties. If you want this to be done differently for a certain

overlay, give it an `isearch-open-invisible-temporary` property which is a function. The function is called with two arguments: the first is the overlay, and the second is `nil` to make the overlay visible, or `t` to make it invisible again.

## 41.7 Selective Display

*Selective display* refers to a pair of related features for hiding certain lines on the screen.

The first variant, explicit selective display, was designed for use in a Lisp program: it controls which lines are hidden by altering the text. This kind of hiding is now obsolete and deprecated; instead you should use the `invisible` property (see Section 41.6 [Invisible Text], page 1142) to get the same effect.

In the second variant, the choice of lines to hide is made automatically based on indentation. This variant is designed to be a user-level feature.

The way you control explicit selective display is by replacing a newline (control-j) with a carriage return (control-m). The text that was formerly a line following that newline is now hidden. Strictly speaking, it is temporarily no longer a line at all, since only newlines can separate lines; it is now part of the previous line.

Selective display does not directly affect editing commands. For example, `C-f` (`forward-char`) moves point unhesitatingly into hidden text. However, the replacement of newline characters with carriage return characters affects some editing commands. For example, `next-line` skips hidden lines, since it searches only for newlines. Modes that use selective display can also define commands that take account of the newlines, or that control which parts of the text are hidden.

When you write a selectively displayed buffer into a file, all the control-m's are output as newlines. This means that when you next read in the file, it looks OK, with nothing hidden. The selective display effect is seen only within Emacs.

### `selective-display`

[Variable]

This buffer-local variable enables selective display. This means that lines, or portions of lines, may be made hidden.

- If the value of `selective-display` is `t`, then the character control-m marks the start of hidden text; the control-m, and the rest of the line following it, are not displayed. This is explicit selective display.
- If the value of `selective-display` is a positive integer, then lines that start with more than that many columns of indentation are not displayed.

When some portion of a buffer is hidden, the vertical movement commands operate as if that portion did not exist, allowing a single `next-line` command to skip any number of hidden lines. However, character movement commands (such as `forward-char`) do not skip the hidden portion, and it is possible (if tricky) to insert or delete text in a hidden portion.

In the examples below, we show the *display appearance* of the buffer `foo`, which changes with the value of `selective-display`. The *contents* of the buffer do not change.

```
(setq selective-display nil)
⇒ nil

----- Buffer: foo -----
1 on this column
2on this column
3n this column
3n this column
2on this column
1 on this column
----- Buffer: foo -----

(setq selective-display 2)
⇒ 2

----- Buffer: foo -----
1 on this column
2on this column
2on this column
1 on this column
----- Buffer: foo -----
```

**selective-display-ellipses**

[User Option]

If this buffer-local variable is non-nil, then Emacs displays ‘...’ at the end of a line that is followed by hidden text. This example is a continuation of the previous one.

```
(setq selective-display-ellipses t)
⇒ t

----- Buffer: foo -----
1 on this column
2on this column ...
2on this column
1 on this column
----- Buffer: foo -----
```

You can use a display table to substitute other text for the ellipsis (‘...’). See Section 41.23.2 [Display Tables], page 1243.

## 41.8 Temporary Displays

Temporary displays are used by Lisp programs to put output into a buffer and then present it to the user for perusal rather than for editing. Many help commands use this feature.

**with-output-to-temp-buffer *buffer-name* *body*...** [Macro]

This function executes the forms in *body* while arranging to insert any output they print into the buffer named *buffer-name*, which is first created if necessary, and put into Help mode. (See the similar form **with-temp-buffer-window** below.) Finally, the buffer is displayed in some window, but that window is not selected.

If the forms in *body* do not change the major mode in the output buffer, so that it is still Help mode at the end of their execution, then `with-output-to-temp-buffer` makes this buffer read-only at the end, and also scans it for function and variable names to make them into clickable cross-references. See [Tips for Documentation Strings], page 1339, in particular the item on hyperlinks in documentation strings, for more details.

The string *buffer-name* specifies the temporary buffer, which need not already exist. The argument must be a string, not a buffer. The buffer is erased initially (with no questions asked), and it is marked as unmodified after `with-output-to-temp-buffer` exits.

`with-output-to-temp-buffer` binds `standard-output` to the temporary buffer, then it evaluates the forms in *body*. Output using the Lisp output functions within *body* goes by default to that buffer (but screen display and messages in the echo area, although they are “output” in the general sense of the word, are not affected). See Section 20.5 [Output Functions], page 377.

Several hooks are available for customizing the behavior of this construct; they are listed below.

The value of the last form in *body* is returned.

```
----- Buffer: foo -----
This is the contents of foo.
----- Buffer: foo -----

(with-output-to-temp-buffer "foo"
 (print 20)
 (print standard-output))
⇒ #<buffer foo>

----- Buffer: foo -----

20

#<buffer foo>

----- Buffer: foo -----
```

#### `temp-buffer-show-function` [User Option]

If this variable is non-nil, `with-output-to-temp-buffer` calls it as a function to do the job of displaying a help buffer. The function gets one argument, which is the buffer it should display.

It is a good idea for this function to run `temp-buffer-show-hook` just as `with-output-to-temp-buffer` normally would, inside of `save-selected-window` and with the chosen window and buffer selected.

#### `temp-buffer-setup-hook` [Variable]

This normal hook is run by `with-output-to-temp-buffer` before evaluating *body*. When the hook runs, the temporary buffer is current. This hook is normally set up with a function to put the buffer in Help mode.

**temp-buffer-show-hook**

[Variable]

This normal hook is run by `with-output-to-temp-buffer` after displaying the temporary buffer. When the hook runs, the temporary buffer is current, and the window it was displayed in is selected.

**with-temp-buffer-window** *buffer-or-name action quit-function*  
*body...* [Macro]

This macro is similar to `with-output-to-temp-buffer`. Like that construct, it executes *body* while arranging to insert any output it prints into the buffer named *buffer-or-name* and displays that buffer in some window. Unlike `with-output-to-temp-buffer`, however, it does not automatically switch that buffer to Help mode.

The argument *buffer-or-name* specifies the temporary buffer. It can be either a buffer, which must already exist, or a string, in which case a buffer of that name is created, if necessary. The buffer is marked as unmodified and read-only when `with-temp-buffer-window` exits.

This macro does not call `temp-buffer-show-function`. Rather, it passes the *action* argument to `display-buffer` (see Section 29.13.1 [Choosing Window], page 724) in order to display the buffer.

The value of the last form in *body* is returned, unless the argument *quit-function* is specified. In that case, it is called with two arguments: the window showing the buffer and the result of *body*. The final return value is then whatever *quit-function* returns.

This macro uses the normal hooks `temp-buffer-window-setup-hook` and `temp-buffer-window-show-hook` in place of the analogous hooks run by `with-output-to-temp-buffer`.

The two constructs described next are mostly identical to `with-temp-buffer-window` but differ from it as specified:

**with-current-buffer-window** *buffer-or-name action quit-function*  
*&rest body* [Macro]

This macro is like `with-temp-buffer-window` but unlike that makes the buffer specified by *buffer-or-name* current for running *body*.

A window showing a temporary buffer can be fitted to the size of that buffer using the following mode:

**temp-buffer-resize-mode** [User Option]

When this minor mode is enabled, windows showing a temporary buffer are automatically resized to fit their buffer's contents.

A window is resized if and only if it has been specially created for the buffer. In particular, windows that have shown another buffer before are not resized. By default, this mode uses `fit-window-to-buffer` (see Section 29.5 [Resizing Windows], page 703) for resizing. You can specify a different function by customizing the options `temp-buffer-max-height` and `temp-buffer-max-width` below.

The effect of this option can be overridden by providing a suitable `window-height`, `window-width` or `window-size` action alist entry for `display-buffer` (see Section 29.13.3 [Buffer Display Action Alists], page 730).

**temp-buffer-max-height**

[User Option]

This option specifies the maximum height (in lines) of a window displaying a temporary buffer when `temp-buffer-resize-mode` is enabled. It can also be a function to be called to choose the height for such a buffer. It gets one argument, the buffer, and should return a positive integer. At the time the function is called, the window to be resized is selected.

**temp-buffer-max-width**

[User Option]

This option specifies the maximum width of a window (in columns) displaying a temporary buffer when `temp-buffer-resize-mode` is enabled. It can also be a function to be called to choose the width for such a buffer. It gets one argument, the buffer, and should return a positive integer. At the time the function is called, the window to be resized is selected.

The following function uses the current buffer for temporary display:

**momentary-string-display string position &optional char message** [Function]

This function momentarily displays *string* in the current buffer at *position*. It has no effect on the undo list or on the buffer's modification status.

The momentary display remains until the next input event. If the next input event is *char*, `momentary-string-display` ignores it and returns. Otherwise, that event remains buffered for subsequent use as input. Thus, typing *char* will simply remove the string from the display, while typing (say) `C-f` will remove the string from the display and later (presumably) move point forward. The argument *char* is a space by default.

The return value of `momentary-string-display` is not meaningful.

If the string *string* does not contain control characters, you can do the same job in a more general way by creating (and then subsequently deleting) an overlay with a `before-string` property. See Section 41.9.2 [Overlay Properties], page 1153.

If *message* is non-`nil`, it is displayed in the echo area while *string* is displayed in the buffer. If it is `nil`, a default message says to type *char* to continue.

In this example, point is initially located at the beginning of the second line:

```
----- Buffer: foo -----
This is the contents of foo.
*Second line.
----- Buffer: foo -----

(momentary-string-display
 "**** Important Message! ****"
 (point) ?\r
 "Type RET when done reading")
⇒ t
```

```
----- Buffer: foo -----
This is the contents of foo.
**** Important Message! ****Second line.
----- Buffer: foo -----

----- Echo Area -----
Type RET when done reading
----- Echo Area -----
```

## 41.9 Overlays

You can use *overlays* to alter the appearance of a buffer's text on the screen, for the sake of presentation features. An overlay is an object that belongs to a particular buffer, and has a specified beginning and end. It also has properties that you can examine and set; these affect the display of the text within the overlaid portion of the buffer.

Editing the text of the buffer adjusts the beginning and end of each overlay so that it stays with the text. When you create the overlay, you can specify whether text inserted at the beginning should be inside the overlay or outside, and likewise for the end of the overlay.

### 41.9.1 Managing Overlays

This section describes the functions to create, delete and move overlays, and to examine their contents. Overlay changes are not recorded in the buffer's undo list, since the overlays are not considered part of the buffer's contents.

**overlayp** *object*

[Function]

This function returns `t` if *object* is an overlay.

**make-overlay** *start end &optional buffer front-advance rear-advance* [Function]

This function creates and returns an overlay that belongs to *buffer* and ranges from *start* to *end*. Both *start* and *end* must specify buffer positions; they may be integers or markers. If *buffer* is omitted, the overlay is created in the current buffer.

An overlay whose *start* and *end* specify the same buffer position is known as *empty*. A non-empty overlay can become empty if the text between its *start* and *end* is deleted. When that happens, the overlay is by default not deleted, but you can cause it to be deleted by giving it the '*evaporate*' property (see Section 41.9.2 [Overlay Properties], page 1153).

The arguments *front-advance* and *rear-advance* specify what happens when text is inserted at the beginning (i.e., before *start*) and at the end. If they are both `nil`, the default, then the overlay extends to include any text inserted at the beginning, but not text inserted at the end. If *front-advance* is non-`nil`, text inserted at the beginning of the overlay is excluded from the overlay. If *rear-advance* is non-`nil`, text inserted at the end of the overlay is included in the overlay.

**overlay-start** *overlay*

[Function]

This function returns the position at which *overlay* starts, as an integer.

**overlay-end** *overlay*

[Function]

This function returns the position at which *overlay* ends, as an integer.

**overlay-buffer** *overlay* [Function]

This function returns the buffer that *overlay* belongs to. It returns `nil` if *overlay* has been deleted.

**delete-overlay** *overlay* [Function]

This function deletes the specified *overlay*. The overlay continues to exist as a Lisp object, and its property list is unchanged, but it ceases to be attached to the buffer it belonged to, and ceases to have any effect on display.

A deleted overlay is not permanently disconnected. You can give it a position in a buffer again by calling `move-overlay`.

**move-overlay** *overlay start end &optional buffer* [Function]

This function moves *overlay* to *buffer*, and places its bounds at *start* and *end* in that buffer. Both arguments *start* and *end* must specify buffer positions; they may be integers or markers.

If *buffer* is omitted, *overlay* stays in the same buffer it was already associated with; if *overlay* was previously deleted (and thus isn't associated with any buffer), it goes into the current buffer.

The return value is *overlay*.

This function is the only valid way to change the endpoints of an overlay.

**remove-overlays** *&optional start end name value* [Function]

This function removes all the overlays between *start* and *end* whose property *name* has the specified *value*. It can move the endpoints of the overlays in the region, or split them.

If *name* is omitted or `nil`, it means to delete all overlays in the specified region. If *start* and/or *end* are omitted or `nil`, that means the beginning and end of the buffer respectively. Therefore, (`remove-overlays`) removes all the overlays in the current buffer.

**copy-overlay** *overlay* [Function]

This function returns a copy of *overlay*. The copy has the same endpoints and properties as *overlay*. However, the text insertion type for the start of the overlay and for the end of the overlay are set to their default values.

Here are some examples:

```
;; Create an overlay.
(setq foo (make-overlay 1 10))
 ⇒ #<overlay from 1 to 10 in display.texi>
(overlay-start foo)
 ⇒ 1
```

```
(overlay-end foo)
 ⇒ 10
(overlay-buffer foo)
 ⇒ #<buffer display.texi>
;; Give it a property we can check later.
(overlay-put foo 'happy t)
 ⇒ t
;; Verify the property is present.
(overlay-get foo 'happy)
 ⇒ t
;; Move the overlay.
(move-overlay foo 5 20)
 ⇒ #<overlay from 5 to 20 in display.texi>
(overlay-start foo)
 ⇒ 5
(overlay-end foo)
 ⇒ 20
;; Delete the overlay.
(delete-overlay foo)
 ⇒ nil
;; Verify it is deleted.
foo
 ⇒ #<overlay in no buffer>
;; A deleted overlay has no position.
(overlay-start foo)
 ⇒ nil
(overlay-end foo)
 ⇒ nil
(overlay-buffer foo)
 ⇒ nil
;; Undelete the overlay.
(move-overlay foo 1 20)
 ⇒ #<overlay from 1 to 20 in display.texi>
;; Verify the results.
(overlay-start foo)
 ⇒ 1
(overlay-end foo)
 ⇒ 20
(overlay-buffer foo)
 ⇒ #<buffer display.texi>
;; Moving and deleting the overlay does not change its properties.
(overlay-get foo 'happy)
 ⇒ t
```

### 41.9.2 Overlay Properties

Overlay properties are like text properties in that the properties that alter how a character is displayed can come from either source. But in most respects they are different. See Section 33.19 [Text Properties], page 917, for comparison.

Text properties are considered a part of the text; overlays and their properties are specifically considered not to be part of the text. Thus, copying text between various buffers and strings preserves text properties, but does not try to preserve overlays. Changing a buffer's text properties marks the buffer as modified, while moving an overlay or changing its properties does not. Unlike text property changes, overlay property changes are not recorded in the buffer's undo list.

Since more than one overlay can specify a property value for the same character, Emacs lets you specify a priority value of each overlay. The priority value is used to decide which of the overlapping overlays will “win”.

These functions read and set the properties of an overlay:

**overlay-get** *overlay prop*

[Function]

This function returns the value of property *prop* recorded in *overlay*, if any. If *overlay* does not record any value for that property, but it does have a **category** property which is a symbol, that symbol's *prop* property is used. Otherwise, the value is **nil**.

**overlay-put** *overlay prop value*

[Function]

This function sets the value of property *prop* recorded in *overlay* to *value*. It returns *value*.

**overlay-properties** *overlay*

[Function]

This returns a copy of the property list of *overlay*.

See also the function **get-char-property** which checks both overlay properties and text properties for a given character. See Section 33.19.1 [Examining Properties], page 917.

Many overlay properties have special meanings; here is a table of them:

**priority** This property's value determines the priority of the overlay. If you want to specify a priority value, use either **nil** (or zero), or a positive integer, or a cons of two values. Any other value triggers undefined behavior.

The priority matters when two or more overlays cover the same character and both specify the same property with different values; the one whose **priority** value is higher overrides the other. (For the **face** property, the higher priority overlay's value does not completely override the other value; instead, its individual face attributes override the corresponding face attributes of the **face** property whose priority is lower.) If two overlays have the same priority value, and one is “nested” in the other (i.e., covers fewer buffer or string positions), then the inner one will prevail over the outer one. If neither is nested in the other then you should not make assumptions about which overlay will prevail.

When a Lisp program puts overlays with defined priorities on text that might have overlays without priorities, this could cause undesirable results, because any overlay with a positive priority value will override all the overlays without a priority. Since most Emacs features that use overlays don't specify priorities

for their overlays, integer priorities should be used with care. Instead of using integer priorities and risk overriding other overlays, you can use priority values of the form `(primary . secondary)`, where the *primary* value is used as described above, and *secondary* is the fallback value used when *primary* and the nesting considerations fail to resolve the precedence between overlays. In particular, priority value `(nil . n)`, with *n* a positive integer, allows to have the overlays ordered by priority when necessary without completely overriding other overlays.

Currently, all overlays take priority over text properties.

If you need to put overlays in priority order, use the *sorted* argument of `overlays-at`. See Section 41.9.3 [Finding Overlays], page 1157.

|                         |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
|-------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>window</code>     | If the <code>window</code> property is non- <code>nil</code> , then the overlay applies only on that window.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| <code>category</code>   | If an overlay has a <code>category</code> property, we call it the <code>category</code> of the overlay. It should be a symbol. The properties of the symbol serve as defaults for the properties of the overlay.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| <code>face</code>       | This property controls the appearance of the text (see Section 41.12 [Faces], page 1164). The value of the property can be the following: <ul style="list-style-type: none"> <li>• A face name (a symbol or string).</li> <li>• An anonymous face: a property list of the form <code>(keyword value ...)</code>, where each <code>keyword</code> is a face attribute name and <code>value</code> is a value for that attribute.</li> <li>• A list of faces. Each list element should be either a face name or an anonymous face. This specifies a face which is an aggregate of the attributes of each of the listed faces. Faces occurring earlier in the list have higher priority.</li> <li>• A cons cell of the form <code>(foreground-color . color-name)</code> or <code>(background-color . color-name)</code>. This specifies the foreground or background color, similar to <code>(:foreground color-name)</code> or <code>(:background color-name)</code>. This form is supported for backward compatibility only, and should be avoided.</li> </ul> |
| <code>mouse-face</code> | This property is used instead of <code>face</code> when the mouse is within the range of the overlay. However, Emacs ignores all face attributes from this property that alter the text size (e.g., <code>:height</code> , <code>:weight</code> , and <code>:slant</code> ); those attributes are always the same as in the unhighlighted text.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| <code>display</code>    | This property activates various features that change the way text is displayed. For example, it can make text appear taller or shorter, higher or lower, wider or narrower, or replaced with an image. See Section 41.16 [Display Property], page 1198.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| <code>help-echo</code>  | If an overlay has a <code>help-echo</code> property, then when you move the mouse onto the text in the overlay, Emacs displays a help string in the echo area, or as a tooltip. For details see [Text help-echo], page 926.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |

**field** Consecutive characters with the same **field** property constitute a *field*. Some motion functions including **forward-word** and **beginning-of-line** stop moving at a field boundary. See Section 33.19.9 [Fields], page 936.

#### **modification-hooks**

This property's value is a list of functions to be called if any character within the overlay is changed or if text is inserted strictly within the overlay.

The hook functions are called both before and after each change. If the functions save the information they receive, and compare notes between calls, they can determine exactly what change has been made in the buffer text.

When called before a change, each function receives four arguments: the overlay, **nil**, and the beginning and end of the text range to be modified.

When called after a change, each function receives five arguments: the overlay, **t**, the beginning and end of the text range just modified, and the length of the pre-change text replaced by that range. (For an insertion, the pre-change length is zero; for a deletion, that length is the number of characters deleted, and the post-change beginning and end are equal.)

When these functions are called, **inhibit-modification-hooks** is bound to **non-nil**. If the functions modify the buffer, you might want to bind **inhibit-modification-hooks** to **nil**, so as to cause the change hooks to run for these modifications. However, doing this may call your own change hook recursively, so be sure to prepare for that. See Section 33.34 [Change Hooks], page 961.

Text properties also support the **modification-hooks** property, but the details are somewhat different (see Section 33.19.4 [Special Properties], page 924).

#### **insert-in-front-hooks**

This property's value is a list of functions to be called before and after inserting text right at the beginning of the overlay. The calling conventions are the same as for the **modification-hooks** functions.

#### **insert-behind-hooks**

This property's value is a list of functions to be called before and after inserting text right at the end of the overlay. The calling conventions are the same as for the **modification-hooks** functions.

#### **invisible**

The **invisible** property can make the text in the overlay invisible, which means that it does not appear on the screen. See Section 41.6 [Invisible Text], page 1142, for details.

#### **intangible**

The **intangible** property on an overlay works just like the **intangible** text property. It is obsolete. See Section 33.19.4 [Special Properties], page 924, for details.

#### **isearch-open-invisible**

This property tells incremental search (see Section “Incremental Search” in *The GNU Emacs Manual*) how to make an invisible overlay visible, permanently, if the final match overlaps it. See Section 41.6 [Invisible Text], page 1142.

**isearch-open-invisible-temporary**

This property tells incremental search how to make an invisible overlay visible, temporarily, during the search. See Section 41.6 [Invisible Text], page 1142.

**before-string**

This property's value is a string to add to the display at the beginning of the overlay. The string does not appear in the buffer in any sense—only on the screen. Note that if the text at the beginning of the overlay is made invisible, the string will not be displayed.

**after-string**

This property's value is a string to add to the display at the end of the overlay. The string does not appear in the buffer in any sense—only on the screen. Note that if the text at the end of the overlay is made invisible, the string will not be displayed.

**line-prefix**

This property specifies a display spec to prepend to each non-continuation line at display-time. See Section 41.3 [Truncation], page 1130.

**wrap-prefix**

This property specifies a display spec to prepend to each continuation line at display-time. See Section 41.3 [Truncation], page 1130.

**evaporate**

If this property is `non-nil`, the overlay is deleted automatically if it becomes empty (i.e., if its length becomes zero). If you give an empty overlay (see Section 41.9.1 [Managing Overlays], page 1150) a `non-nil` `evaporate` property, that deletes it immediately. Note that, unless an overlay has this property, it will not be deleted when the text between its starting and ending positions is deleted from the buffer.

**keymap**

If this property is `non-nil`, it specifies a keymap for a portion of the text. This keymap takes precedence over most other keymaps (see Section 23.7 [Active Keymaps], page 489), and it is used when point is within the overlay, where the front- and rear-advance properties define whether the boundaries are considered as being *within* or not.

**local-map**

The `local-map` property is similar to `keymap` but replaces the buffer's local map rather than augmenting existing keymaps. This also means it has lower precedence than minor mode keymaps.

The `keymap` and `local-map` properties do not affect a string displayed by the `before-string`, `after-string`, or `display` properties. This is only relevant for mouse clicks and other mouse events that fall on the string, since point is never on the string. To bind special mouse events for the string, assign it a `keymap` or `local-map` text property. See Section 33.19.4 [Special Properties], page 924.

### 41.9.3 Searching for Overlays

**overlays-at pos &optional sorted** [Function]

This function returns a list of all the overlays that cover the character at position *pos* in the current buffer. If *sorted* is non-*nil*, the list is in decreasing order of priority, otherwise it is in no particular order. An overlay contains position *pos* if it begins at or before *pos*, and ends after *pos*.

To illustrate usage, here is a Lisp function that returns a list of the overlays that specify property *prop* for the character at point:

```
(defun find-overlays-specifying (prop)
 (let ((overlays (overlays-at (point)))
 found)
 (while overlays
 (let ((overlay (car overlays)))
 (if (overlay-get overlay prop)
 (setq found (cons overlay found))))
 (setq overlays (cdr overlays)))
 found))
```

**overlays-in beg end** [Function]

This function returns a list of the overlays that overlap the region *beg* through *end*. An overlay overlaps with a region if it contains one or more characters in the region; empty overlays (see Section 41.9.1 [Managing Overlays], page 1150) overlap if they are at *beg*, strictly between *beg* and *end*, or at *end* when *end* denotes the position at the end of the accessible part of the buffer.

**next-overlay-change pos** [Function]

This function returns the buffer position of the next beginning or end of an overlay, after *pos*. If there is none, it returns (*point-max*).

**previous-overlay-change pos** [Function]

This function returns the buffer position of the previous beginning or end of an overlay, before *pos*. If there is none, it returns (*point-min*).

As an example, here's a simplified (and inefficient) version of the primitive function **next-single-char-property-change** (see Section 33.19.3 [Property Search], page 921). It searches forward from position *pos* for the next position where the value of a given property *prop*, as obtained from either overlays or text properties, changes.

```
(defun next-single-char-property-change (position prop)
 (save-excursion
 (goto-char position)
 (let ((propval (get-char-property (point) prop)))
 (while (and (not (eobp))
 (eq (get-char-property (point) prop) propval))
 (goto-char (min (next-overlay-change (point))
 (next-single-property-change (point) prop)))))
 (point))))
```

## 41.10 Size of Displayed Text

Since not all characters have the same width, these functions let you check the width of a character. See Section 33.17.1 [Primitive Indent], page 910, and Section 31.2.5 [Screen Lines], page 858, for related functions.

**char-width** *char* [Function]

This function returns the width in columns of the character *char*, if it were displayed in the current buffer (i.e., taking into account the buffer's display table, if any; see Section 41.23.2 [Display Tables], page 1243). The width of a tab character is usually **tab-width** (see Section 41.23.1 [Usual Display], page 1242).

**char-uppercase-p** *char* [Function]

Return non-**nil** if *char* is an uppercase character according to Unicode.

**string-width** *string* &**optional** *from* *to* [Function]

This function returns the width in columns of the string *string*, if it were displayed in the current buffer and the selected window. Optional arguments *from* and *to* specify the substring of *string* to consider, and are interpreted as in **substring** (see Section 4.3 [Creating Strings], page 55).

The return value is an approximation: it only considers the values returned by **char-width** for the constituent characters, always takes a tab character as taking **tab-width** columns, ignores display properties and fonts, etc. For these reasons, we recommend using **window-text-pixel-size** or **string-pixel-width**, described below, instead.

**truncate-string-to-width** *string* *width* &**optional** *start-column* [Function]  
*padding* *ellipsis* *ellipsis-text-property*

This function returns a new string that is a truncation of *string* which fits within *width* columns on display.

If *string* is narrower than *width*, the result is equal to *string*; otherwise excess characters are omitted from the result. If a multi-column character in *string* exceeds the goal *width*, that character is omitted from the result. Thus, the result can sometimes fall short of *width*, but cannot go beyond it.

The optional argument *start-column* specifies the starting column; it defaults to zero. If this is non-**nil**, then the first *start-column* columns of the string are omitted from the result. If one multi-column character in *string* extends across the column *start-column*, that character is omitted.

The optional argument *padding*, if non-**nil**, is a padding character added at the beginning and end of the result string, to extend it to exactly *width* columns. The padding character is appended at the end of the result if it falls short of *width*, as many times as needed to reach *width*. It is also prepended at the beginning of the result if a multi-column character in *string* extends across the column *start-column*.

If *ellipsis* is non-**nil**, it should be a string which will replace the end of *string* when it is truncated. In this case, more characters will be removed from *string* to free enough space for *ellipsis* to fit within *width* columns. However, if the display width of *string* is less than the display width of *ellipsis*, *ellipsis* will not be appended to the result. If *ellipsis* is non-**nil** and not a string, it stands for the value returned by the function **truncate-string-ellipsis**, described below.

The optional argument *ellipsis-text-property*, if non-**nil**, means hide the excess parts of *string* with a **display** text property (see Section 41.16 [Display Property], page 1198) showing the ellipsis, instead of actually truncating the string.

```
(truncate-string-to-width "\tab\t" 12 4)
 ⇒ "ab"
(truncate-string-to-width "\tab\t" 12 4 ?\s)
 ⇒ " ab "
```

This function uses `string-width` and `char-width` to find the suitable truncation point when `string` is too wide, so it suffers from the same basic issues as `string-width` does. In particular, when character composition happens within `string`, the display width of a string could be smaller than the sum of widths of the constituent characters, and this function might return inaccurate results.

**truncate-string-ellipsis**

[Function]

This function returns the string to be used as an ellipses in `truncate-string-to-width` and other similar contexts. The value is that of the variable `truncate-string-ellipsis`, if it's non-`nil`, the string with the single character U+2026 HORIZONTAL ELLIPSIS if that character can be displayed on the selected frame, and the string ‘...’ otherwise.

The following function returns the size in pixels of text as if it were displayed in a given window. This function is used by `fit-window-to-buffer` and `fit-frame-to-buffer` (see Section 29.5 [Resizing Windows], page 703) to make a window exactly as large as the text it contains.

**window-text-pixel-size &optional window from to x-limit y-limit**

[Function]

*mode-lines ignore-line-at-end*

This function returns the size of the text of `window`'s buffer in pixels. `window` must be a live window and defaults to the selected one. The return value is a cons of the maximum pixel-width of any text line and the maximum pixel-height of all text lines. This function exists to allow Lisp programs to adjust the dimensions of `window` to the buffer text it needs to display, and for other similar situations.

The return value can also optionally (see below) include the buffer position of the first line whose dimensions were measured.

The optional argument `from`, if non-`nil`, specifies the first text position to consider, and defaults to the minimum accessible position of the buffer. If `from` is `t`, it stands for the minimum accessible position that is not a newline character. If `from` is a cons, its `car` specifies a buffer position, and its `cdr` specifies the vertical offset in pixels from that position to the first screen line whose text is to be measured. (The measurement will start from the visual beginning of that screen line.) In that case, the return value will instead be a list of the pixel-width, pixel-height, and the buffer position of the first line that was measured. The optional argument `to`, if non-`nil`, specifies the last text position to consider, and defaults to the maximum accessible position of the buffer. If `to` is `t`, it stands for the maximum accessible position that is not a newline character.

The optional argument `x-limit`, if non-`nil`, specifies the maximum X coordinate beyond which text should be ignored; it is therefore also the largest value of pixel-width that the function can return. If `x-limit nil` or omitted, it means to use the pixel-width of `window`'s body (see Section 29.4 [Window Sizes], page 699); this default means that text of truncated lines wider than the window will be ignored. This default is useful when the caller does not intend to change the width of `window`. Otherwise, the caller

should specify here the maximum width *window*'s body may assume; in particular, if truncated lines are expected and their text needs to be accounted for, *x-limit* should be set to a large value. Since calculating the width of long lines can take some time, it's always a good idea to make this argument as small as needed; in particular, if the buffer might contain long lines that will be truncated anyway.

The optional argument *y-limit*, if non-*nil*, specifies the maximum Y coordinate beyond which text is to be ignored; it is therefore also the maximum pixel-height that the function can return. If *y-limit* is *nil* or omitted, it means to consider all the lines of text till the buffer position specified by *to*. Since calculating the pixel-height of a large buffer can take some time, it makes sense to specify this argument; in particular, if the caller does not know the size of the buffer.

The optional argument *mode-lines* *nil* or omitted means to not include the height of the mode-, tab- or header-line of *window* in the return value. If it is either the symbol **mode-line**, **tab-line** or **header-line**, include only the height of that line, if present, in the return value. If it is **t**, include the height of all of these lines, if present, in the return value.

The optional argument *ignore-line-at-end* controls whether or not to count the height of text in *to*'s screen line as part of the returned pixel-height. This is useful if your Lisp program is only interested in the dimensions of text up to and excluding the visual beginning of *to*'s screen line.

**window-text-pixel-size** treats the text displayed in a window as a whole and does not care about the size of individual lines. The following function does.

**window-lines-pixel-dimensions** &**optional** *window first last body* [Function]  
*inverse left*

This function calculates the pixel dimensions of each line displayed in the specified *window*. It does so by walking *window*'s current glyph matrix—a matrix storing the glyph (see Section 41.23.4 [Glyphs], page 1245) of each buffer character currently displayed in *window*. If successful, it returns a list of cons pairs representing the x- and y-coordinates of the lower right corner of the last character of each line. Coordinates are measured in pixels from an origin (0, 0) at the top-left corner of *window*. *window* must be a live window and defaults to the selected one.

If the optional argument *first* is an integer, it denotes the index (starting with 0) of the first line of *window*'s glyph matrix to be returned. Note that if *window* has a header line, the line with index 0 is that header line. If *first* is *nil*, the first line to be considered is determined by the value of the optional argument *body*: If *body* is non-*nil*, this means to start with the first line of *window*'s body, skipping any header line, if present. Otherwise, this function will start with the first line of *window*'s glyph matrix, possibly the header line.

If the optional argument *last* is an integer, it denotes the index of the last line of *window*'s glyph matrix that shall be returned. If *last* is *nil*, the last line to be considered is determined by the value of *body*: If *body* is non-*nil*, this means to use the last line of *window*'s body, omitting *window*'s mode line, if present. Otherwise, this means to use the last line of *window* which may be the mode line.

The optional argument *inverse*, if *nil*, means that the y-pixel value returned for any line specifies the distance in pixels from the left edge (body edge if *body* is non-*nil*)

of *window* to the right edge of the last glyph of that line. *inverse non-nil* means that the y-pixel value returned for any line specifies the distance in pixels from the right edge of the last glyph of that line to the right edge (body edge if *body* is non-*nil*) of *window*. This is useful for determining the amount of slack space at the end of each line.

The optional argument *left*, if non-*nil* means to return the x- and y-coordinates of the lower left corner of the leftmost character on each line. This is the value that should be used for windows that mostly display text from right to left.

If *left* is non-*nil* and *inverse* is *nil*, this means that the y-pixel value returned for any line specifies the distance in pixels from the left edge of the last (leftmost) glyph of that line to the right edge (body edge if *body* is non-*nil*) of *window*. If *left* and *inverse* are both non-*nil*, the y-pixel value returned for any line specifies the distance in pixels from the left edge (body edge if *body* is non-*nil*) of *window* to the left edge of the last (leftmost) glyph of that line.

This function returns *nil* if the current glyph matrix of *window* is not up-to-date which usually happens when Emacs is busy, for example, when processing a command. The value should be retrievable though when this function is run from an idle timer with a delay of zero seconds.

**buffer-text-pixel-size** &optional *buffer-or-name* *window* *from* *to* [Function]  
*x-limit* *y-limit*

This is much like *window-text-pixel-size*, but can be used when the buffer isn't shown in a window. (*window-text-pixel-size* is faster when it is, so this function shouldn't be used in that case.)

*buffer-or-name* must specify a live buffer or the name of a live buffer and defaults to the current buffer. *window* must be a live window and defaults to the selected one; the function will compute the text dimensions as if *buffer* is displayed in *window*. The return value is a cons of the maximum pixel-width of any text line and the pixel-height of all the text lines of the buffer specified by *buffer-or-name*.

The optional arguments *x-limit* and *y-limit* have the same meaning as with *window-text-pixel-size*.

**string-pixel-width** *string* [Function]

This is a convenience function that uses *window-text-pixel-size* to compute the width of *string* (in pixels).

**line-pixel-height** [Function]

This function returns the height in pixels of the line at point in the selected window. The value includes the line spacing of the line (see Section 41.11 [Line Height], page 1162).

**string-glyph-split** *string* [Function]

When character compositions are in effect, sequence of characters can be composed for display to form *grapheme clusters*, for example to display accented characters, or ligatures, or Emoji, or when complex text shaping requires that for some scripts. When that happens, characters no longer map in a simple way to display columns, and display layout decisions with such strings, such as truncating too wide strings, can be a complex job. This function helps in performing such jobs: it splits up its argument

*string* into a list of substrings, where each substring produces a single grapheme cluster that should be displayed as a unit. Lisp programs can then use this list to construct visually-valid substrings of *string* which will look correctly on display, or compute the width of any substring of *string* by adding the width of its constituents in the returned list, etc.

For instance, if you want to display a string without the first glyph, you can say:

```
(apply #'insert (cdr (string-glyph-split string))))
```

When a buffer is displayed with line numbers (see Section “Display Custom” in *The GNU Emacs Manual*), it is sometimes useful to know the width taken for displaying the line numbers. The following function is for Lisp programs which need this information for layout calculations.

**line-number-display-width** &optional *pixelwise* [Function]

This function returns the width used for displaying the line numbers in the selected window. If the optional argument *pixelwise* is the symbol `columns`, the return value is a float number of the frame’s canonical columns; if *pixelwise* is `t` or any other non-`nil` value, the value is an integer and is measured in pixels. If *pixelwise* is omitted or `nil`, the value is the integer number of columns of the font defined for the `line-number` face, and doesn’t include the 2 columns used to pad the numbers on display. If line numbers are not displayed in the selected window, the value is zero regardless of the value of *pixelwise*. Use `with-selected-window` (see Section 29.3 [Selecting Windows], page 696) if you need this information about another window.

## 41.11 Line Height

The total height of each display line consists of the height of the contents of the line, plus optional additional vertical line spacing above or below the display line.

The height of the line contents is the maximum height of any character or image on that display line, including the final newline if there is one. (A display line that is continued doesn’t include a final newline.) That is the default line height, if you do nothing to specify a greater height. (In the most common case, this equals the height of the corresponding frame’s default font, see Section 30.3.2 [Frame Font], page 797.)

There are several ways to explicitly specify a larger line height, either by specifying an absolute height for the display line, or by specifying vertical space. However, no matter what you specify, the actual line height can never be less than the default.

A newline can have a `line-height` text or overlay property that controls the total height of the display line ending in that newline. The property value can be one of several forms:

`t` If the property value is `t`, the newline character has no effect on the displayed height of the line—the visible contents alone determine the height. The `line-spacing` property of the newline, described below, is also ignored in this case. This is useful for tiling small images (or image slices) without adding blank areas between the images.

`(height total)`

If the property value is a list of the form shown, that adds extra space *below* the display line. First Emacs uses `height` as a height spec to control extra space

*above* the line; then it adds enough space *below* the line to bring the total line height up to *total*. In this case, any value of `line-spacing` property for the newline is ignored.

Any other kind of property value is a height spec, which translates into a number—the specified line height. There are several ways to write a height spec; here's how each of them translates into a number:

**integer** If the height spec is a positive integer, the height value is that integer.

**float** If the height spec is a float, *float*, the numeric height value is *float* times the frame's default line height.

**(face . ratio)**

If the height spec is a cons of the format shown, the numeric height is *ratio* times the height of face *face*. *ratio* can be any type of number, or `nil` which means a ratio of 1. If *face* is `t`, it refers to the current face.

**(nil . ratio)**

If the height spec is a cons of the format shown, the numeric height is *ratio* times the height of the contents of the line.

Thus, any valid height spec determines the height in pixels, one way or another. If the line contents' height is less than that, Emacs adds extra vertical space above the line to achieve the specified total height.

If you don't specify the `line-height` property, the line's height consists of the contents' height plus the line spacing. There are several ways to specify the line spacing for different parts of Emacs text.

On graphical terminals, you can specify the line spacing for all lines in a frame, using the `line-spacing` frame parameter (see Section 30.4.3.4 [Layout Parameters], page 810). However, if the default value of `line-spacing` is non-`nil`, it overrides the frame's `line-spacing` parameter. An integer specifies the number of pixels put below lines. A floating-point number specifies the spacing relative to the frame's default line height.

You can specify the line spacing for all lines in a buffer via the buffer-local `line-spacing` variable. An integer specifies the number of pixels put below lines. A floating-point number specifies the spacing relative to the default frame line height. This overrides line spacings specified for the frame.

Finally, a newline can have a `line-spacing` text or overlay property that can enlarge the default frame line spacing and the buffer local `line-spacing` variable: if its value is larger than the buffer or frame defaults, that larger value is used instead, for the display line ending in that newline (unless the newline also has the `line-height` property whose value is one of the special values which cause `line-spacing` to be ignored, see above).

One way or another, these mechanisms specify a Lisp value for the spacing of each line. The value is a height spec, and it translates into a Lisp value as described above. However, in this case the numeric height value specifies the line spacing, rather than the line height.

On text terminals, the line spacing cannot be altered.

## 41.12 Faces

A *face* is a collection of graphical attributes for displaying text: font, foreground color, background color, optional underlining, etc. Faces control how Emacs displays text in buffers, as well as other parts of the frame such as the mode line.

One way to represent a face is as a property list of attributes, like `(:foreground "red" :weight bold)`. Such a list is called an *anonymous face*. For example, you can assign an anonymous face as the value of the `face` text property, and Emacs will display the underlying text with the specified attributes. See Section 33.19.4 [Special Properties], page 924.

More commonly, a face is referred to via a *face name*: a Lisp symbol associated with a set of face attributes<sup>1</sup>. Named faces are defined using the `defface` macro (see Section 41.12.2 [Defining Faces], page 1168). Emacs comes with several standard named faces (see Section 41.12.8 [Basic Faces], page 1178).

Some parts of Emacs require named faces (e.g., the functions documented in Section 41.12.3 [Attribute Functions], page 1171). Unless otherwise stated, we will use the term *face* to refer only to named faces.

### `facep object`

[Function]

This function returns a non-`nil` value if *object* is a named face: a Lisp symbol or string which serves as a face name. Otherwise, it returns `nil`.

### 41.12.1 Face Attributes

*Face attributes* determine the visual appearance of a face. The following table lists all the face attributes, their possible values, and their effects.

Apart from the values given below, each face attribute can have the value `unspecified`. This special value means that the face doesn't specify that attribute directly. An `unspecified` attribute tells Emacs to refer instead to a parent face (see the description `:inherit` attribute below); or, failing that, to an underlying face (see Section 41.12.4 [Displaying Faces], page 1174). (However, `unspecified` is not a valid value in `defface`.)

A face attribute can also have the value `reset`. This special value stands for the value of the corresponding attribute of the `default` face.

The `default` face must explicitly specify all attributes, and cannot use the special value `reset`.

Some of these attributes are meaningful only on certain kinds of displays. If your display cannot handle a certain attribute, the attribute is ignored.

- :family** Font family name (a string). See Section “Fonts” in *The GNU Emacs Manual*, for more information about font families. The function `font-family-list` (see below) returns a list of available family names.
- :foundry** The name of the *font foundry* for the font family specified by the `:family` attribute (a string). See Section “Fonts” in *The GNU Emacs Manual*.
- :width** Relative character width. This should be one of the symbols `ultra-condensed`, `extra-condensed`, `condensed`, `semi-condensed`, `normal`, `regular`, `medium`, `semi-expanded`, `expanded`, `extra-expanded`, or `ultra-expanded`.

---

<sup>1</sup> For backward compatibility, you can also use a string to specify a face name; that is equivalent to a Lisp symbol with the same name.

- :height** The height of the font. In the simplest case, this is an integer in units of 1/10 point.  
The value can also be floating point or a function, which specifies the height relative to an *underlying face* (see Section 41.12.4 [Displaying Faces], page 1174). A floating-point value specifies the amount by which to scale the height of the underlying face. A function value is called with one argument, the height of the underlying face, and returns the height of the new face. If the function is passed an integer argument, it must return an integer.  
The height of the default face must be specified using an integer; floating point and function values are not allowed.
- :weight** Font weight—one of the symbols (from densest to faintest) **ultra-bold**, **extra-bold**, **bold**, **semi-bold**, **normal**, **semi-light**, **light**, **extra-light**, or **ultra-light**. On text terminals which support variable-brightness text, any weight greater than normal is displayed as extra bright, and any weight less than normal is displayed as half-bright.
- :slant** Font slant—one of the symbols **italic**, **oblique**, **normal**, **reverse-italic**, or **reverse-oblique**. On text terminals that support variable-brightness text, slanted text is displayed as half-bright.
- :foreground**  
Foreground color, a string. The value can be a system-defined color name, or a hexadecimal color specification. See Section 30.23 [Color Names], page 846. On black-and-white displays, certain shades of gray are implemented by stipple patterns.
- :distant-foreground**  
Alternative foreground color, a string. This is like **:foreground** but the color is only used as a foreground when the background color is near to the foreground that would have been used. This is useful for example when marking text (i.e., the region face). If the text has a foreground that is visible with the region face, that foreground is used. If the foreground is near the region face background, **:distant-foreground** is used instead so the text is readable.
- :background**  
Background color, a string. The value can be a system-defined color name, or a hexadecimal color specification. See Section 30.23 [Color Names], page 846.
- :underline**  
Whether or not characters should be underlined, and in what way. The possible values of the **:underline** attribute are:
- nil** Don't underline.
  - t** Underline with the foreground color of the face.
  - color** Underline in color *color*, a string specifying a color.
- (:color color :style style :position position)**  
*color* is either a string, or the symbol **foreground-color**, meaning the foreground color of the face. Omitting the attribute **:color**

means to use the foreground color of the face. *style* should be a symbol `line` or `wave`, meaning to use a straight or wavy line. Omitting the attribute `:style` means to use a straight line. *position*, if non-`nil`, means to display the underline at the descent of the text, instead of at the baseline level. If it is a number, then it specifies the amount of pixels above the descent to display the underline.

#### `:overline`

Whether or not characters should be overlined, and in what color. If the value is `t`, overlining uses the foreground color of the face. If the value is a string, overlining uses that color. The value `nil` means do not overline.

#### `:strike-through`

Whether or not characters should be strike-through, and in what color. The value is used like that of `:overline`.

#### `:box`

Whether or not a box should be drawn around characters, its color, the width of the box lines, and 3D appearance. Here are the possible values of the `:box` attribute, and what they mean:

`nil`      Don't draw a box.

`t`      Draw a box with lines of width 1, in the foreground color.

`color`      Draw a box with lines of width 1, in color *color*.

`(:line-width (vwidth . hwidth) :color color :style style)`

You can explicitly specify all aspects of the box with a plist on this form. Any element in this plist can be omitted.

The values of *vwidth* and *hwidth* specify respectively the width of the vertical and horizontal lines to draw; they default to `(1 . 1)`. A negative horizontal or vertical width `-n` means to draw a line of width *n* that occupies the space of the underlying text, thus avoiding any increase in the character height or width. For simplification the width could be specified with only a single number *n* instead of a list, such case is equivalent to `((abs n) . n)`.

The value of *color* specifies the color to draw with. The default is the background color of the face for 3D boxes and `flat-button`, and the foreground color of the face for other boxes.

The value of *style* specifies whether to draw a 3D box. If it is `released-button`, the box looks like a 3D button that is not being pressed. If it is `pressed-button`, the box looks like a 3D button that is being pressed. If it is `nil`, `flat-button` or omitted, a plain 2D box is used.

If you use the `:box` face attribute on strings displayed instead of buffer text via the `display` text property, special considerations might apply if the surrounding buffer text also has the `:box` face attribute. See Section 41.16.1 [Replacing Specs], page 1199.

**:inverse-video**

Whether or not characters should be displayed in inverse video. The value should be `t` (yes) or `nil` (no).

**:stipple** The background stipple, a bitmap.

The value can be a string; that should be the name of a file containing external-format X bitmap data. The file is found in the directories listed in the variable `x-bitmap-file-path`.

Alternatively, the value can specify the bitmap directly, with a list of the form `(width height data)`. Here, `width` and `height` specify the size in pixels, and `data` is a string containing the raw bits of the bitmap, row by row. Each row occupies  $(width+7)/8$  consecutive bytes in the string (which should be a unibyte string for best results). This means that each row always occupies at least one whole byte.

If the value is `nil`, that means use no stipple pattern.

Normally you do not need to set the stipple attribute, because it is used automatically to handle certain shades of gray.

**:font**

The font used to display the face. Its value should be a font object or a fontset. If it is a font object, it specifies the font to be used by the face for displaying ASCII characters. See Section 41.12.12 [Low-Level Font], page 1184, for information about font objects, font specs, and font entities. See Section 41.12.11 [Fontsets], page 1182, for information about fontsets.

When specifying this attribute using `set-face-attribute` or `set-face-font` (see Section 41.12.3 [Attribute Functions], page 1171), you may also supply a font spec, a font entity, or a string. Emacs converts such values to an appropriate font object, and stores that font object as the actual attribute value. If you specify a string, the contents of the string should be a font name (see Section “Fonts” in *The GNU Emacs Manual*); if the font name is an XLFD containing wildcards, Emacs chooses the first font matching those wildcards. Specifying this attribute also changes the values of the `:family`, `:foundry`, `:width`, `:height`, `:weight`, and `:slant` attributes.

**:inherit**

The name of a face from which to inherit attributes, or a list of face names. Attributes from inherited faces are merged into the face like an underlying face would be, with higher priority than underlying faces (see Section 41.12.4 [Displaying Faces], page 1174). If the face to inherit from is `unspecified`, it is treated the same as `nil`, since Emacs never merges `:inherit` attributes. If a list of faces is used, attributes from faces earlier in the list override those from later faces.

**:extend**

Whether or not this face will be extended beyond end of line and will affect the display of the empty space between the end of line and the edge of the window. The value should be `t` to display the empty space between end of line and edge of the window using this face, or `nil` to not use this face for the space between the end of the line and the edge of the window. When Emacs merges several faces for displaying the empty space beyond end of line, only those faces with `:extend` non-`nil` will be merged. By default, only a small number of faces,

notably, `region`, have this attribute set. This attribute is different from the others in that when a theme doesn't specify an explicit value for a face, the value from the original face definition by `defface` is inherited (see Section 41.12.2 [Defining Faces], page 1168).

Some modes, like `hl-line-mode`, use a face with an `:extend` property to mark the entire current line. Note, however, that Emacs will always allow you to move point after the final character in a buffer, and if the buffer ends with a newline character, point can be placed on what is seemingly a line at the end of the buffer—but Emacs can't highlight that “line”, because it doesn't really exist.

#### `font-family-list` &optional `frame`

[Function]

This function returns a list of available font family names. The optional argument `frame` specifies the frame on which the text is to be displayed; if it is `nil`, the selected frame is used.

#### `underline-minimum-offset`

[User Option]

This variable specifies the minimum distance between the baseline and the underline, in pixels, when displaying underlined text.

#### `x-bitmap-file-path`

[User Option]

This variable specifies a list of directories for searching for bitmap files, for the `:stipple` attribute.

#### `bitmap-spec-p` *object*

[Function]

This returns `t` if *object* is a valid bitmap specification, suitable for use with `:stipple` (see above). It returns `nil` otherwise.

## 41.12.2 Defining Faces

The usual way to define a face is through the `defface` macro. This macro associates a face name (a symbol) with a default *face spec*. A face spec is a construct which specifies what attributes a face should have on any given terminal; for example, a face spec might specify one foreground color on high-color terminals, and a different foreground color on low-color terminals.

People are sometimes tempted to create a variable whose value is a face name. In the vast majority of cases, this is not necessary; the usual procedure is to define a face with `defface`, and then use its name directly.

Note that once you have defined a face (usually with `defface`), you cannot later undefine this face safely, except by restarting Emacs.

#### `defface` *face spec doc* [keyword value]...

[Macro]

This macro declares *face* as a named face whose default face spec is given by *spec*. You should not quote the symbol *face*, and it should not end in ‘`-face`’ (that would be redundant). The argument *doc* is a documentation string for the face. The additional keyword arguments have the same meanings as in `defgroup` and `defcustom` (see Section 15.1 [Common Keywords], page 277).

If *face* already has a default face spec, this macro does nothing.

The default face spec determines *face*'s appearance when no customizations are in effect (see Chapter 15 [Customization], page 277). If *face* has already been customized (via Custom themes or via customizations read from the init file), its appearance is determined by the custom face spec(s), which override the default face spec *spec*. However, if the customizations are subsequently removed, the appearance of *face* will again be determined by its default face spec.

As an exception, if you evaluate a `defface` form with *C-M-x (eval-defun)* or with *C-x C-e (eval-last-sexp)* in Emacs Lisp mode, a special feature of these commands overrides any custom face specs on the face, causing the face to reflect exactly what the `defface` says.

The *spec* argument is a *face spec*, which states how the face should appear on different kinds of terminals. It should be an alist whose elements each have the form

`(display . plist)`

*display* specifies a class of terminals (see below). *plist* is a property list of face attributes and their values, specifying how the face appears on such terminals. For backward compatibility, you can also write an element as `(display plist)`.

The *display* part of an element of *spec* determines which terminals the element matches. If more than one element of *spec* matches a given terminal, the first element that matches is the one used for that terminal. There are three possibilities for *display*:

**default** This element of *spec* doesn't match any terminal; instead, it specifies defaults that apply to all terminals. This element, if used, must be the first element of *spec*. Each of the following elements can override any or all of these defaults.

**t** This element of *spec* matches all terminals. Therefore, any subsequent elements of *spec* are never used. Normally **t** is used in the last (or only) element of *spec*.

**a list** If *display* is a list, each element should have the form `(characteristic value...)`. Here *characteristic* specifies a way of classifying terminals, and the *values* are possible classifications which *display* should apply to. Here are the possible values of *characteristic*:

**type** The kind of window system the terminal uses—either `graphic` (any graphics-capable display), `x`, `pc` (for the MS-DOS console), `w32` (for MS Windows 9X/NT/2K/XP), `haiku` (for Haiku), `pgtk` (for pure GTK), or `tty` (a non-graphics-capable display). See Section 41.25 [Window Systems], page 1248.

**class** What kinds of colors the terminal supports—either `color`, `grayscale`, or `mono`.

**background**

The kind of background—either `light` or `dark`.

**min-colors**

An integer that represents the minimum number of colors the terminal should support. This matches a terminal if its `display-color-cells` value is at least the specified integer.

**supports** Whether or not the terminal can display the face attributes given in *value...* (see Section 41.12.1 [Face Attributes], page 1164). See [Display Face Attribute Testing], page 850, for more information on exactly how this testing is done.

If an element of *display* specifies more than one *value* for a given *characteristic*, any of those values is acceptable. If *display* has more than one element, each element should specify a different *characteristic*; then *each* characteristic of the terminal must match one of the values specified for it in *display*.

For example, here's the definition of the standard face **highlight**:

```
(defface highlight
 '(((class color) (min-colors 88) (background light))
 :background "darkseagreen2")
 (((class color) (min-colors 88) (background dark))
 :background "darkolivegreen")
 (((class color) (min-colors 16) (background light))
 :background "darkseagreen2")
 (((class color) (min-colors 16) (background dark))
 :background "darkolivegreen")
 (((class color) (min-colors 8))
 :background "green" :foreground "black")
 (t :inverse-video t))
"Basic face for highlighting."
:group 'basic-faces)
```

Internally, Emacs stores each face's default spec in its **face-defface-spec** symbol property (see Section 9.4 [Symbol Properties], page 138). The **saved-face** property stores any face spec saved by the user using the customization buffer; the **customized-face** property stores the face spec customized for the current session, but not saved; and the **theme-face** property stores an alist associating the active customization settings and Custom themes with the face specs for that face. The face's documentation string is stored in the **face-documentation** property.

Normally, a face is declared just once, using **defface**, and any further changes to its appearance are applied using the Customize framework (e.g., via the Customize user interface or via the **custom-set-faces** function; see Section 15.5 [Applying Customizations], page 294), or by face remapping (see Section 41.12.5 [Face Remapping], page 1175). In the rare event that you need to change a face spec directly from Lisp, you can use the **face-spec-set** function.

#### **face-spec-set** *face* *spec* &**optional** *spec-type*

[Function]

This function applies *spec* as a face spec for *face*. *spec* should be a face spec, as described in the above documentation for **defface**.

This function also defines *face* as a valid face name if it is not already one, and (re)calculates its attributes on existing frames.

The optional argument *spec-type* determines which spec to set. If it is omitted or **nil** or **face-override-spec**, this function sets the **override spec**, which overrides face

specs on *face* of all the other types mentioned below. This is useful when calling this function outside of Custom code. If *spec-type* is `customized-face` or `saved-face`, this function sets the customized spec or the saved custom spec, respectively. If it is `face-defface-spec`, this function sets the default face spec (the same one set by `defface`). If it is `reset`, this function clears out all customization specs and override specs from *face* (in this case, the value of *spec* is ignored). The effect of any other value of *spec-type* on the face specs is reserved for internal use, but the function will still define *face* itself and recalculate its attributes, as described above.

### 41.12.3 Face Attribute Functions

This section describes functions for directly accessing and modifying the attributes of a named face.

**face-attribute** *face* *attribute* &**optional** *frame* *inherit* [Function]

This function returns the value of the *attribute* attribute for *face* on *frame*. See Section 41.12.1 [Face Attributes], page 1164, for the supported attributes.

If *frame* is omitted or `nil`, that means the selected frame (see Section 30.10 [Input Focus], page 824). If *frame* is `t`, this function returns the value of the specified attribute for newly-created frames, i.e. the value of the attribute before applying the face spec in the face's `defface` definition (see Section 41.12.2 [Defining Faces], page 1168) or the spec set by `face-spec-set`. This default value of *attribute* is normally `unspecified`, unless you have specified some other value using `set-face-attribute`; see below.

If *inherit* is `nil`, only attributes directly defined by *face* are considered, so the return value may be `unspecified`, or a relative value. If *inherit* is non-`nil`, *face*'s definition of *attribute* is merged with the faces specified by its `:inherit` attribute; however the return value may still be `unspecified` or relative. If *inherit* is a face or a list of faces, then the result is further merged with that face (or faces), until it becomes specified and absolute.

To ensure that the return value is always specified and absolute, use a value of `default` for *inherit*; this will resolve any unspecified or relative values by merging with the `default` face (which is always completely specified).

For example,

```
(face-attribute 'bold :weight)
⇒ bold
```

**face-attribute-relative-p** *attribute* *value* [Function]

This function returns non-`nil` if *value*, when used as the value of the face attribute *attribute*, is relative. This means it would modify, rather than completely override, any value that comes from a subsequent face in the face list or that is inherited from another face.

`unspecified` is a relative value for all attributes. For `:height`, floating point and function values are also relative.

For example:

```
(face-attribute-relative-p :height 2.0)
⇒ t
```

**face-all-attributes** *face* &**optional frame** [Function]

This function returns an alist of attributes of *face*. The elements of the result are name-value pairs of the form (**attr-name** . **attr-value**). Optional argument *frame* specifies the frame whose definition of *face* to return; if omitted or **nil**, the returned value describes the default attributes of *face* for newly created frames, i.e. the values these attributes have before applying the face spec in the face's **defface** definition or the spec set by **face-spec-set**. These default values of the attributes are normally **unspecified**, unless you have specified some other value using **set-face-attribute**; see below.

**merge-face-attribute** *attribute value1 value2* [Function]

If *value1* is a relative value for the face attribute *attribute*, returns it merged with the underlying value *value2*; otherwise, if *value1* is an absolute value for the face attribute *attribute*, returns *value1* unchanged.

Normally, Emacs uses the face specs of each face to automatically calculate its attributes on each frame (see Section 41.12.2 [Defining Faces], page 1168). The function **set-face-attribute** can override this calculation by directly assigning attributes to a face, either on a specific frame or for all frames. This function is mostly intended for internal usage.

**set-face-attribute** *face frame* &**rest arguments** [Function]

This function sets one or more attributes of *face* for *frame*. The attributes specified in this way override the face spec(s) belonging to *face*. See Section 41.12.1 [Face Attributes], page 1164, for the supported attributes.

The extra arguments *arguments* specify the attributes to set, and the values for them. They should consist of alternating attribute names (such as **:family** or **:underline**) and values. Thus,

```
(set-face-attribute 'foo nil :weight 'bold :slant 'italic)
```

sets the attribute **:weight** to **bold** and the attribute **:slant** to **italic**.

If *frame* is **t**, this function sets the default attributes for newly created frames; they will effectively override the attribute values specified by **defface**. If *frame* is **nil**, this function sets the attributes for all existing frames, as well as for newly created frames.

To *reset* the value of an attribute, that is, to indicate that the face doesn't by itself specify a value for the attribute, use the special value **unspecified** (*not nil!*) for the attribute, and set the *frame* argument to **t**, in addition to the call with *frame* set to **nil**. This is because the default attributes for newly created frames are merged with the face's spec in **defface** when a new frame is created, and so having **unspecified** in the default attributes for new frames will be unable to override **defface**; the special call to this function as described above will arrange for **defface** to be overridden.

Note that the attribute-value pairs are evaluated in the order they are specified, with the exception of the **:family** and **:foundry** attributes, which are evaluated first. This means that if a certain attribute is specified more than once, only the last value will be used. It also means that in some cases a different order of attributes will produce different results. For example, when **:weight** is placed before **:font**, the weight value is applied to the current font of the face, and might be rounded to the closest available weight of that font, whereas when **:font** is placed before **:weight** the weight value is applied to the specified font.

The following commands and functions mostly provide compatibility with old versions of Emacs. They work by calling `set-face-attribute`. Values of `t` and `nil` (or omitted) for their `frame` argument are handled just like `set-face-attribute` and `face-attribute`. The commands read their arguments using the minibuffer, if called interactively.

**set-face-foreground** *face color &optional frame* [Command]  
**set-face-background** *face color &optional frame* [Command]

These set the `:foreground` attribute (or `:background` attribute, respectively) of *face* to *color*.

**set-face-stipple** *face pattern &optional frame* [Command]  
This sets the `:stipple` attribute of *face* to *pattern*.

**set-face-font** *face font &optional frame* [Command]  
Change the font-related attributes of *face* to those of *font* (a string or a font object). See [face-font-attribute], page 1167, for the supported formats of the *font* argument. This function sets the attribute `:font` of the face, and indirectly also the `:family`, `:foundry`, `:width`, `:height`, `:weight`, and `:slant` attributes, as defined by the font. If *frame* is non-`nil`, only change the attributes on the specified frame.

**set-face-bold** *face bold-p &optional frame* [Function]  
This sets the `:weight` attribute of *face* to *normal* if *bold-p* is `nil`, and to *bold* otherwise.

**set-face-italic** *face italic-p &optional frame* [Function]  
This sets the `:slant` attribute of *face* to *normal* if *italic-p* is `nil`, and to *italic* otherwise.

**set-face-underline** *face underline &optional frame* [Command]  
This sets the `:underline` attribute of *face* to *underline*.

**set-face-inverse-video** *face inverse-video-p &optional frame* [Command]  
This sets the `:inverse-video` attribute of *face* to *inverse-video-p*.

**invert-face** *face &optional frame* [Command]  
This swaps the foreground and background colors of face *face*.

**set-face-extend** *face extend &optional frame* [Command]  
This sets the `:extend` attribute of *face* to *extend*.

The following functions examine the attributes of a face. They mostly provide compatibility with old versions of Emacs. If you don't specify `frame`, they refer to the selected frame; `t` refers to the default data for new frames. They return `unspecified` if the face doesn't define any value for that attribute. If `inherit` is `nil`, only an attribute directly defined by the face is returned. If `inherit` is non-`nil`, any faces specified by its `:inherit` attribute are considered as well, and if `inherit` is a face or a list of faces, then they are also considered, until a specified attribute is found. To ensure that the return value is always specified, use a value of `default` for `inherit`.

**face-font** *face &optional frame character* [Function]

This function returns the name of the font used by the specified *face*.

If the optional argument *frame* is specified, it returns the name of the font of *face* for that frame; *frame* defaults to the selected frame if it is `nil` or omitted. If *frame* is `t`, the function reports on the font defaults for *face* to be used for new frames.

By default, the returned font is for displaying ASCII characters, but if *frame* is anything but `t`, and the optional third argument *character* is supplied, the function returns the font name used by *face* for that character.

**face-foreground** *face &optional frame inherit* [Function]

**face-background** *face &optional frame inherit* [Function]

These functions return the foreground color (or background color, respectively) of face *face*, as a string. If the color is unspecified, they return `nil`.

**face-stipple** *face &optional frame inherit* [Function]

This function returns the name of the background stipple pattern of face *face*, or `nil` if it doesn't have one.

**face-bold-p** *face &optional frame inherit* [Function]

This function returns a non-`nil` value if the `:weight` attribute of *face* is bolder than normal (i.e., one of `semi-bold`, `bold`, `extra-bold`, or `ultra-bold`). Otherwise, it returns `nil`.

**face-italic-p** *face &optional frame inherit* [Function]

This function returns a non-`nil` value if the `:slant` attribute of *face* is `italic` or `oblique`, and `nil` otherwise.

**face-underline-p** *face &optional frame inherit* [Function]

This function returns non-`nil` if face *face* specifies a non-`nil` `:underline` attribute.

**face-inverse-video-p** *face &optional frame inherit* [Function]

This function returns non-`nil` if face *face* specifies a non-`nil` `:inverse-video` attribute.

**face-extend-p** *face &optional frame inherit* [Function]

This function returns non-`nil` if face *face* specifies a non-`nil` `:extend` attribute. The *inherit* argument is passed to `face-attribute`.

#### 41.12.4 Displaying Faces

When Emacs displays a given piece of text, the visual appearance of the text may be determined by faces drawn from different sources. If these various sources together specify more than one face for a particular character, Emacs merges the attributes of the various faces. Here is the order in which Emacs merges the faces, from highest to lowest priority:

- If the text consists of a special glyph, the glyph can specify a particular face. See Section 41.23.4 [Glyphs], page 1245.
- If the text lies within an active region, Emacs highlights it using the `region` face. See Section “Standard Faces” in *The GNU Emacs Manual*.

- If the text lies within an overlay with a non-nil `face` property, Emacs applies the face(s) specified by that property. If the overlay has a `mouse-face` property and the mouse is near enough to the overlay, Emacs applies the face or face attributes specified by the `mouse-face` property instead. See Section 41.9.2 [Overlay Properties], page 1153. When multiple overlays cover the same character, an overlay with higher priority overrides those with lower priority. See Section 41.9 [Overlays], page 1150.
- If the text contains a `face` or `mouse-face` property, Emacs applies the specified faces and face attributes. See Section 33.19.4 [Special Properties], page 924. (This is how Font Lock mode faces are applied. See Section 24.6 [Font Lock Mode], page 563.)
- If the text lies within the mode line of the selected window, Emacs applies the `mode-line` face. For the mode line of a non-selected window, Emacs applies the `mode-line-inactive` face. For a header line, Emacs applies the `header-line` face. For a tab line, Emacs applies the `tab-line` face.
- If the text comes from an overlay string via `before-string` or `after-string` properties (see Section 41.9.2 [Overlay Properties], page 1153), or from a display string (see Section 41.16.4 [Other Display Specs], page 1203), and the string doesn't contain a `face` or `mouse-face` property, or these properties leave some face attributes undefined, but the buffer text affected by the overlay/display property does define a face or those attributes, Emacs applies the face attributes of the “underlying” buffer text. Note that this is so even if the overlay or display string is displayed in the display margins (see Section 41.16.5 [Display Margins], page 1205).
- If any given attribute has not been specified during the preceding steps, Emacs applies the attribute of the `default` face.

At each stage, if a face has a valid `:inherit` attribute, Emacs treats any attribute with an `unspecified` value as having the corresponding value drawn from the parent face(s). see Section 41.12.1 [Face Attributes], page 1164. Note that the parent face(s) may also leave the attribute unspecified; in that case, the attribute remains unspecified at the next level of face merging.

### 41.12.5 Face Remapping

The variable `face-remapping-alist` is used for buffer-local or global changes in the appearance of a face. For instance, it is used to implement the `text-scale-adjust` command (see Section “Text Scale” in *The GNU Emacs Manual*).

#### `face-remapping-alist`

[Variable]

The value of this variable is an alist whose elements have the form (`face . remapping`). This causes Emacs to display any text having the face `face` with `remapping`, rather than the ordinary definition of `face`.

`remapping` may be any face spec suitable for a `face` text property: either a face (i.e., a face name or a property list of attribute/value pairs), or a list of faces. For details, see the description of the `face` text property in Section 33.19.4 [Special Properties], page 924. `remapping` serves as the complete specification for the remapped face—it replaces the normal definition of `face`, instead of modifying it.

If `face-remapping-alist` is buffer-local, its local value takes effect only within that buffer. If `face-remapping-alist` includes faces applicable only to certain windows,

by using the `(:filtered (:window param val) spec)`, that face takes effect only in windows that match the filter conditions (see Section 33.19.4 [Special Properties], page 924). To turn off face filtering temporarily, bind `face-filters-always-match` to a non-`nil` value, then all face filters will match any window.

Note: face remapping is non-recursive. If `remapping` references the same face name `face`, either directly or via the `:inherit` attribute of some other face in `remapping`, that reference uses the normal definition of `face`. For instance, if the `mode-line` face is remapped using this entry in `face-remapping-alist`:

```
(mode-line italic mode-line)
```

then the new definition of the `mode-line` face inherits from the `italic` face, and the *normal* (non-remapped) definition of `mode-line` face.

The following functions implement a higher-level interface to `face-remapping-alist`. Most Lisp code should use these functions instead of setting `face-remapping-alist` directly, to avoid trampling on remappings applied elsewhere. These functions are intended for buffer-local remappings, so they all make `face-remapping-alist` buffer-local as a side-effect. They manage `face-remapping-alist` entries of the form

```
(face relative-spec-1 relative-spec-2 ... base-spec)
```

where, as explained above, each of the `relative-spec-N` and `base-spec` is either a face name, or a property list of attribute/value pairs. Each of the `relative` remapping entries, `relative-spec-N`, is managed by the `face-remap-add-relative` and `face-remap-remove-relative` functions; these are intended for simple modifications like changing the text size. The `base` remapping entry, `base-spec`, has the lowest priority and is managed by the `face-remap-set-base` and `face-remap-reset-base` functions; it is intended for major modes to remap faces in the buffers they control.

#### `face-remap-add-relative face &rest specs`

[Function]

This function adds `specs` as relative remappings for face `face` in the current buffer. `specs` should be a list where each element is either a face name, or a property list of attribute/value pairs.

The return value is a Lisp object that serves as a cookie; you can pass this object as an argument to `face-remap-remove-relative` if you need to remove the remapping later.

```
; ; Remap the 'escape-glyph' face into a combination
; ; of the 'highlight' and 'italic' faces:
(face-remap-add-relative 'escape-glyph 'highlight 'italic)

; ; Increase the size of the 'default' face by 50%:
(face-remap-add-relative 'default :height 1.5)
```

Note that buffer-local face remapping does not work reliably for parent faces of basic faces (see Section 41.12.8 [Basic Faces], page 1178). (These are the faces that are used in mode lines, header lines, and other basic decorations of windows and frames.) For instance, `mode-line-inactive` inherits from `mode-line`, but remapping `mode-line` won't normally have the desired effect on `mode-line-inactive`, especially if done locally for some buffers. Instead you have to remap `mode-line-inactive` directly.

**face-remap-remove-relative cookie** [Function]

This function removes a relative remapping previously added by `face-remap-add-relative`. `cookie` should be the Lisp object returned by `face-remap-add-relative` when the remapping was added.

**face-remap-set-base face &rest specs** [Function]

This function sets the base remapping of `face` in the current buffer to `specs`. If `specs` is empty, the default base remapping is restored, similar to calling `face-remap-reset-base` (see below); note that this is different from `specs` containing a single value `nil`, which has the opposite result (the global definition of `face` is ignored).

This overwrites the default `base-spec`, which inherits the global face definition, so it is up to the caller to add such inheritance if so desired.

**face-remap-reset-base face** [Function]

This function sets the base remapping of `face` to its default value, which inherits from `face`'s global definition.

## 41.12.6 Functions for Working with Faces

Here are additional functions for creating and working with faces.

**face-list** [Function]

This function returns a list of all defined face names.

**face-id face** [Function]

This function returns the *face number* of face `face`. This is a number that uniquely identifies a face at low levels within Emacs. It is seldom necessary to refer to a face by its face number. However, functions that manipulate glyphs, such as `make-glyph-code` and `glyph-face` (see Section 41.23.4 [Glyphs], page 1245) access the face numbers internally. Note that the face number is stored as the value of the `face` property of the face symbol, so we recommend not to set that property of a face to any value of your own.

**face-documentation face** [Function]

This function returns the documentation string of face `face`, or `nil` if none was specified for it.

**face-equal face1 face2 &optional frame** [Function]

This returns `t` if the faces `face1` and `face2` have the same attributes for display.

**face-differs-from-default-p face &optional frame** [Function]

This returns non-`nil` if the face `face` displays differently from the default face.

A *face alias* provides an equivalent name for a face. You can define a face alias by giving the alias symbol the `face-alias` property, with a value of the target face name. The following example makes `modeline` an alias for the `mode-line` face.

```
(put 'modeline 'face-alias 'mode-line)
```

**define-obsolete-face-alias obsolete-face current-face when** [Macro]

This macro defines `obsolete-face` as an alias for `current-face`, and also marks it as obsolete, indicating that it may be removed in future. `when` should be a string indicating when `obsolete-face` was made obsolete (usually a version number string).

### 41.12.7 Automatic Face Assignment

This hook is used for automatically assigning faces to text in the buffer. It is part of the implementation of Jit-Lock mode, used by Font-Lock.

#### `fontification-functions`

[Variable]

This variable holds a list of functions that are called by Emacs redisplay as needed, just before doing redisplay. They are called even when Font Lock Mode isn't enabled. When Font Lock Mode is enabled, this variable usually holds just one function, `jit-lock-function`.

The functions are called in the order listed, with one argument, a buffer position `pos`. Collectively they should attempt to assign faces to the text in the current buffer starting at `pos`.

The functions should record the faces they assign by setting the `face` property. They should also add a non-`nil` `fontified` property to all the text they have assigned faces to. That property tells redisplay that faces have been assigned to that text already.

It is probably a good idea for the functions to do nothing if the character after `pos` already has a non-`nil` `fontified` property, but this is not required. If one function overrides the assignments made by a previous one, the properties after the last function finishes are the ones that really matter.

For efficiency, we recommend writing these functions so that they usually assign faces to around 400 to 600 characters at each call.

Note that, when the buffer text includes very long lines, these functions are called as if they were in a `with-restriction` form (see Section 31.4 [Narrowing], page 865), with a `long-line-optimizations-in-fontification-functions` label and with the buffer narrowed to a portion around `pos`.

### 41.12.8 Basic Faces

If your Emacs Lisp program needs to assign some faces to text, it is often a good idea to use certain existing faces or inherit from them, rather than defining entirely new faces. This way, if other users have customized those existing faces to give Emacs a certain look, your program will fit in without additional customization.

Some of the *basic faces* defined in Emacs are listed below. In addition to these, you might want to make use of the Font Lock faces for syntactic highlighting, if highlighting is not already handled by Font Lock mode, or if some Font Lock faces are not in use. See Section 24.6.7 [Faces for Font Lock], page 573.

**default** The default face, whose attributes are all specified. All other faces implicitly inherit from it: any unspecified attribute defaults to the attribute on this face (see Section 41.12.1 [Face Attributes], page 1164).

**mode-line-active**

**mode-line-inactive**

**header-line**

**tab-line** Basic faces used for the mode line, header line, and tab line.

`tool-bar`  
`tab-bar`  
`fringe`  
`scroll-bar`  
`window-divider`  
`border`  
`child-frame-border`

Basic faces used for the corresponding decorations of GUI frames.

`cursor` The basic face used for the text cursor.

`mouse` The basic face used for displaying mouse-sensitive text when the mouse pointer is on that text.

`bold`  
`italic`  
`bold-italic`  
`underline`  
`fixed-pitch`  
`fixed-pitch-serif`  
`variable-pitch`

These have the attributes indicated by their names (e.g., `bold` has a bold `:weight` attribute), with all other attributes unspecified (and so given by `default`).

`shadow` For dimmed-out text. For example, it is used for the ignored part of a filename in the minibuffer (see Section “Minibuffers for File Names” in *The GNU Emacs Manual*).

`link`  
`link-visited`

For clickable text buttons that send the user to a different buffer or location.

`highlight`

For stretches of text that should temporarily stand out. For example, it is commonly assigned to the `mouse-face` property for cursor highlighting (see Section 33.19.4 [Special Properties], page 924).

`match`  
`isearch`  
`lazy-highlight`

For text matching (respectively) permanent search matches, interactive search matches, and lazy highlighting other matches than the current interactive one.

`error`  
`warning`

`success` For text concerning errors, warnings, or successes. For example, these are used for messages in `*Compilation*` buffers.

### 41.12.9 Font Selection

Before Emacs can draw a character on a graphical display, it must select a *font* for that character<sup>2</sup>. See Section “Fonts” in *The GNU Emacs Manual*. Normally, Emacs automatically chooses a font based on the faces assigned to that character—specifically, the face attributes `:family`, `:weight`, `:slant`, and `:width` (see Section 41.12.1 [Face Attributes], page 1164). The choice of font also depends on the character to be displayed; some fonts can only display a limited set of characters. If no available font exactly fits the requirements, Emacs looks for the *closest matching font*. The variables in this section control how Emacs makes this selection.

#### `face-font-family-alternatives`

[User Option]

If a given family is specified but does not exist, this variable specifies alternative font families to try. Each element should have this form:

(*family alternate-families...*)

If *family* is specified but not available, Emacs will try the other families given in *alternate-families*, one by one, until it finds a family that does exist.

#### `face-font-selection-order`

[User Option]

If there is no font that exactly matches all desired face attributes (`:width`, `:height`, `:weight`, and `:slant`), this variable specifies the order in which these attributes should be considered when selecting the closest matching font. The value should be a list containing those four attribute symbols, in order of decreasing importance. The default is (`:width :height :weight :slant`).

Font selection first finds the best available matches for the first attribute in the list; then, among the fonts which are best in that way, it searches for the best matches in the second attribute, and so on.

The attributes `:weight` and `:width` have symbolic values in a range centered around `normal`. Matches that are more extreme (farther from `normal`) are somewhat preferred to matches that are less extreme (closer to `normal`); this is designed to ensure that non-normal faces contrast with normal ones, whenever possible.

One example of a case where this variable makes a difference is when the default font has no italic equivalent. With the default ordering, the `italic` face will use a non-italic font that is similar to the default one. But if you put `:slant` before `:height`, the `italic` face will use an italic font, even if its height is not quite right.

#### `face-font-registry-alternatives`

[User Option]

This variable lets you specify alternative font registries to try, if a given registry is specified and doesn’t exist. Each element should have this form:

(*registry alternate-registries...*)

If *registry* is specified but not available, Emacs will try the other registries given in *alternate-registries*, one by one, until it finds a registry that does exist.

Emacs can make use of scalable fonts, but by default it does not use them.

---

<sup>2</sup> In this context, the term *font* has nothing to do with Font Lock (see Section 24.6 [Font Lock Mode], page 563).

**scalable-fonts-allowed**

[User Option]

This variable controls which scalable fonts to use. A value of `nil`, the default, means do not use scalable fonts. `t` means to use any scalable font that seems appropriate for the text.

Otherwise, the value must be a list of regular expressions. Then a scalable font is enabled for use if its name matches any regular expression in the list. For example,

```
(setq scalable-fonts-allowed '("iso10646-1$"))
```

allows the use of scalable fonts with registry `iso10646-1`.

**face-font-rescale-alist**

[Variable]

This variable specifies scaling for certain faces. Its value should be a list of elements of the form

```
(fontname-regexp . scale-factor)
```

If `fontname-regexp` matches the font name that is about to be used, this says to choose a larger similar font according to the factor `scale-factor`. You would use this feature to normalize the font size if certain fonts are bigger or smaller than their nominal heights and widths would suggest.

### 41.12.10 Looking Up Fonts

**x-list-fonts name &optional reference-face frame maximum width** [Function]

This function returns a list of available font names that match `name`. `name` should be a string containing a font name in either the Fontconfig, GTK+, or XLFM format (see Section “Fonts” in *The GNU Emacs Manual*). Within an XLFM string, wildcard characters may be used: the ‘\*’ character matches any substring, and the ‘?’ character matches any single character. Case is ignored when matching font names.

If the optional arguments `reference-face` and `frame` are specified, the returned list includes only fonts that are the same size as `reference-face` (a face name) currently is on the frame `frame`.

The optional argument `maximum` sets a limit on how many fonts to return. If it is non-`nil`, then the return value is truncated after the first `maximum` matching fonts. Specifying a small value for `maximum` can make this function much faster, in cases where many fonts match the pattern.

The optional argument `width` specifies a desired font width. If it is non-`nil`, the function only returns those fonts whose characters are (on average) `width` times as wide as `reference-face`.

**x-family-fonts &optional family frame**

[Function]

This function returns a list describing the available fonts for family `family` on `frame`. If `family` is omitted or `nil`, this list applies to all families, and therefore, it contains all available fonts. Otherwise, `family` must be a string; it may contain the wildcards ‘?’ and ‘\*’.

The list describes the display that `frame` is on; if `frame` is omitted or `nil`, it applies to the selected frame’s display (see Section 30.10 [Input Focus], page 824).

Each element in the list is a vector of the following form:

```
[family width point-size weight slant]
```

*fixed-p full registry-and-encoding]*

The first five elements correspond to face attributes; if you specify these attributes for a face, it will use this font.

The last three elements give additional information about the font. *fixed-p* is non-*nil* if the font is fixed-pitch. *full* is the full name of the font, and *registry-and-encoding* is a string giving the registry and encoding of the font.

#### 41.12.11 Fontsets

A *fontset* is a list of fonts, each assigned to a range of character codes. An individual font cannot display the whole range of characters that Emacs supports, but a fontset can. Fontsets have names, just as fonts do, and you can use a fontset name in place of a font name when you specify the font for a frame or a face. Here is information about defining a fontset under Lisp program control.

**create-fontset-from-fontset-spec** *fontset-spec* &*optional style-variant-p* *noerror* [Function]

This function defines a new fontset according to the specification string *fontset-spec*. The string should have this format:

*fontpattern*, [*charset:font*]...

Whitespace characters before and after the commas are ignored.

The first part of the string, *fontpattern*, should have the form of a standard X font name, except that the last two fields should be ‘*fontset-alias*’.

The new fontset has two names, one long and one short. The long name is *fontpattern* in its entirety. The short name is ‘*fontset-alias*’. You can refer to the fontset by either name. If a fontset with the same name already exists, an error is signaled, unless *noerror* is non-*nil*, in which case this function does nothing.

If optional argument *style-variant-p* is non-*nil*, that says to create bold, italic and bold-italic variants of the fontset as well. These variant fontsets do not have a short name, only a long one, which is made by altering *fontpattern* to indicate the bold and/or italic status.

The specification string also says which fonts to use in the fontset. See below for the details.

The construct ‘*charset:font*’ specifies which font to use (in this fontset) for one particular character set. Here, *charset* is the name of a character set, and *font* is the font to use for that character set. You can use this construct any number of times in the specification string.

For the remaining character sets, those that you don’t specify explicitly, Emacs chooses a font based on *fontpattern*: it replaces ‘*fontset-alias*’ with a value that names one character set. For the ASCII character set, ‘*fontset-alias*’ is replaced with ‘ISO8859-1’.

In addition, when several consecutive fields are wildcards, Emacs collapses them into a single wildcard. This is to prevent use of auto-scaled fonts. Fonts made by scaling larger fonts are not usable for editing, and scaling a smaller font is not useful because it is better to use the smaller font in its own size, which Emacs does.

Thus if *fontpattern* is this,

—\*—fixed—medium—r—normal—\*—24—\*—\*—\*—\*—fontset—24

the font specification for ASCII characters would be this:

```
--fixed-medium-r-normal--24--IS08859-1
```

and the font specification for Chinese GB2312 characters would be this:

```
--fixed-medium-r-normal--24--gb2312--*
```

You may not have any Chinese font matching the above font specification. Most X distributions include only Chinese fonts that have ‘song ti’ or ‘fangsong ti’ in the *family* field. In such a case, ‘Fontset-n’ can be specified as below:

```
Emacs.Fontset-0: --fixed-medium-r-normal--24----fontset-24,\n chinese-gb2312:--*-medium-r-normal--24--gb2312--*
```

Then, the font specifications for all but Chinese GB2312 characters have ‘fixed’ in the *family* field, and the font specification for Chinese GB2312 characters has a wild card ‘\*’ in the *family* field.

**set-fontset-font** *fontset* *characters* *font-spec* &**optional** *frame* *add* [Function]

This function modifies the existing *fontset* to use the font specified by *font-spec* for displaying the specified *characters*.

If *fontset* is **nil**, this function modifies the fontset of the selected frame or that of *frame* if *frame* is not **nil**.

If *fontset* is **t**, this function modifies the default fontset, whose short name as a string is ‘**fontset-default**’.

The *characters* argument can be a single character which should be displayed using *font-spec*. It can also be a cons cell (*from* . *to*), where *from* and *to* are characters. In that case, use *font-spec* for all the characters in the range *from* and *to* (inclusive). *characters* may be a charset symbol (see Section 34.7 [Character Sets], page 973). In that case, use *font-spec* for all the characters in the charset.

*characters* may be a script symbol (see Section 34.6 [Character Properties], page 968). In that case, use *font-spec* for all the characters belonging to the script.

*characters* may be **nil**, which means to use *font-spec* for any character in *fontset* for which no *font-spec* is specified.

*font-spec* may be a font-spec object created by the function **font-spec** (see Section 41.12.12 [Low-Level Font], page 1184).

*font-spec* may be a cons cell (*family* . *registry*), where *family* is a family name of a font (possibly including a foundry name at the head), and *registry* is a registry name of a font (possibly including an encoding name at the tail).

*font-spec* may be a font name, a string.

*font-spec* may be **nil**, which explicitly specifies that there’s no font for the specified *characters*. This is useful, for example, to avoid expensive system-wide search for fonts for characters that have no glyphs, like those from the Unicode Private Use Area (PUA).

The optional argument *add*, if non-**nil**, specifies how to add *font-spec* to the font specifications previously set for *characters*. If it is **prepend**, *font-spec* is prepended to the existing specs. If it is **append**, *font-spec* is appended. By default, *font-spec* overwrites the previously set font specs.

For instance, this changes the default fontset to use a font whose family name is ‘*Kochi Gothic*’ for all characters belonging to the charset `japanese-jisx0208`:

```
(set-fontset-font t 'japanese-jisx0208
 (font-spec :family "Kochi Gothic"))
```

Note that this function should generally be called from the user’s init files, and more generally before any of *characters* were displayed in the current Emacs session. That’s because for some scripts, Emacs caches the way they are displayed, and the cached information includes the font used for them – once these characters are displayed once, the cached font will continue to be used regardless of changes in the fontsets.

#### `char-displayable-p char`

[Function]

This function returns `non-nil` if Emacs ought to be able to display *char*. Or more precisely, if the selected frame’s fontset has a font to display the character set that *char* belongs to.

Fontsets can specify a font on a per-character basis; when the fontset does that, this function’s value may not be accurate.

This function may return `non-nil` even when there is no font available, since it also checks whether the coding system for the text terminal can encode the character (see Section 34.10.8 [Terminal I/O Encoding], page 990).

### 41.12.12 Low-Level Font Representation

Normally, it is not necessary to manipulate fonts directly. In case you need to do so, this section explains how.

In Emacs Lisp, fonts are represented using three different Lisp object types: *font objects*, *font specs*, and *font entities*.

#### `fontp object &optional type`

[Function]

Return `t` if *object* is a font object, font spec, or font entity. Otherwise, return `nil`.

The optional argument *type*, if `non-nil`, determines the exact type of Lisp object to check for. In that case, *type* should be one of `font-object`, `font-spec`, or `font-entity`.

A font object is a Lisp object that represents a font that Emacs has opened. Font objects cannot be modified in Lisp, but they can be inspected.

#### `font-at position &optional window string`

[Function]

Return the font object that is being used to display the character at position *position* in the window *window*. If *window* is `nil`, it defaults to the selected window. If *string* is `nil`, *position* specifies a position in the current buffer; otherwise, *string* should be a string, and *position* specifies a position in that string.

A font spec is a Lisp object that contains a set of specifications that can be used to find a font. More than one font may match the specifications in a font spec.

#### `font-spec &rest arguments`

[Function]

Return a new font spec using the specifications in *arguments*, which should come in *property-value* pairs. The possible specifications are as follows:

|                    |                                                                                                                               |
|--------------------|-------------------------------------------------------------------------------------------------------------------------------|
| <code>:name</code> | The font name (a string), in either XLFM, Fontconfig, or GTK+ format.<br>See Section “Fonts” in <i>The GNU Emacs Manual</i> . |
|--------------------|-------------------------------------------------------------------------------------------------------------------------------|

|                        |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |

| <code>:family</code>   |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| <code>:foundry</code>  |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| <code>:weight</code>   |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| <code>:slant</code>    |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| <code>:width</code>    | These have the same meanings as the face attributes of the same name. See Section 41.12.1 [Face Attributes], page 1164. <code>:family</code> and <code>:foundry</code> are strings, while the other three are symbols. As example values, <code>:slant</code> may be <code>italic</code> , <code>:weight</code> may be <code>bold</code> and <code>:width</code> may be <code>normal</code> .                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
| <code>:size</code>     | The font size—either a non-negative integer that specifies the pixel size, or a floating-point number that specifies the point size.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
| <code>:adstyle</code>  | Additional typographic style information for the font, such as ‘ <code>sans</code> ’. The value should be a string or a symbol.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| <code>:registry</code> | The charset registry and encoding of the font, such as ‘ <code>iso8859-1</code> ’. The value should be a string or a symbol.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
| <code>:dpi</code>      | The resolution in dots per inch for which the font is designed. The value must be a non-negative number.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| <code>:spacing</code>  | The spacing of the font: proportional, dual, mono, or charcell. The value should be either an integer (0 for proportional, 90 for dual, 100 for mono, 110 for charcell) or a one-letter symbol (one of P, D, M, or C).                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| <code>:avgwidth</code> | The average width of the font in 1/10 pixel units. The value should be a non-negative number.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
| <code>:script</code>   | The script that the font must support (a symbol).                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| <code>:lang</code>     | The language that the font should support. The value should be a symbol whose name is a two-letter ISO-639 language name. On X, the value is matched against the “Additional Style” field of the XLFD name of a font, if it is non-empty. On MS-Windows, fonts matching the spec are required to support codepages needed for the language. Currently, only a small set of CJK languages is supported with this property: ‘ja’, ‘ko’, and ‘zh’.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| <code>:otf</code>      | The font must be an OpenType font that supports these OpenType features, provided Emacs is compiled with a library, such as ‘ <code>libotf</code> ’ on GNU/Linux, that supports complex text layout for scripts which need that. The value must be a list of the form<br>$(\text{script-tag} \text{ langsys-tag} \text{ gsub} \text{ gpos})$ where <code>script-tag</code> is the OpenType script tag symbol; <code>langsys-tag</code> is the OpenType language system tag symbol, or <code>nil</code> to use the default language system; <code>gsub</code> is a list of OpenType GSUB feature tag symbols, or <code>nil</code> if none is required; and <code>gpos</code> is a list of OpenType GPOS feature tag symbols, or <code>nil</code> if none is required. If <code>gsub</code> or <code>gpos</code> is a list, a <code>nil</code> element in that list means that the font must not match any of the remaining tag symbols. The <code>gpos</code> element may be omitted. For the list of OpenType script, |

language, and feature tags, see the list of registered OTF tags (<https://docs.microsoft.com/en-us/typography/opentype/spec/ttoreg>).

**:type** The symbol that specifies the *font backend* used to draw the characters. The possible values depend on the platform and on how Emacs was configured at build time. Typical values include `ftcrhb` and `xfthb` on X, `harfbuzz` on MS-Windows, `ns` on GNUstep, etc. It can also be `nil` if left unspecified, typically in a font-spec.

**font-put** *font-spec* *property* *value* [Function]

Set the font property *property* in the font-spec *font-spec* to *value*. The *property* can any of the ones described above.

A font entity is a reference to a font that need not be open. Its properties are intermediate between a font object and a font spec: like a font object, and unlike a font spec, it refers to a single, specific font. Unlike a font object, creating a font entity does not load the contents of that font into computer memory. Emacs may open multiple font objects of different sizes from a single font entity referring to a scalable font.

**find-font** *font-spec* &optional *frame* [Function]

This function returns a font entity that best matches the font spec *font-spec* on frame *frame*. If *frame* is `nil`, it defaults to the selected frame.

**list-fonts** *font-spec* &optional *frame* *num* *prefer* [Function]

This function returns a list of all font entities that match the font spec *font-spec*.

The optional argument *frame*, if non-`nil`, specifies the frame on which the fonts are to be displayed. The optional argument *num*, if non-`nil`, should be an integer that specifies the maximum length of the returned list. The optional argument *prefer*, if non-`nil`, should be another font spec, which is used to control the order of the returned list; the returned font entities are sorted in order of decreasing closeness to that font spec.

If you call `set-face-attribute` and pass a font spec, font entity, or font name string as the value of the `:font` attribute, Emacs opens the best matching font that is available for display. It then stores the corresponding font object as the actual value of the `:font` attribute for that face.

The following functions can be used to obtain information about a font. For these functions, the *font* argument can be a font object, a font entity, or a font spec.

**font-get** *font* *property* [Function]

This function returns the value of the font property *property* for *font*. The *property* can any of the ones that `font-spec` supports.

If *font* is a font spec and the font spec does not specify *property*, the return value is `nil`. If *font* is a font object or font entity, the value for the `:script` property may be a list of scripts supported by the font, and the value of the `:otf` property is a cons of the form `(gsub . gpos)`, where `gsub` and `gpos` are lists representing OpenType features supported by the font, of the form

```
((script-tag (langsystag feature...) ...) ...)
```

where *script-tag*, *langsystag*, and *feature* are symbols representing OpenType layout tags.

If *font* is a font object, the special property `:combining-capability` is non-*nil* if the font backend of *font* supports rendering of combining characters for non-OpenType fonts.

**font-face-attributes** *font* &**optional** *frame* [Function]

This function returns a list of face attributes corresponding to *font*. The optional argument *frame* specifies the frame on which the font is to be displayed. If it is *nil*, the selected frame is used. The return value has the form

```
(:family family :height height :weight weight
 :slant slant :width width)
```

where the values of *family*, *height*, *weight*, *slant*, and *width* are face attribute values. Some of these key-attribute pairs may be omitted from the list if they are not specified by *font*.

**font-xlfd-name** *font* &**optional** *fold-wildcards* [Function]

This function returns the XLFD (X Logical Font Descriptor), a string, matching *font*. See Section “Fonts” in *The GNU Emacs Manual*, for information about XLFDs. If the name is too long for an XLFD (which can contain at most 255 characters), the function returns *nil*.

If the optional argument *fold-wildcards* is non-*nil*, consecutive wildcards in the XLFD are folded into one.

The following two functions return important information about a font.

**font-info** *name* &**optional** *frame* [Function]

This function returns information about a font specified by its *name*, a string, as it is used on *frame*. If *frame* is omitted or *nil*, it defaults to the selected frame.

The value returned by the function is a vector of the form [*opened-name* *full-name* *size* *height* *baseline-offset* *relative-compose* *default-ascent* *max-width* *ascent* *descent* *space-width* *average-width* *filename* *capability*]. Here’s the description of each components of this vector:

*opened-name*

The name used to open the font, a string.

*full-name* The full name of the font, a string.

*size* The pixel size of the font.

*height* The height of the font in pixels.

*baseline-offset*

The offset in pixels from the ASCII baseline, positive upward.

*relative-compose*

*default-ascent*

Numbers controlling how to compose characters.

*max-width*

The maximum advance width of the font.

|                      |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
|----------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <i>ascent</i>        |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| <i>descent</i>       | The ascent and descent of this font. The sum of these two numbers should be equal to the value of <i>height</i> above.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| <i>space-width</i>   | The width, in pixels, of the font's space character.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| <i>average-width</i> | The average width of the font characters. If this is zero, Emacs uses the value of <i>space-width</i> instead, when it calculates text layout on display.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |
| <i>filename</i>      | The file name of the font as a string. This can be <code>nil</code> if the font back-end does not provide a way to find out the font's file name.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| <i>capability</i>    | A list whose first element is a symbol representing the font type, one of <code>x</code> , <code>opentype</code> , <code>truetype</code> , <code>type1</code> , <code>pcf</code> , or <code>bdf</code> . For OpenType fonts, the list includes 2 additional elements describing the GSUB and GPOS features supported by the font. Each of these elements is a list of the form <code>((script (langsys feature ...) ...) ...)</code> , where <i>script</i> is a symbol representing an OpenType script tag, <i>langsys</i> is a symbol representing an OpenType langsys tag (or <code>nil</code> , which stands for the default langsys), and each <i>feature</i> is a symbol representing an OpenType feature tag. |

**query-font *font-object*** [Function]

This function returns information about a *font-object*. (This is in contrast to `font-info`, which takes the font name, a string, as its argument.)

The value returned by the function is a vector of the form `[name filename pixel-size max-width ascent descent space-width average-width capability]`. Here's the description of each components of this vector:

|                      |                                                                                                                                                                                                                                                                                                   |
|----------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <i>name</i>          | The font name, a string.                                                                                                                                                                                                                                                                          |
| <i>filename</i>      | The file name of the font as a string. This can be <code>nil</code> if the font back-end does not provide a way to find out the font's file name.                                                                                                                                                 |
| <i>pixel-size</i>    | The pixel size of the font used to open the font.                                                                                                                                                                                                                                                 |
| <i>max-width</i>     | The maximum advance width of the font.                                                                                                                                                                                                                                                            |
| <i>ascent</i>        |                                                                                                                                                                                                                                                                                                   |
| <i>descent</i>       | The ascent and descent of this font. The sum of these two numbers gives the font height.                                                                                                                                                                                                          |
| <i>space-width</i>   | The width, in pixels, of the font's space character.                                                                                                                                                                                                                                              |
| <i>average-width</i> | The average width of the font characters. If this is zero, Emacs uses the value of <i>space-width</i> instead, when it calculates text layout on display.                                                                                                                                         |
| <i>capability</i>    | A list whose first element is a symbol representing the font type, one of <code>x</code> , <code>opentype</code> , <code>truetype</code> , <code>type1</code> , <code>pcf</code> , or <code>bdf</code> . For OpenType fonts, the list includes 2 additional elements describing the GSUB and GPOS |

features supported by the font. Each of these elements is a list of the form `((script (langsys feature ...) ...) ...)`, where *script* is a symbol representing an OpenType script tag, *langsys* is a symbol representing an OpenType langsys tag (or `nil`, which stands for the default langsys), and each *feature* is a symbol representing an OpenType feature tag.

The following four functions return size information about fonts used by various faces, allowing various layout considerations in Lisp programs. These functions take face remapping into consideration, returning information about the remapped face, if the face in question was remapped. See Section 41.12.5 [Face Remapping], page 1175.

**default-font-width**

[Function]

This function returns the average width in pixels of the font used by the current buffer's default face, as that face is defined for the selected frame.

**default-font-height**

[Function]

This function returns the height in pixels of the font used by the current buffer's default face, as that face is defined for the selected frame.

**window-font-width &optional window face**

[Function]

This function returns the average width in pixels for the font used by *face* in *window*. The specified *window* must be a live window. If `nil` or omitted, *window* defaults to the selected window, and *face* defaults to the default face in *window*.

**window-font-height &optional window face**

[Function]

This function returns the height in pixels for the font used by *face* in *window*. The specified *window* must be a live window. If `nil` or omitted, *window* defaults to the selected window, and *face* defaults to the default face in *window*.

## 41.13 Fringes

On graphical displays, Emacs draws *fringes* next to each window: thin vertical strips down the sides which can display bitmaps indicating truncation, continuation, horizontal scrolling, and so on.

### 41.13.1 Fringe Size and Position

The following buffer-local variables control the position and width of fringes in windows showing that buffer.

**fringes-outside-margins**

[Variable]

The fringes normally appear between the display margins and the window text. If the value is non-`nil`, they appear outside the display margins. See Section 41.16.5 [Display Margins], page 1205.

**left-fringe-width**

[Variable]

This variable, if non-`nil`, specifies the width of the left fringe in pixels. A value of `nil` means to use the left fringe width from the window's frame.

**right-fringe-width**

[Variable]

This variable, if non-`nil`, specifies the width of the right fringe in pixels. A value of `nil` means to use the right fringe width from the window's frame.

Any buffer which does not specify values for these variables uses the values specified by the `left-fringe` and `right-fringe` frame parameters (see Section 30.4.3.4 [Layout Parameters], page 810).

The above variables actually take effect via the function `set-window-buffer` (see Section 29.11 [Buffers and Windows], page 720), which calls `set-window-fringes` as a subroutine. If you change one of these variables, the fringe display is not updated in existing windows showing the buffer, unless you call `set-window-buffer` again in each affected window. You can also use `set-window-fringes` to control the fringe display in individual windows.

**set-window-fringes** *window left &optional right outside-margins persistent* [Function]

This function sets the fringe widths of window *window*. If *window* is `nil`, the selected window is used.

The argument *left* specifies the width in pixels of the left fringe, and likewise *right* for the right fringe. A value of `nil` for either one stands for the default width. If *outside-margins* is non-`nil`, that specifies that fringes should appear outside of the display margins.

If *window* is not large enough to accommodate fringes of the desired width, this leaves the fringes of *window* unchanged.

The values specified here may be later overridden by invoking `set-window-buffer` (see Section 29.11 [Buffers and Windows], page 720) on *window* with its *keep-margins* argument `nil` or omitted. However, if the optional fifth argument *persistent* is non-`nil` and the other arguments are processed successfully, the values specified here unconditionally survive subsequent invocations of `set-window-buffer`. This can be used to permanently turn off fringes in the minibuffer window, consult the description of `set-window-scroll-bars` for an example (see Section 41.14 [Scroll Bars], page 1195).

**window-fringes** *&optional window* [Function]

This function returns information about the fringes of a window *window*. If *window* is omitted or `nil`, the selected window is used. The value has the form (*left-width* *right-width* *outside-margins* *persistent*).

### 41.13.2 Fringe Indicators

*Fringe indicators* are tiny icons displayed in the window fringe to indicate truncated or continued lines, buffer boundaries, etc.

**indicate-empty-lines** [User Option]

When this is non-`nil`, Emacs displays a special glyph in the fringe of each empty line at the end of the buffer, on graphical displays. See Section 41.13 [Fringes], page 1189. This variable is automatically buffer-local in every buffer.

**indicate-buffer-boundaries** [User Option]

This buffer-local variable controls how the buffer boundaries and window scrolling are indicated in the window fringes.

Emacs can indicate the buffer boundaries—that is, the first and last line in the buffer—with angle icons when they appear on the screen. In addition, Emacs can display an

up-arrow in the fringe to show that there is text above the screen, and a down-arrow to show there is text below the screen.

There are three kinds of basic values:

- nil**      Don't display any of these fringe icons.
- left**     Display the angle icons and arrows in the left fringe.
- right**    Display the angle icons and arrows in the right fringe.
- any non-alist**
  - Display the angle icons in the left fringe and don't display the arrows.

Otherwise the value should be an alist that specifies which fringe indicators to display and where. Each element of the alist should have the form (*indicator* . *position*). Here, *indicator* is one of **top**, **bottom**, **up**, **down**, and **t** (which covers all the icons not yet specified), while *position* is one of **left**, **right** and **nil**.

For example, ((**top** . **left**) (**t** . **right**)) places the top angle bitmap in left fringe, and the bottom angle bitmap as well as both arrow bitmaps in right fringe. To show the angle bitmaps in the left fringe, and no arrow bitmaps, use ((**top** . **left**) (**bottom** . **left**)).

#### **fringe-indicator-alist** [Variable]

This buffer-local variable specifies the mapping from logical fringe indicators to the actual bitmaps displayed in the window fringes. The value is an alist of elements (*indicator* . *bitmaps*), where *indicator* specifies a logical indicator type and *bitmaps* specifies the fringe bitmaps to use for that indicator.

Each *indicator* should be one of the following symbols:

##### **truncation, continuation.**

Used for truncation and continuation lines.

##### **up, down, top, bottom, top-bottom**

Used when **indicate-buffer-boundaries** is non-nil: **up** and **down** indicate a buffer boundary lying above or below the window edge; **top** and **bottom** indicate the topmost and bottommost buffer text line; and **top-bottom** indicates where there is just one line of text in the buffer.

##### **empty-line**

Used to indicate empty lines after the buffer end when **indicate-empty-lines** is non-nil.

##### **overlay-arrow**

Used for overlay arrows (see Section 41.13.6 [Overlay Arrow], page 1194).

Each *bitmaps* value may be a list of symbols (**left** **right** [**left1** **right1**]). The **left** and **right** symbols specify the bitmaps shown in the left and/or right fringe, for the specific indicator. **left1** and **right1** are specific to the **bottom** and **top-bottom** indicators, and are used to indicate that the last text line has no final newline. Alternatively, *bitmaps* may be a single symbol which is used in both left and right fringes.

See Section 41.13.4 [Fringe Bitmaps], page 1192, for a list of standard bitmap symbols and how to define your own. In addition, `nil` represents the empty bitmap (i.e., an indicator that is not shown).

When `fringe-indicator-alist` has a buffer-local value, and there is no bitmap defined for a logical indicator, or the bitmap is `t`, the corresponding value from the default value of `fringe-indicator-alist` is used.

### 41.13.3 Fringe Cursors

When a line is exactly as wide as the window, Emacs displays the cursor in the right fringe instead of using two lines. Different bitmaps are used to represent the cursor in the fringe depending on the current buffer's cursor type.

#### `overflow-newline-into-fringe`

[User Option]

If this is non-`nil`, lines exactly as wide as the window (not counting the final newline character) are not continued. Instead, when point is at the end of the line, the cursor appears in the right fringe.

#### `fringe-cursor-alist`

[Variable]

This variable specifies the mapping from logical cursor type to the actual fringe bitmaps displayed in the right fringe. The value is an alist where each element has the form `(cursor-type . bitmap)`, which means to use the fringe bitmap `bitmap` to display cursors of type `cursor-type`.

Each `cursor-type` should be one of `box`, `hollow`, `bar`, `hbar`, or `hollow-small`. The first four have the same meanings as in the `cursor-type` frame parameter (see Section 30.4.3.9 [Cursor Parameters], page 817). The `hollow-small` type is used instead of `hollow` when the normal `hollow-rectangle` bitmap is too tall to fit on a specific display line.

Each `bitmap` should be a symbol specifying the fringe bitmap to be displayed for that logical cursor type. See the next subsection for details.

When `fringe-cursor-alist` has a buffer-local value, and there is no bitmap defined for a cursor type, the corresponding value from the default value of `fringes-indicator-alist` is used.

### 41.13.4 Fringe Bitmaps

The `fringe bitmaps` are the actual bitmaps which represent the logical fringe indicators for truncated or continued lines, buffer boundaries, overlay arrows, etc. Each bitmap is represented by a symbol. These symbols are referred to by the variables `fringe-indicator-alist` and `fringe-cursor-alist`, described in the previous subsections.

Lisp programs can also directly display a bitmap in the left or right fringe, by using a `display` property for one of the characters appearing in the line (see Section 41.16.4 [Other Display Specs], page 1203). Such a display specification has the form

`(fringe bitmap [face])`

`fringe` is either the symbol `left-fringe` or `right-fringe`. `bitmap` is a symbol identifying the bitmap to display. The optional `face` names a face whose foreground and background colors are to be used to display the bitmap, using the attributes of the `fringe` face for colors that `face` didn't specify. If `face` is omitted, that means to use the attributes of the `default`

face for the colors which the `fringe` face didn't specify. For predictable results that don't depend on the attributes of the `default` and `fringe` faces, we recommend you never omit `face`, but always provide a specific face. In particular, if you want the bitmap to be always displayed in the `fringe` face, use `fringe` as `face`.

For instance, to display an arrow in the left fringe, using the `warning` face, you could say something like:

```
(overlay-put
 (make-overlay (point) (point))
 'before-string (propertize
 "x" 'display
 `(left-fringe right-arrow warning)))
```

Here is a list of the standard fringe bitmaps defined in Emacs, and how they are currently used in Emacs (via `fringe-indicator-alist` and `fringe-cursor-alist`):

`left-arrow, right-arrow`

Used to indicate truncated lines.

`left-curly-arrow, right-curly-arrow`

Used to indicate continued lines.

`right-triangle, left-triangle`

The former is used by overlay arrows. The latter is unused.

`up-arrow, down-arrow`

`bottom-left-angle, bottom-right-angle`

`top-left-angle, top-right-angle`

`left-bracket, right-bracket`

`empty-line`

Used to indicate buffer boundaries.

`filled-rectangle, hollow-rectangle`

`filled-square, hollow-square`

`vertical-bar, horizontal-bar`

Used for different types of fringe cursors.

`exclamation-mark, question-mark`

`large-circle`

Not used by core Emacs features.

The next subsection describes how to define your own fringe bitmaps.

`fringe-bitmaps-at-pos &optional pos window`

[Function]

This function returns the fringe bitmaps of the display line containing position `pos` in window `window`. The return value has the form `(left right ov)`, where `left` is the symbol for the fringe bitmap in the left fringe (or `nil` if no bitmap), `right` is similar for the right fringe, and `ov` is non-`nil` if there is an overlay arrow in the left fringe.

The value is `nil` if `pos` is not visible in `window`. If `window` is `nil`, that stands for the selected window. If `pos` is `nil`, that stands for the value of point in `window`.

### 41.13.5 Customizing Fringe Bitmaps

**define-fringe-bitmap** *bitmap bits &optional height width align* [Function]

This function defines the symbol *bitmap* as a new fringe bitmap, or replaces an existing bitmap with that name.

The argument *bits* specifies the image to use. It should be either a string or a vector of integers, where each element (an integer) corresponds to one row of the bitmap. Each bit of an integer corresponds to one pixel of the bitmap, where the low bit corresponds to the rightmost pixel of the bitmap. (Note that this order of bits is opposite of the order in XBM images; see Section 41.17.3 [XBM Images], page 1211.)

The height is normally the length of *bits*. However, you can specify a different height with non-nil *height*. The width is normally 8, but you can specify a different width with non-nil *width*. The width must be an integer between 1 and 16.

The argument *align* specifies the positioning of the bitmap relative to the range of rows where it is used; the default is to center the bitmap. The allowed values are `top`, `center`, or `bottom`.

The *align* argument may also be a list (*align periodic*) where *align* is interpreted as described above. If *periodic* is non-nil, it specifies that the rows in *bits* should be repeated enough times to reach the specified height.

**destroy-fringe-bitmap** *bitmap* [Function]

This function destroys the fringe bitmap identified by *bitmap*. If *bitmap* identifies a standard fringe bitmap, it actually restores the standard definition of that bitmap, instead of eliminating it entirely.

**set-fringe-bitmap-face** *bitmap &optional face* [Function]

This sets the face for the fringe bitmap *bitmap* to *face*. If *face* is `nil`, it selects the `fringe` face. The bitmap's face controls the color to draw it in.

*face* is merged with the `fringe` face, so normally *face* should specify only the foreground color.

### 41.13.6 The Overlay Arrow

The *overlay arrow* is useful for directing the user's attention to a particular line in a buffer. For example, in the modes used for interface to debuggers, the overlay arrow indicates the line of code about to be executed. This feature has nothing to do with overlays (see Section 41.9 [Overlays], page 1150).

**overlay-arrow-string** [Variable]

This variable holds the string to display to call attention to a particular line, or `nil` if the arrow feature is not in use. On a graphical display the contents of the string are ignored if the left fringe is shown; instead a glyph is displayed in the fringe area to the left of the display area.

**overlay-arrow-position** [Variable]

This variable holds a marker that indicates where to display the overlay arrow. It should point at the beginning of a line. On a non-graphical display, or when the left fringe is not shown, the arrow text appears at the beginning of that line, overlaying

any text that would otherwise appear. Since the arrow is usually short, and the line usually begins with indentation, normally nothing significant is overwritten.

The overlay-arrow string is displayed in any given buffer if the value of `overlay-arrow-position` in that buffer points into that buffer. Thus, it is possible to display multiple overlay arrow strings by creating buffer-local bindings of `overlay-arrow-position`. However, it is usually cleaner to use `overlay-arrow-variable-list` to achieve this result.

You can do a similar job by creating an overlay with a `before-string` property. See Section 41.9.2 [Overlay Properties], page 1153.

You can define multiple overlay arrows via the variable `overlay-arrow-variable-list`.

**overlay-arrow-variable-list** [Variable]

This variable's value is a list of variables, each of which specifies the position of an overlay arrow. The variable `overlay-arrow-position` has its normal meaning because it is on this list.

Each variable on this list can have properties `overlay-arrow-string` and `overlay-arrow-bitmap` that specify an overlay arrow string (for text terminals or graphical terminals without the left fringe shown) or fringe bitmap (for graphical terminals with a left fringe) to display at the corresponding overlay arrow position. If either property is not set, the default `overlay-arrow-string` or `overlay-arrow` fringe indicator is used.

## 41.14 Scroll Bars

Normally the frame parameter `vertical-scroll-bars` controls whether the windows in the frame have vertical scroll bars, and whether they are on the left or right. The frame parameter `scroll-bar-width` specifies how wide they are (`nil` meaning the default).

The frame parameter `horizontal-scroll-bars` controls whether the windows in the frame have horizontal scroll bars. The frame parameter `scroll-bar-height` specifies how high they are (`nil` meaning the default). See Section 30.4.3.4 [Layout Parameters], page 810.

Horizontal scroll bars are not available on all platforms. The function `horizontal-scroll-bars-available-p` which takes no argument returns non-`nil` if they are available on your system.

The following three functions take as argument a live frame which defaults to the selected one.

**frame-current-scroll-bars** &optional *frame* [Function]

This function reports the scroll bar types for frame *frame*. The value is a cons cell (`vertical-type . horizontal-type`), where `vertical-type` is either `left`, `right`, or `nil` (which means no vertical scroll bar.) `horizontal-type` is either `bottom` or `nil` (which means no horizontal scroll bar).

**frame-scroll-bar-width** &optional *frame* [Function]

This function returns the width of vertical scroll bars of *frame* in pixels.

**frame-scroll-bar-height** &optional *frame* [Function]

This function returns the height of horizontal scroll bars of *frame* in pixels.

You can override the frame specific settings for individual windows by using the following function:

**set-window-scroll-bars** *window* &optional *width vertical-type* [Function]  
*height horizontal-type persistent*

This function sets the width and/or height and the types of scroll bars for window *window*. If *window* is `nil`, the selected window is used.

*width* specifies the width of the vertical scroll bar in pixels (`nil` means use the width specified for the frame). *vertical-type* specifies whether to have a vertical scroll bar and, if so, where. The possible values are `left`, `right`, `t`, which means to use the frame's default, and `nil` for no vertical scroll bar.

*height* specifies the height of the horizontal scroll bar in pixels (`nil` means use the height specified for the frame). *horizontal-type* specifies whether to have a horizontal scroll bar. The possible values are `bottom`, `t`, which means to use the frame's default, and `nil` for no horizontal scroll bar. Note that for a mini window the value `t` has the same meaning as `nil`, namely to not show a horizontal scroll bar. You have to explicitly specify `bottom` in order to show a horizontal scroll bar in a mini window.

If *window* is not large enough to accommodate a scroll bar of the desired dimension, this leaves the corresponding scroll bar unchanged.

The values specified here may be later overridden by invoking **set-window-buffer** (see Section 29.11 [Buffers and Windows], page 720) on *window* with its *keep-margins* argument `nil` or omitted. However, if the optional fifth argument *persistent* is non-`nil` and the other arguments are processed successfully, the values specified here unconditionally survive subsequent invocations of **set-window-buffer**.

Using the *persistent* argument of **set-window-scroll-bars** and **set-window-fringes** (see Section 41.13.1 [Fringe Size/Pos], page 1189) you can reliably and permanently turn off scroll bars and/or fringes in any minibuffer window by adding the following snippet to your early init file (see Section 42.1.2 [Init File], page 1258).

```
(add-hook 'after-make-frame-functions
 (lambda (frame)
 (set-window-scroll-bars
 (minibuffer-window frame) 0 nil 0 nil t)
 (set-window-fringes
 (minibuffer-window frame) 0 0 nil t)))
```

The following four functions take as argument a live window which defaults to the selected one.

**window-scroll-bars** &optional *window* [Function]

This function returns a list of the form (*width columns vertical-type height lines horizontal-type persistent*).

The value *width* is the value that was specified for the width of the vertical scroll bar (which may be `nil`); *columns* is the (possibly rounded) number of columns that the vertical scroll bar actually occupies.

The value *height* is the value that was specified for the height of the horizontal scroll bar (which may be `nil`); *lines* is the (possibly rounded) number of lines that the horizontally scroll bar actually occupies.

The value of *persistent* is the value specified for *window* with the last successful invocation of `set-window-scroll-bars`, `nil` if there never was one.

**window-current-scroll-bars &optional window** [Function]

This function reports the scroll bar type for window *window*. The value is a cons cell (*vertical-type . horizontal-type*). Unlike `window-scroll-bars`, this reports the scroll bar type actually used, once frame defaults and `scroll-bar-mode` are taken into account.

**window-scroll-bar-width &optional window** [Function]

This function returns the width in pixels of *window*'s vertical scrollbar.

**window-scroll-bar-height &optional window** [Function]

This function returns the height in pixels of *window*'s horizontal scrollbar.

If you do not specify a window's scroll bar settings via `set-window-scroll-bars`, the buffer-local variables `vertical-scroll-bar`, `horizontal-scroll-bar`, `scroll-bar-width` and `scroll-bar-height` in the buffer being displayed control the window's scroll bars. The function `set-window-buffer` examines these variables. If you change them in a buffer that is already visible in a window, you can make the window take note of the new values by calling `set-window-buffer` specifying the same buffer that is already displayed.

You can control the appearance of scroll bars for a particular buffer by setting the following variables which automatically become buffer-local when set.

**vertical-scroll-bar** [Variable]

This variable specifies the location of the vertical scroll bar. The possible values are `left`, `right`, `t`, which means to use the frame's default, and `nil` for no scroll bar.

**horizontal-scroll-bar** [Variable]

This variable specifies the location of the horizontal scroll bar. The possible values are `bottom`, `t`, which means to use the frame's default, and `nil` for no scroll bar.

**scroll-bar-width** [Variable]

This variable specifies the width of the buffer's vertical scroll bars, measured in pixels. A value of `nil` means to use the value specified by the frame.

**scroll-bar-height** [Variable]

This variable specifies the height of the buffer's horizontal scroll bar, measured in pixels. A value of `nil` means to use the value specified by the frame.

Finally you can toggle the display of scroll bars on all frames by customizing the variables `scroll-bar-mode` and `horizontal-scroll-bar-mode`.

**scroll-bar-mode** [User Option]

This variable controls whether and where to put vertical scroll bars in all frames. The possible values are `nil` for no scroll bars, `left` to put scroll bars on the left and `right` to put scroll bars on the right.

**horizontal-scroll-bar-mode** [User Option]

This variable controls whether to display horizontal scroll bars on all frames.

## 41.15 Window Dividers

Window dividers are bars drawn between a frame's windows. A right divider is drawn between a window and any adjacent windows on the right. Its width (thickness) is specified by the frame parameter `right-divider-width`. A bottom divider is drawn between a window and adjacent windows on the bottom or the echo area. Its width is specified by the frame parameter `bottom-divider-width`. In either case, specifying a width of zero means to not draw such dividers. See Section 30.4.3.4 [Layout Parameters], page 810.

Technically, a right divider belongs to the window on its left, which means that its width contributes to the total width of that window. A bottom divider belongs to the window above it, which means that its width contributes to the total height of that window. See Section 29.4 [Window Sizes], page 699. When a window has both, a right and a bottom divider, the bottom divider prevails. This means that a bottom divider is drawn over the full total width of its window while the right divider ends above the bottom divider.

Dividers can be dragged with the mouse and are therefore useful for adjusting the sizes of adjacent windows with the mouse. They also serve to visually set apart adjacent windows when no scroll bars or mode lines are present. The following three faces allow the customization of the appearance of dividers:

### `window-divider`

When a divider is less than three pixels wide, it is drawn solidly with the foreground of this face. For larger dividers this face is used for the inner part only, excluding the first and last pixel.

### `window-divider-first-pixel`

This is the face used for drawing the first pixel of a divider that is at least three pixels wide. To obtain a solid appearance, set this to the same value used for the `window-divider` face.

### `window-divider-last-pixel`

This is the face used for drawing the last pixel of a divider that is at least three pixels wide. To obtain a solid appearance, set this to the same value used for the `window-divider` face.

You can get the sizes of the dividers of a specific window with the following two functions.

### `window-right-divider-width &optional window` [Function]

Return the width (thickness) in pixels of `window`'s right divider. `window` must be a live window and defaults to the selected one. The return value is always zero for a rightmost window.

### `window-bottom-divider-width &optional window` [Function]

Return the width (thickness) in pixels of `window`'s bottom divider. `window` must be a live window and defaults to the selected one. The return value is zero for the minibuffer window or a bottommost window on a minibuffer-less frame.

## 41.16 The `display` Property

The `display` text property (or overlay property) is used to insert images into text, and to control other aspects of how text displays. Display specifications in the same `display` property value generally apply in parallel to the text they cover.

If several sources (overlays and/or a text property) specify values for the `display` property, only one of the values takes effect, following the rules of `get-char-property`. See Section 33.19.1 [Examining Properties], page 917.

The value of the `display` property should be a display specification, or a list or vector containing several display specifications.

**get-display-property** *position prop &optional object properties* [Function]

This convenience function can be used to get a specific display property, no matter whether the `display` property is a vector, a list or a simple property. This is like `get-text-property` (see Section 33.19.1 [Examining Properties], page 917), but works on the `display` property only.

*position* is the position in the buffer or string to examine, and *prop* is the `display` property to return. The optional *object* argument should be either a string or a buffer, and defaults to the current buffer. If the optional *properties* argument is non-`nil`, it should be a `display` property, and in that case, *position* and *object* are ignored. (This can be useful if you've already gotten the `display` property with `get-char-property`, for instance (see Section 33.19.1 [Examining Properties], page 917)).

**add-display-text-property** *start end prop value &optional object* [Function]

Add `display` property *prop* of *value* to the text from *start* to *end*.

If any text in the region has a non-`nil` `display` property, those properties are retained. For instance:

```
(add-display-text-property 4 8 'height 2.0)
 (add-display-text-property 2 12 'raise 0.5)
```

After doing this, the region from 2 to 4 will have the `raise` `display` property, the region from 4 to 8 will have both the `raise` and `height` `display` properties, and finally the region from 8 to 12 will only have the `raise` `display` property.

If *object* is non-`nil`, it should be a string or a buffer. If `nil`, this defaults to the current buffer.

Some of the display specifications allow inclusion of Lisp forms, which are evaluated at display time. This could be unsafe in certain situations, e.g., when the display specification was generated by some external program/agent. Wrapping a display specification in a list that begins with the special symbol `disable-eval`, as in `(disable-eval spec)`, will disable evaluation of any Lisp in *spec*, while still supporting all the other display property features.

The rest of this section describes several kinds of display specifications and what they mean.

### 41.16.1 Display Specs That Replace The Text

Some kinds of display specifications specify something to display instead of the text that has the property. These are called *replacing* display specifications. Emacs does not allow the user to interactively move point into the middle of buffer text that is replaced in this way.

If a list of display specifications includes more than one replacing display specification, the first overrides the rest. Replacing display specifications make most other display specifications irrelevant, since those don't apply to the replacement.

For replacing display specifications, *the text that has the property* means all the consecutive characters that have the same Lisp object as their `display` property; these characters are replaced as a single unit. If two characters have different Lisp objects as their `display` properties (i.e., objects which are not `eq`), they are handled separately.

Here is an example which illustrates this point. A string serves as a replacing display specification, which replaces the text that has the property with the specified string (see Section 41.16.4 [Other Display Specs], page 1203). Consider the following function:

```
(defun foo ()
 (dotimes (i 5)
 (let ((string (concat "A")))
 (start (+ i i (point-min))))
 (put-text-property start (1+ start) 'display string)
 (put-text-property start (+ 2 start) 'display string))))
```

This function gives each of the first ten characters in the buffer a `display` property which is a string "A", but they don't all get the same string object. The first two characters get the same string object, so they are replaced with one 'A'; the fact that the `display` property was assigned in two separate calls to `put-text-property` is irrelevant. Similarly, the next two characters get a second string (`concat` creates a new string object), so they are replaced with one 'A'; and so on. Thus, the ten characters appear as five A's.

Note: Using `:box` face attribute (see Section 41.12.1 [Face Attributes], page 1164) on a replacing `display` string that is adjacent to normal text with the same `:box` style can lead to display artifacts when moving the cursor across the text with this face attribute. These can be avoided by applying the `:box` attribute directly to the text being replaced, rather than (or in addition to) the `display` string itself. Here's an example:

```
; ; Causes display artifacts when moving the cursor across text
(progn
 (put-text-property 1 2 'display (propertize " [" 'face '(:box t)))
 (put-text-property 2 3 'face '(:box t))
 (put-text-property 3 4 'display (propertize "] " 'face '(:box t)))

; ; No display artifacts due to `:box'
(progn
 (add-text-properties 1 2 '(face (:box t) display " ["))
 (put-text-property 2 3 'face '(:box t))
 (add-text-properties 3 4 '(face (:box t) display "] ")))
```

## 41.16.2 Specified Spaces

To display a space of specified width and/or height, use a display specification of the form `(space . props)`, where *props* is a property list (a list of alternating properties and values). You can put this property on one or more consecutive characters; a space of the specified height and width is displayed in place of *all* of those characters. These are the properties you can use in *props* to specify the weight of the space:

### `:width width`

If *width* is a number, it specifies that the space width should be *width* times the normal character width. *width* can also be a *pixel width* specification (see Section 41.16.3 [Pixel Specification], page 1201).

### `:relative-width factor`

Specifies that the width of the stretch should be computed from the first character in the group of consecutive characters that have the same `display` property.

The space width is the pixel width of that character, multiplied by *factor*. (On text-mode terminals, the “pixel width” of a character is usually 1, but it could be more for TABs and double-width CJK characters.)

**:align-to *hpos***

Specifies that the space should be wide enough to reach the column *hpos*. If *hpos* is a number, it is a column number, and is measured in units of the canonical character width (see Section 30.3.2 [Frame Font], page 797). *hpos* can also be a *pixel width* specification (see Section 41.16.3 [Pixel Specification], page 1201). When the current line is wider than the window, and is either displayed by one or more continuation lines, or is truncated and possibly scrolled horizontally (see Section 29.23 [Horizontal Scrolling], page 767), *hpos* is measured from the beginning of the logical line, not from the visual beginning of the screen line. This way, alignment produced by **:align-to** is consistent with functions that count columns, such as **current-column** and **move-to-column** (see Section 33.16 [Columns], page 909).

You should use one and only one of the above properties. You can also specify the height of the space, with these properties:

**:height *height***

Specifies the height of the space. If *height* is a number, it specifies that the space height should be *height* times the normal character height. The *height* may also be a *pixel height* specification (see Section 41.16.3 [Pixel Specification], page 1201).

**:relative-height *factor***

Specifies the height of the space, multiplying the ordinary height of the text having this display specification by *factor*.

**:ascent *ascent***

If the value of *ascent* is a non-negative number no greater than 100, it specifies that *ascent* percent of the height of the space should be considered as the ascent of the space—that is, the part above the baseline. The ascent may also be specified in pixel units with a *pixel ascent* specification (see Section 41.16.3 [Pixel Specification], page 1201).

Don’t use both **:height** and **:relative-height** together.

The **:width** and **:align-to** properties are supported on non-graphic terminals, but the other space properties in this section are not.

Note that space properties are treated as paragraph separators for the purposes of reordering bidirectional text for display. See Section 41.27 [Bidirectional Display], page 1250, for the details.

### 41.16.3 Pixel Specification for Spaces

The value of the **:width**, **:align-to**, **:height**, and **:ascent** properties can be a special kind of expression that is evaluated during redisplay. The result of the evaluation is used as an absolute number of pixels.

The following expressions are supported:

```

expr ::= num | (num) | unit | elem | pos | image | xwidget | form
num ::= integer | float | symbol
unit ::= in | mm | cm | width | height
elem ::= left-fringe | right-fringe | left-margin | right-margin
 | scroll-bar | text
pos ::= left | center | right
form ::= (num . expr) | (op expr ...)
op ::= + | -

```

The form *num* specifies a fraction of the default frame font height or width. The form (*num*) specifies an absolute number of pixels. If *num* is a symbol, *symbol*, its buffer-local variable binding is used; that binding can be either a number or a cons cell of the forms shown above (including yet another cons cell whose *car* is a symbol that has a buffer-local binding).

The *in*, *mm*, and *cm* units specify the number of pixels per inch, millimeter, and centimeter, respectively. The *width* and *height* units correspond to the default width and height of the current face. An image specification of the form (*image* . *props*) (see Section 41.17.2 [Image Descriptors], page 1207) corresponds to the width or height of the specified image. Similarly, an xwidget specification of the form (*xwidget* . *props*) stands for the width or height of the specified xwidget. See Section 41.19 [Xwidgets], page 1228.

The elements *left-fringe*, *right-fringe*, *left-margin*, *right-margin*, *scroll-bar*, and *text* specify the width of the corresponding area of the window. When the window displays line numbers (see Section 41.10 [Size of Displayed Text], page 1157), the width of the *text* area is decreased by the screen space taken by the line-number display.

The *left*, *center*, and *right* positions can be used with *:align-to* to specify a position relative to the left edge, center, or right edge of the text area. When the window displays line numbers, and *:align-to* is used in display properties of buffer text (as opposed to header line, see below), the *left* and the *center* positions are offset to account for the screen space taken by the line-number display.

Any of the above window elements (except *text*) can also be used with *:align-to* to specify that the position is relative to the left edge of the given area. Once the base offset for a relative position has been set (by the first occurrence of one of these symbols), further occurrences of these symbols are interpreted as the width of the specified area. For example, to align to the center of the left-margin, use

```
:align-to (+ left-margin (0.5 . left-margin))
```

If no specific base offset is set for alignment, it is always relative to the left edge of the text area. For example, ‘*:align-to 0*’ aligns with the first text column in the text area. When the window displays line numbers, the text is considered to start where the space used for line-number display ends.

A value of the form (*num* . *expr*) stands for the product of the values of *num* and *expr*. For example, (2 . *in*) specifies a width of 2 inches, while (0.5 . *image*) specifies half the width (or height) of the specified *image* (which should be given by its *image spec*).

The form (+ *expr* ...) adds up the value of the expressions. The form (- *expr* ...) negates or subtracts the value of the expressions.

Text shown in the header line that uses *:align-to* display specifications is not automatically realigned when *display-line-numbers-mode* is turned on and off, or when the width of line numbers on display changes. To arrange for the header-line text alignment

to be updated, thus keeping the header-line text aligned with the buffer text, turn on the `header-line-indent-mode` in the buffer and use its two variables, `header-line-indent` and `header-line-indent-width`, in the display specification. See Section 24.4.7 [Header Lines], page 559. Here's a simple example:

```
(setq header-line-format
 (concat (propertize " "
 'display
 '(space :align-to
 (+ header-line-indent-width 10)))
 "Column"))
```

This will keep the text ‘Column’ on the header line aligned with column 10 of buffer text, regardless of whether `display-line-numbers-mode` is on or off, and also when line-number display changes its width.

#### 41.16.4 Other Display Specifications

Here are the other sorts of display specifications that you can use in the `display` text property.

`string`      Display *string* instead of the text that has this property.

Recursive display specifications are not supported—*string*’s `display` properties, if any, are not used.

`(image . image-props)`

This kind of display specification is an image descriptor (see Section 41.17.2 [Image Descriptors], page 1207). When used as a display specification, it means to display the image instead of the text that has the display specification.

`(slice x y width height)`

This specification together with `image` specifies a *slice* (a partial area) of the image to display. The elements *y* and *x* specify the top left corner of the slice, within the image; *width* and *height* specify the width and height of the slice. Integers are numbers of pixels. A floating-point number in the range 0.0–1.0 stands for that fraction of the width or height of the entire image.

`((margin nil) string)`

A display specification of this form means to display *string* instead of the text that has the display specification, at the same position as that text. It is equivalent to using just *string*, but it is done as a special case of marginal display (see Section 41.16.5 [Display Margins], page 1205).

`(left-fringe bitmap [face])`

`(right-fringe bitmap [face])`

This display specification on any character of a line of text causes the specified *bitmap* be displayed in the left or right fringes for that line, instead of the characters that have the display specification. The optional *face* specifies the face whose colors are to be used for the bitmap display. See Section 41.13.4 [Fringe Bitmaps], page 1192, for the details.

**(space-width *factor*)**

This display specification affects all the space characters within the text that has the specification. It displays all of these spaces *factor* times as wide as normal. The element *factor* should be an integer or float. Characters other than spaces are not affected at all; in particular, this has no effect on tab characters.

**(min-width (*width*))**

This display specification ensures the text that has it takes at least *width* space on display, by adding a stretch of white space to the end of the text if the text is shorter than *width*. The text is partitioned using the identity of the parameter, which is why the parameter is a list with one element. For instance:

```
(insert (propertize "foo" 'display '(min-width (6.0))))
```

This will add padding after ‘foo’ bringing the total width up to the width of six normal characters. Note that the affected characters are identified by the (6.0) list in the display property, compared with `eq`. The element *width* can be either an integer or a float specifying the required minimum width of the text (see Section 41.16.3 [Pixel Specification], page 1201).

**(height *height*)**

This display specification makes the text taller or shorter. Here are the possibilities for *height*:

**(+ *n*)** This means to use a font that is *n* steps larger. A *step* is defined by the set of available fonts—specifically, those that match what was otherwise specified for this text, in all attributes except height. Each size for which a suitable font is available counts as another step. *n* should be an integer.

**(- *n*)** This means to use a font that is *n* steps smaller.

a number, *factor*

A number, *factor*, means to use a font that is *factor* times as tall as the default font.

a symbol, *function*

A symbol is a function to compute the height. It is called with the current height as argument, and should return the new height to use.

anything else, *form*

If the *height* value doesn’t fit the previous possibilities, it is a form. Emacs evaluates it to get the new height, with the symbol `height` bound to the current specified font height.

**(raise *factor*)**

This kind of display specification raises or lowers the text it applies to, relative to the baseline of the line. It is mainly meant to support display of subscripts and superscripts.

The *factor* must be a number, which is interpreted as a multiple of the height of the affected text. If it is positive, that means to display the characters raised. If it is negative, that means to display them lower down.

Note that if the text also has a `height` display specification, which was specified before (i.e. to the left of) `raise`, the latter will affect the amount of raising or lowering in pixels, because that is based on the height of the text being raised. Therefore, if you want to display a sub- or superscript that is smaller than the normal text height, consider specifying `raise` before `height`.

You can make any display specification conditional. To do that, package it in another list of the form `(when condition . spec)`. Then the specification `spec` applies only when `condition` evaluates to a non-`nil` value. During the evaluation, `object` is bound to the string or buffer having the conditional `display` property. `position` and `buffer-position` are bound to the position within `object` and the buffer position where the `display` property was found, respectively. Both positions can be different when `object` is a string.

Note that `condition` will only be evaluated when redisplay examines the text where this display spec is located, so this feature is best suited for conditions that are relatively stable, i.e. yield, for each particular buffer position, the same results on every evaluation. If the results change for the same text location, e.g., if the result depends on the position of point, then the conditional specification might not do what you want, because redisplay examines only those parts of buffer text where it has reasons to assume that something changed since the last display cycle.

### 41.16.5 Displaying in the Margins

A buffer can have blank areas called *display margins* on the left and on the right. Ordinary text never appears in these areas, but you can put things into the display margins using the `display` property. There is currently no way to make text or images in the margin mouse-sensitive.

The way to display something in the margins is to specify it in a margin display specification in the `display` property of some text. This is a replacing display specification, meaning that the text you put it on does not get displayed; the margin display appears, but that text does not.

A margin display specification looks like `((margin right-margin) spec)` or `((margin left-margin) spec)`. Here, `spec` is another display specification that says what to display in the margin. Typically it is a string of text to display, or an image descriptor.

To display something in the margin *in association with* certain buffer text, without altering or preventing the display of that text, put on that text an overlay with a `before-string` property, and put the margin display specification on the contents of the before-string.

Note that if the string to be displayed in the margin doesn't specify a face, its face is determined using the same rules and priorities as it is for strings displayed in the text area (see Section 41.12.4 [Displaying Faces], page 1174). If this results in undesirable "leaking" of faces into the margin, make sure the string has an explicit face specified for it.

Before the display margins can display anything, you must give them a nonzero width. The usual way to do that is to set these variables:

`left-margin-width` [Variable]

This variable specifies the width of the left margin, in character cell (a.k.a. "column") units. It is buffer-local in all buffers. A value of `nil` means no left marginal area.

**right-margin-width** [Variable]

This variable specifies the width of the right margin, in character cell units. It is buffer-local in all buffers. A value of `nil` means no right marginal area.

Setting these variables does not immediately affect the window. These variables are checked when a new buffer is displayed in the window. Thus, you can make changes take effect by calling `set-window-buffer`. Do not use these variables to try to determine the current width of the left or right margin. Instead, use the function `window-margins`.

You can also set the margin widths immediately.

**set-window-margins** *window* *left* &**optional** *right* [Function]

This function specifies the margin widths for window *window*, in character cell units. The argument *left* controls the left margin, and *right* controls the right margin (default 0).

If *window* is not large enough to accommodate margins of the desired width, this leaves the margins of *window* unchanged.

The values specified here may be later overridden by invoking `set-window-buffer` (see Section 29.11 [Buffers and Windows], page 720) on *window* with its `keep-margins` argument `nil` or omitted.

**window-margins** &**optional** *window* [Function]

This function returns the width of the left and right margins of *window* as a cons cell of the form `(left . right)`. If one of the two marginal areas does not exist, its width is returned as `nil`; if neither of the two margins exist, the function returns `(nil)`. If *window* is `nil`, the selected window is used.

## 41.17 Images

To display an image in an Emacs buffer, you must first create an image descriptor, then use it as a display specifier in the `display` property of text that is displayed (see Section 41.16 [Display Property], page 1198).

Emacs is usually able to display images when it is run on a graphical terminal. Images cannot be displayed in a text terminal, on certain graphical terminals that lack the support for this, or if Emacs is compiled without image support. You can use the function `display-images-p` to determine if images can in principle be displayed (see Section 30.26 [Display Feature Testing], page 849).

### 41.17.1 Image Formats

Emacs can display a number of different image formats. Some of these image formats are supported only if particular support libraries are installed. On some platforms, Emacs can load support libraries on demand; if so, the variable `dynamic-library-alist` can be used to modify the set of known names for these dynamic libraries. See Section 42.21 [Dynamic Libraries], page 1299.

Supported image formats (and the required support libraries) include PBM and XBM (which do not depend on support libraries and are always available), XPM (`libXpm`), GIF (`libgif` or `libungif`), JPEG (`libjpeg`), TIFF (`libtiff`), PNG (`libpng`), SVG (`librsvg`), and WebP (`libwebp`).

Each of these image formats is associated with an *image type symbol*. The symbols for the above formats are, respectively, `pbm`, `xbm`, `xpm`, `gif`, `jpeg`, `tiff`, `png`, `svg`, and `webp`.

On some platforms, the built-in image support that doesn't require any optional libraries includes BMP images.<sup>3</sup>

Furthermore, if you build Emacs with ImageMagick (`libMagickWand`) support, Emacs can display any image format that ImageMagick can. See Section 41.17.5 [ImageMagick Images], page 1212. All images displayed via ImageMagick have type symbol `imagemagick`.

#### `image-types` [Variable]

This variable contains a list of type symbols for image formats which are potentially supported in the current configuration.

“Potentially” means that Emacs knows about the image types, not necessarily that they can be used (for example, they could depend on unavailable dynamic libraries).

To know which image types are really available, use `image-type-available-p`.

#### `image-type-available-p type` [Function]

This function returns non-`nil` if images of type `type` can be loaded and displayed. `type` must be an image type symbol.

For image types whose support libraries are statically linked, this function always returns `t`. For image types whose support libraries are dynamically loaded, it returns `t` if the library could be loaded and `nil` otherwise.

## 41.17.2 Image Descriptors

An *image descriptor* is a list which specifies the underlying data for an image, and how to display it. It is typically used as the value of a `display` overlay or text property (see Section 41.16.4 [Other Display Specs], page 1203); but See Section 41.17.9 [Showing Images], page 1222, for convenient helper functions to insert images into buffers.

Each image descriptor has the form `(image . props)`, where `props` is a property list of alternating keyword symbols and values, including at least the pair `:type type` that specifies the image type.

Image descriptors which define image dimensions, `:width`, `:height`, `:max-width` and `:max-height`, may take either an integer, which represents the dimension in pixels, or a pair `(value . em)`, where `value` is the dimension's length in `ems`<sup>4</sup>. One em is equivalent to the height of the font and `value` may be an integer or a float.

The following is a list of properties that are meaningful for all image types (there are also properties which are meaningful only for certain image types, as documented in the following subsections):

#### `:type type`

The image type. Every image descriptor must include this property.

#### `:file file`

This says to load the image from file `file`. If `file` is not an absolute file name, it is expanded relative to each of the directories mentioned by `image-load-path` (see Section 41.17.8 [Defining Images], page 1220).

---

<sup>3</sup> On MS-Windows, this requires `w32-use-native-image-API` to be set non-`nil`.

<sup>4</sup> In typography an em is a distance equivalent to the height of the type. For example when using 12 point type 1 em is equal to 12 points. Its use ensures distances and type remain proportional.

**:data data**

This specifies the raw image data. Each image descriptor must have either **:data** or **:file**, but not both.

For most image types, the value of a **:data** property should be a string containing the image data. Some image types do not support **:data**; for some others, **:data** alone is not enough, so you need to use other image properties along with **:data**. See the following subsections for details.

**:margin margin**

This specifies how many pixels to add as an extra margin around the image. The value, *margin*, must be a non-negative number, or a pair (*x . y*) of such numbers. If it is a pair, *x* specifies how many pixels to add horizontally, and *y* specifies how many pixels to add vertically. If **:margin** is not specified, the default is zero.

**:ascent ascent**

This specifies the amount of the image's height to use for its ascent—that is, the part above the baseline. The value, *ascent*, must be a number in the range 0 to 100, or the symbol **center**.

If *ascent* is a number, that percentage of the image's height is used for its ascent.

If *ascent* is **center**, the image is vertically centered around a centerline which would be the vertical centerline of text drawn at the position of the image, in the manner specified by the text properties and overlays that apply to the image.

If this property is omitted, it defaults to 50.

**:relief relief**

This adds a shadow rectangle around the image. The value, *relief*, specifies the width of the shadow lines, in pixels. If *relief* is negative, shadows are drawn so that the image appears as a pressed button; otherwise, it appears as an unpressed button.

**:width width, :height height**

The **:width** and **:height** keywords are used for scaling the image. If only one of them is specified, the other one will be calculated so as to preserve the aspect ratio. If both are specified, aspect ratio may not be preserved.

**:max-width max-width, :max-height max-height**

The **:max-width** and **:max-height** keywords are used for scaling if the size of the image exceeds these values. If **:width** is set, it will have precedence over **max-width**, and if **:height** is set, it will have precedence over **max-height**, but you can otherwise mix these keywords as you wish.

If both **:max-width** and **:height** are specified, but **:width** is not, preserving the aspect ratio might require that width exceeds **:max-width**. If this happens, scaling will use a smaller value for the height so as to preserve the aspect ratio while not exceeding **:max-width**. Similarly when both **:max-height** and **:width** are specified, but **:height** is not. For example, if you have a 200x100 image and specify that **:width** should be 400 and **:max-height** should be 150, you'll end up with an image that is 300x150: Preserving the aspect ratio and not exceeding the “max” setting. This combination of parameters is a useful way of

saying “display this image as large as possible, but no larger than the available display area”.

**:scale scale**

This should be a number, where values higher than 1 means to increase the size, and lower means to decrease the size, by multiplying both the width and height. For instance, a value of 0.25 will make the image a quarter size of what it originally was. If the scaling makes the image larger than specified by `:max-width` or `:max-height`, the resulting size will not exceed those two values. If both `:scale` and `:height/:width` are specified, the height/width will be adjusted by the specified scaling factor.

**:rotation angle**

Specifies a rotation angle in degrees. Only multiples of 90 degrees are supported, unless the image type is `imagemagick`. Positive values rotate clockwise, negative values counter-clockwise. Rotation is performed after scaling and cropping.

**:flip flip**

If this is `t`, the image will be horizontally flipped. Currently it has no effect if the image type is `imagemagick`. Vertical flipping can be achieved by rotating the image 180 degrees and toggling this value.

**:transform-smoothing smooth**

If this is `t`, any image transform will have smoothing applied; if `nil`, no smoothing will be applied. The exact algorithm used is platform dependent, but should be equivalent to bilinear filtering. Disabling smoothing will use the nearest neighbor algorithm.

If this property is not specified, `create-image` will use the `image-transform-smoothing` user option to say whether scaling should be done or not. This option can be `nil` (no smoothing), `t` (use smoothing) or a predicate function that’s called with the image object as the only parameter, and should return either `nil` or `t`. The default is for down-scaling to apply smoothing, and for large up-scaling to not apply smoothing.

**:index frame**

See Section 41.17.10 [Multi-Frame Images], page 1224.

**:conversion algorithm**

This specifies a conversion algorithm that should be applied to the image before it is displayed; the value, `algorithm`, specifies which algorithm.

`laplace`

`emboss` Specifies the Laplace edge detection algorithm, which blurs out small differences in color while highlighting larger differences. People sometimes consider this useful for displaying the image for a disabled button.

`(edge-detection :matrix matrix :color-adjust adjust)`

Specifies a general edge-detection algorithm. `matrix` must be either a nine-element list or a nine-element vector of numbers. A pixel at position  $x/y$  in the transformed image is computed from original

pixels around that position. *matrix* specifies, for each pixel in the neighborhood of  $x/y$ , a factor with which that pixel will influence the transformed pixel; element 0 specifies the factor for the pixel at  $x - 1/y - 1$ , element 1 the factor for the pixel at  $x/y - 1$  etc., as shown below:

$$\begin{pmatrix} x - 1/y - 1 & x/y - 1 & x + 1/y - 1 \\ x - 1/y & x/y & x + 1/y \\ x - 1/y + 1 & x/y + 1 & x + 1/y + 1 \end{pmatrix}$$

The resulting pixel is computed from the color intensity of the color resulting from summing up the RGB values of surrounding pixels, multiplied by the specified factors, and dividing that sum by the sum of the factors' absolute values.

Laplace edge-detection currently uses a matrix of

$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{pmatrix}$$

Emboss edge-detection uses a matrix of

$$\begin{pmatrix} 2 & -1 & 0 \\ -1 & 0 & 1 \\ 0 & 1 & -2 \end{pmatrix}$$

**disabled** Specifies transforming the image so that it looks disabled.

**:mask mask**

If *mask* is `heuristic` or (`heuristic bg`), build a clipping mask for the image, so that the background of a frame is visible behind the image. If *bg* is not specified, or if *bg* is `t`, determine the background color of the image by looking at the four corners of the image, assuming the most frequently occurring color from the corners is the background color of the image. Otherwise, *bg* must be a list (`red green blue`) specifying the color to assume for the background of the image.

If *mask* is `nil`, remove a mask from the image, if it has one. Images in some formats include a mask which can be removed by specifying `:mask nil`.

**:pointer shape**

This specifies the pointer shape when the mouse pointer is over this image. See Section 30.19 [Pointer Shape], page 839, for available pointer shapes.

**:map map** This associates an image map of *hot spots* with this image.

An image map is an alist where each element has the format (`area id plist`). An area is specified as either a rectangle, a circle, or a polygon.

A rectangle is a cons (`rect . ((x0 . y0) . (x1 . y1))`) which specifies the pixel coordinates of the upper left and bottom right corners of the rectangle area.

A circle is a cons (`(circle . ((x0 . y0) . r))`) which specifies the center and the radius of the circle; `r` may be a float or integer.

A polygon is a cons (`(poly . [x0 y0 x1 y1 ...])`) where each pair in the vector describes one corner in the polygon.

When the mouse pointer lies on a hot-spot area of an image, the *plist* of that hot-spot is consulted; if it contains a `help-echo` property, that defines a tool-tip for the hot-spot, and if it contains a `pointer` property, that defines the shape of the mouse cursor when it is on the hot-spot. See Section 30.19 [Pointer Shape], page 839, for available pointer shapes.

When you click the mouse when the mouse pointer is over a hot-spot, an event is composed by combining the `id` of the hot-spot with the mouse event; for instance, `[area4 mouse-1]` if the hot-spot's `id` is `area4`.

Note that the map's coordinates should reflect the displayed image after all transforms have been done (rotation, scaling and so on), and also note that Emacs (by default) performs auto-scaling of images, so to make things match up, you should either specify `:scale 1.0` when creating the image, or use the result of `image-compute-scaling-factor` to compute the elements of the map.

#### **image-mask-p** *spec* &**optional** *frame* [Function]

This function returns `t` if image *spec* has a mask bitmap. *frame* is the frame on which the image will be displayed. *frame nil* or omitted means to use the selected frame (see Section 30.10 [Input Focus], page 824).

#### **image-transforms-p** &**optional** *frame* [Function]

This function returns non-`nil` if *frame* supports image scaling and rotation. *frame nil* or omitted means to use the selected frame (see Section 30.10 [Input Focus], page 824). The returned list includes symbols that indicate which image transform operations are supported:

**scale** Image scaling is supported by *frame* via the `:scale`, `:width`, `:height`, `:max-width`, and `:max-height` properties.

**rotate90** Image rotation is supported by *frame* if the rotation angle is an integral multiple of 90 degrees.

If image transforms are not supported, `:rotation`, `:crop`, `:width`, `:height`, `:scale`, `:max-width` and `:max-height` will only be usable through ImageMagick, if available (see Section 41.17.5 [ImageMagick Images], page 1212).

### 41.17.3 XBM Images

To use XBM format, specify `xbm` as the image type. This image format doesn't require an external library, so images of this type are always supported.

Additional image properties supported for the `xbm` image type are:

#### **:foreground** *foreground*

The value, *foreground*, should be a string specifying the image foreground color, or `nil` for the default color. This color is used for each pixel in the XBM that is 1. The default is the frame's foreground color.

**:background *background***

The value, *background*, should be a string specifying the image background color, or `nil` for the default color. This color is used for each pixel in the XBM that is 0. The default is the frame's background color.

If you specify an XBM image using data within Emacs instead of an external file, use the following three properties:

**:data *data***

The value, *data*, specifies the contents of the image. There are three formats you can use for *data*:

- A vector of strings or bool-vectors, each specifying one line of the image. Do specify `:data-height` and `:data-width`.
- A string containing the same byte sequence as an XBM file would contain.
- A string or a bool-vector containing the bits of the image (plus perhaps some extra bits at the end that will not be used). It should contain at least `stride * height` bits, where *stride* is the smallest multiple of 8 greater than or equal to the width of the image. In this case, you should specify `:data-height`, `:data-width` and `:stride`, both to indicate that the string contains just the bits rather than a whole XBM file, and to specify the size of the image.

**:stride *stride***

The number of bool vector entries stored for each row; the smallest multiple of 8 greater than or equal to *width*.

#### 41.17.4 XPM Images

To use XPM format, specify `xpm` as the image type. The additional image property `:color-symbols` is also meaningful with the `xpm` image type:

**:color-symbols *symbols***

The value, *symbols*, should be an alist whose elements have the form `(name . color)`. In each element, *name* is the name of a color as it appears in the image file, and *color* specifies the actual color to use for displaying that name.

#### 41.17.5 ImageMagick Images

If your Emacs build has ImageMagick support, you can use the ImageMagick library to load many image formats (see Section “File Conveniences” in *The GNU Emacs Manual*). The image type symbol for images loaded via ImageMagick is `imagemagick`, regardless of the actual underlying image format.

To check for ImageMagick support, use the following:

```
(image-type-available-p 'imagemagick)
```

**imagemagick-types**

[Function]

This function returns a list of image file extensions supported by the current ImageMagick installation. Each list element is a symbol representing an internal ImageMagick name for an image type, such as `BMP` for `.bmp` images.

**imagemagick-enabled-types** [User Option]

The value of this variable is a list of ImageMagick image types which Emacs may attempt to render using ImageMagick. Each list element should be one of the symbols in the list returned by `imagemagick-types`, or an equivalent string. Alternatively, a value of `t` enables ImageMagick for all possible image types. Regardless of the value of this variable, `imagemagick-types-inhibit` (see below) takes precedence.

**imagemagick-types-inhibit** [User Option]

The value of this variable lists the ImageMagick image types which should never be rendered using ImageMagick, regardless of the value of `imagemagick-enabled-types`. A value of `t` disables ImageMagick entirely.

**image-format-suffixes** [Variable]

This variable is an alist mapping image types to file name extensions. Emacs uses this in conjunction with the `:format` image property (see below) to give a hint to the ImageMagick library as to the type of an image. Each element has the form `(type extension)`, where `type` is a symbol specifying an image content-type, and `extension` is a string that specifies the associated file name extension.

Images loaded with ImageMagick support the following additional image descriptor properties:

**:background *background***

`background`, if non-`nil`, should be a string specifying a color, which is used as the image's background color if the image supports transparency. If the value is `nil`, it defaults to the frame's background color.

**:format *type***

The value, `type`, should be a symbol specifying the type of the image data, as found in `image-format-suffixes`. This is used when the image does not have an associated file name, to provide a hint to ImageMagick to help it detect the image type.

**:crop *geometry***

The value of `geometry` should be a list of the form `(width height x y)`. `width` and `height` specify the width and height of the cropped image. If `x` is a positive number it specifies the offset of the cropped area from the left of the original image, and if negative the offset from the right. If `y` is a positive number it specifies the offset from the top of the original image, and if negative from the bottom. If `x` or `y` are `nil` or unspecified the crop area will be centered on the original image.

If the crop area is outside or overlaps the edge of the image it will be reduced to exclude any areas outside of the image. This means it is not possible to use `:crop` to increase the size of the image by entering large `width` or `height` values.

Cropping is performed after scaling but before rotation.

## 41.17.6 SVG Images

SVG (Scalable Vector Graphics) is an XML format for specifying images. SVG images support the following additional image descriptor properties:

**:foreground *foreground***

*foreground*, if non-`nil`, should be a string specifying a color, which is used as the image's foreground color. If the value is `nil`, it defaults to the current face's foreground color.

**:background *background***

*background*, if non-`nil`, should be a string specifying a color, which is used as the image's background color if the image supports transparency. If the value is `nil`, it defaults to the current face's background color.

**:css *css*** *css*, if non-`nil`, should be a string specifying the CSS to override the default CSS used when generating the image.

## SVG library

If your Emacs build has SVG support, you can create and manipulate these images with the following functions from the `svg.el` library.

**svg-create *width height &rest args*** [Function]

Create a new, empty SVG image with the specified dimensions. *args* is an argument plist with you can specify following:

**:stroke-width**

The default width (in pixels) of any lines created.

**:stroke** The default stroke color on any lines created.

This function returns an *SVG object*, a Lisp data structure that specifies an SVG image, and all the following functions work on that structure. The argument `svg` in the following functions specifies such an SVG object.

**svg-gradient *svg id type stops*** [Function]

Create a gradient in `svg` with identifier `id`. `type` specifies the gradient type, and can be either `linear` or `radial`. `stops` is a list of percentage/color pairs.

The following will create a linear gradient that goes from red at the start, to green 25% of the way, to blue at the end:

```
(svg-gradient svg "gradient1" 'linear
 '((0 . "red") (25 . "green") (100 . "blue")))
```

The gradient created (and inserted into the SVG object) can later be used by all functions that create shapes.

All the following functions take an optional list of keyword parameters that alter the various attributes from their default values. Valid attributes include:

**:stroke-width**

The width (in pixels) of lines drawn, and outlines around solid shapes.

**:stroke-color**

The color of lines drawn, and outlines around solid shapes.

**:fill-color**

The color used for solid shapes.

**:id** The identifier of the shape.

**:gradient**

If given, this should be the identifier of a previously defined gradient object.

**:clip-path**

Identifier of a clip path.

**svg-rectangle** *svg x y width height &rest args* [Function]

Add to *svg* a rectangle whose upper left corner is at position *x/y* and whose size is *width/height*.

```
(svg-rectangle svg 100 100 500 500 :gradient "gradient1")
```

**svg-circle** *svg x y radius &rest args* [Function]

Add to *svg* a circle whose center is at *x/y* and whose radius is *radius*.

**svg-ellipse** *svg x y x-radius y-radius &rest args* [Function]

Add to *svg* an ellipse whose center is at *x/y*, and whose horizontal radius is *x-radius* and the vertical radius is *y-radius*.

**svg-line** *svg x1 y1 x2 y2 &rest args* [Function]

Add to *svg* a line that starts at *x1/y1* and extends to *x2/y2*.

**svg-polyline** *svg points &rest args* [Function]

Add to *svg* a multiple-segment line (a.k.a. “polyline”) that goes through *points*, which is a list of X/Y position pairs.

```
(svg-polyline svg '((200 . 100) (500 . 450) (80 . 100))
 :stroke-color "green")
```

**svg-polygon** *svg points &rest args* [Function]

Add a polygon to *svg* where *points* is a list of X/Y pairs that describe the outer circumference of the polygon.

```
(svg-polygon svg '((100 . 100) (200 . 150) (150 . 90))
 :stroke-color "blue" :fill-color "red")
```

**svg-path** *svg commands &rest args* [Function]

Add the outline of a shape to *svg* according to *commands*, see [SVG Path Commands], page 1217.

Coordinates by default are absolute. To use coordinates relative to the last position, or – initially – to the origin, set the attribute *:relative* to *t*. This attribute can be specified for the function or for individual commands. If specified for the function, then all commands use relative coordinates by default. To make an individual command use absolute coordinates, set *:relative* to *nil*.

```
(svg-path svg
 '((moveto ((100 . 100)))
 (lineto ((200 . 0) (0 . 200) (-200 . 0)))
 (lineto ((100 . 100)) :relative nil))
 :stroke-color "blue"
 :fill-color "lightblue"
 :relative t)
```

**svg-text** *svg* *text* &**rest** *args* [Function]

Add the specified *text* to *svg*.

```
(svg-text
 svg "This is a text"
 :font-size "40"
 :font-weight "bold"
 :stroke "black"
 :fill "white"
 :font-family "impact"
 :letter-spacing "4pt"
 :x 300
 :y 400
 :stroke-width 1)
```

**svg-embed** *svg* *image* *image-type* *datap* &**rest** *args* [Function]

Add an embedded (raster) image to *svg*. If *datap* is *nil*, *image* should be a file name; otherwise it should be a string containing the image data as raw bytes. *image-type* should be a MIME image type, for instance "image/jpeg".

```
(svg-embed svg "~/rms.jpg" "image/jpeg" nil
 :width "100px" :height "100px"
 :x "50px" :y "75px")
```

**svg-embed-base-uri-image** *svg* *relative-filename* &**rest** *args* [Function]

To *svg* add an embedded (raster) image placed at *relative-filename*. *relative-filename* is searched inside *file-name-directory* of the *:base-uri* *svg* image property. *:base-uri* specifies a (possibly non-existing) file name of the *svg* image to be created, thus all the embedded files are searched relatively to the *:base-uri* *filename*'s directory. If *:base-uri* is omitted, then *filename* from where *svg* image is loaded is used. Using *:base-uri* improves the performance of embedding large images, comparing to **svg-embed**, because all the work is done directly by librsvg.

```
; ; Embedding /tmp/subdir/rms.jpg and /tmp/another/rms.jpg
(svg-embed-base-uri-image svg "subdir/rms.jpg"
 :width "100px" :height "100px"
 :x "50px" :y "75px")
(svg-embed-base-uri-image svg "another/rms.jpg"
 :width "100px" :height "100px"
 :x "75px" :y "50px")
(svg-image svg :scale 1.0
 :base-uri "/tmp/dummy"
 :width 175 :height 175)
```

**svg-clip-path** *svg* &**rest** *args* [Function]

Add a clipping path to *svg*. If applied to a shape via the *:clip-path* property, parts of that shape which lie outside of the clipping path are not drawn.

```
(let ((clip-path (svg-clip-path svg :id "foo")))
 (svg-circle clip-path 200 200 175))
 (svg-rectangle svg 50 50 300 300)
```

```

 :fill-color "red"
 :clip-path "url(#foo)")

svg-node svg tag &rest args [Function]
 Add the custom node tag to svg.
 (svg-node svg
 'rect
 :width 300 :height 200 :x 50 :y 100 :fill-color "green")

svg-remove svg id [Function]
 Remove the element with identifier id from the svg.

svg-image svg [Function]
 Finally, the svg-image takes an SVG object as its argument and returns an image
 object suitable for use in functions like insert-image.

Here's a complete example that creates and inserts an image with a circle:
(let ((svg (svg-create 400 400 :stroke-width 10)))
 (svg-gradient svg "gradient1" 'linear '((0 . "red") (100 . "blue")))
 (svg-circle svg 200 200 100 :gradient "gradient1"
 :stroke-color "green")
 (insert-image (svg-image svg)))

```

## SVG Path Commands

SVG *paths* allow creation of complex images by combining lines, curves, arcs, and other basic shapes. The functions described below allow invoking SVG path commands from a Lisp program.

**moveto** *points* [Command]
 Move the pen to the first point in *points*. Additional points are connected with lines.
 *points* is a list of X/Y coordinate pairs. Subsequent **moveto** commands represent the
 start of a new *subpath*.
 (svg-path *svg* '((moveto ((200 . 100) (100 . 200) (0 . 100))))
 :fill "white" :stroke "black")

**closepath** [Command]
 End the current subpath by connecting it back to its initial point. A line is drawn
 along the connection.
 (svg-path *svg* '((moveto ((200 . 100) (100 . 200) (0 . 100)))
 (closepath)
 (moveto ((75 . 125) (100 . 150) (125 . 125)))
 (closepath))
 :fill "red" :stroke "black")

**lineto** *points* [Command]
 Draw a line from the current point to the first element in *points*, a list of X/Y position
 pairs. If more than one point is specified, draw a polyline.
 (svg-path *svg* '((moveto ((200 . 100)))
 (lineto ((100 . 200) (0 . 100))))
 :fill "yellow" :stroke "red")

**horizontal-lineto** *x-coordinates* [Command]

Draw a horizontal line from the current point to the first element in *x-coordinates*. Specifying multiple coordinates is possible, although this usually doesn't make sense.

```
(svg-path svg '((moveto ((100 . 200)))
 (horizontal-lineto (300)))
 :stroke "green")
```

**vertical-lineto** *y-coordinates* [Command]

Draw vertical lines.

```
(svg-path svg '((moveto ((200 . 100)))
 (vertical-lineto (300)))
 :stroke "green")
```

**curveto** *coordinate-sets* [Command]

Using the first element in *coordinate-sets*, draw a cubic Bézier curve from the current point. If there are multiple coordinate sets, draw a polybezier. Each coordinate set is a list of the form  $(x_1 \ y_1 \ x_2 \ y_2 \ x \ y)$ , where  $(x, y)$  is the curve's end point.  $(x_1, y_1)$  and  $(x_2, y_2)$  are control points at the beginning and at the end, respectively.

```
(svg-path svg '((moveto ((100 . 100)))
 (curveto ((200 100 100 200 200 200)
 (300 200 0 100 100 100))))
 :fill "transparent" :stroke "red")
```

**smooth-curveto** *coordinate-sets* [Command]

Using the first element in *coordinate-sets*, draw a cubic Bézier curve from the current point. If there are multiple coordinate sets, draw a polybezier. Each coordinate set is a list of the form  $(x_2 \ y_2 \ x \ y)$ , where  $(x, y)$  is the curve's end point and  $(x_2, y_2)$  is the corresponding control point. The first control point is the reflection of the second control point of the previous command relative to the current point, if that command was **curveto** or **smooth-curveto**. Otherwise the first control point coincides with the current point.

```
(svg-path svg '((moveto ((100 . 100)))
 (curveto ((200 100 100 200 200 200)))
 (smooth-curveto ((0 100 100 100))))
 :fill "transparent" :stroke "blue")
```

**quadratic-bezier-curveto** *coordinate-sets* [Command]

Using the first element in *coordinate-sets*, draw a quadratic Bézier curve from the current point. If there are multiple coordinate sets, draw a polybezier. Each coordinate set is a list of the form  $(x_1 \ y_1 \ x \ y)$ , where  $(x, y)$  is the curve's end point and  $(x_1, y_1)$  is the control point.

```
(svg-path svg '((moveto ((200 . 100)))
 (quadratic-bezier-curveto ((300 100 300 200)))
 (quadratic-bezier-curveto ((300 300 200 300)))
 (quadratic-bezier-curveto ((100 300 100 200)))
 (quadratic-bezier-curveto ((100 100 200 100))))
 :fill "transparent" :stroke "pink")
```

**smooth-quadratic-bezier-curveto** coordinate-sets [Command]

Using the first element in *coordinate-sets*, draw a quadratic Bézier curve from the current point. If there are multiple coordinate sets, draw a polybezier. Each coordinate set is a list of the form *(x y)*, where *(x, y)* is the curve's end point. The control point is the reflection of the control point of the previous command relative to the current point, if that command was **quadratic-bezier-curveto** or **smooth-quadratic-bezier-curveto**. Otherwise the control point coincides with the current point.

```
(svg-path svg '((moveto ((200 . 100)))
 (quadratic-bezier-curveto ((300 100 300 200)))
 (smooth-quadratic-bezier-curveto ((200 300)))
 (smooth-quadratic-bezier-curveto ((100 200)))
 (smooth-quadratic-bezier-curveto ((200 100))))
 :fill "transparent" :stroke "lightblue")
```

**elliptical-arc** coordinate-sets [Command]

Using the first element in *coordinate-sets*, draw an elliptical arc from the current point. If there are multiple coordinate sets, draw a sequence of elliptical arcs. Each coordinate set is a list of the form *(rx ry x y)*, where *(x, y)* is the end point of the ellipse, and *(rx, ry)* are its radii. Attributes may be appended to the list:

**:x-axis-rotation**

The angle in degrees by which the x-axis of the ellipse is rotated relative to the x-axis of the current coordinate system.

**:large-arc**

If set to *t*, draw an arc sweep greater than or equal to 180 degrees. Otherwise, draw an arc sweep smaller than or equal to 180 degrees.

**:sweep**

If set to *t*, draw an arc in *positive angle direction*. Otherwise, draw it in *negative angle direction*.

```
(svg-path svg '((moveto ((200 . 250)))
 (elliptical-arc ((75 75 200 350))))
 :fill "transparent" :stroke "red")
(svg-path svg '((moveto ((200 . 250)))
 (elliptical-arc ((75 75 200 350 :large-arc t))))
 :fill "transparent" :stroke "green")
(svg-path svg '((moveto ((200 . 250)))
 (elliptical-arc ((75 75 200 350 :sweep t))))
 :fill "transparent" :stroke "blue")
(svg-path svg '((moveto ((200 . 250)))
 (elliptical-arc ((75 75 200 350 :large-arc t
 :sweep t))))
 :fill "transparent" :stroke "gray")
(svg-path svg '((moveto ((160 . 100)))
 (elliptical-arc ((40 100 80 0)))
 (elliptical-arc ((40 100 -40 -70
 :x-axis-rotation -120)))
 (elliptical-arc ((40 100 -40 70
```

```
:x-axis-rotation -240))))
:stroke "pink" :fill "lightblue"
:relative t)
```

### 41.17.7 Other Image Types

For PBM images, specify image type `pbm`. Color, gray-scale and monochromatic images are supported. For mono PBM images, two additional image properties are supported.

`:foreground foreground`

The value, `foreground`, should be a string specifying the image foreground color, or `nil` for the default color. This color is used for each pixel in the PBM that is 1. The default is the frame's foreground color.

`:background background`

The value, `background`, should be a string specifying the image background color, or `nil` for the default color. This color is used for each pixel in the PBM that is 0. The default is the frame's background color.

The remaining image types that Emacs can support are:

|      |                                                                                                                                 |
|------|---------------------------------------------------------------------------------------------------------------------------------|
| GIF  | Image type <code>gif</code> . Supports the <code>:index</code> property. See Section 41.17.10 [Multi-Frame Images], page 1224.  |
| JPEG | Image type <code>jpeg</code> .                                                                                                  |
| PNG  | Image type <code>png</code> .                                                                                                   |
| TIFF | Image type <code>tiff</code> . Supports the <code>:index</code> property. See Section 41.17.10 [Multi-Frame Images], page 1224. |
| WebP | Image type <code>webp</code> .                                                                                                  |

### 41.17.8 Defining Images

The functions `create-image`, `defimage` and `find-image` provide convenient ways to create image descriptors.

`create-image file-or-data &optional type data-p &rest props` [Function]

This function creates and returns an image descriptor which uses the data in `file-or-data`. `file-or-data` can be a file name or a string containing the image data; `data-p` should be `nil` for the former case, non-`nil` for the latter case. If `file-or-data` is a relative file name, the function will search for it in directories mentioned in `image-load-path`.

The optional argument `type` is a symbol specifying the image type. If `type` is omitted or `nil`, `create-image` tries to determine the image type from the file's first few bytes, or else from the file's name.

The remaining arguments, `props`, specify additional image properties—for example,

```
(create-image "foo.xpm" 'xpm nil :mask 'heuristic)
```

See Section 41.17.2 [Image Descriptors], page 1207, for the list of supported properties. Some properties are specific to certain image types, and are described in subsections specific to those types.

The function returns `nil` if images of this type are not supported. Otherwise it returns an image descriptor.

**defimage** *symbol* *specs* &**optional** *doc* [Macro]

This macro defines *symbol* as an image name. The arguments *specs* is a list which specifies how to display the image. The third argument, *doc*, is an optional documentation string.

Each argument in *specs* has the form of a property list, and each one should specify at least the **:type** property and either the **:file** or the **:data** property. The value of **:type** should be a symbol specifying the image type, the value of **:file** is the file to load the image from, and the value of **:data** is a string containing the actual image data. Here is an example:

```
(defimage test-image
 ((:type xpm :file "~/test1.xpm")
 (:type xbm :file "~/test1.xbm")))
```

**defimage** tests each argument, one by one, to see if it is usable—that is, if the type is supported and the file exists. The first usable argument is used to make an image descriptor which is stored in *symbol*.

If none of the alternatives will work, then *symbol* is defined as **nil**.

**image-property** *image* *property* [Function]

Return the value of *property* in *image*. Properties can be set by using **setf**. Setting a property to **nil** will remove the property from the image.

**find-image** *specs* [Function]

This function provides a convenient way to find an image satisfying one of a list of image specifications *specs*.

Each specification in *specs* is a property list with contents depending on image type. All specifications must at least contain the properties **:type** *type* and either **:file** *file* or **:data** *data*, where *type* is a symbol specifying the image type, e.g., **xbm**, *file* is the file to load the image from, and *data* is a string containing the actual image data. The first specification in the list whose *type* is supported, and *file* exists, is used to construct the image specification to be returned. If no specification is satisfied, **nil** is returned.

The image is looked for in **image-load-path**.

**image-load-path** [User Option]

This variable's value is a list of locations in which to search for image files. If an element is a string or a variable symbol whose value is a string, the string is taken to be the name of a directory to search. If an element is a variable symbol whose value is a list, that is taken to be a list of directories to search.

The default is to search in the **images** subdirectory of the directory specified by **data-directory**, then the directory specified by **data-directory**, and finally in the directories in **load-path**. Subdirectories are not automatically included in the search, so if you put an image file in a subdirectory, you have to supply the subdirectory explicitly. For example, to find the image **images/foo/bar.xpm** within **data-directory**, you should specify the image as follows:

```
(defimage foo-image '((:type xpm :file "foo/bar.xpm")))
```

**image-load-path-for-library** *library image &optional path no-error* [Function]

This function returns a suitable search path for images used by the Lisp package *library*.

The function searches for *image* first using **image-load-path**, excluding **data-directory/images**, and then in **load-path**, followed by a path suitable for *library*, which includes *../etc/images* and *etc/images* relative to the library file itself, and finally in **data-directory/images**.

Then this function returns a list of directories which contains first the directory in which *image* was found, followed by the value of **load-path**. If *path* is given, it is used instead of **load-path**.

If *no-error* is non-**nil** and a suitable path can't be found, don't signal an error. Instead, return a list of directories as before, except that **nil** appears in place of the image directory.

Here is an example of using **image-load-path-for-library**:

```
(defvar image-load-path) ; shush compiler
(let* ((load-path (image-load-path-for-library
 "mh-e" "mh-logo.xpm"))
 (image-load-path (cons (car load-path)
 image-load-path)))
 (mh-tool-bar-folder-buttons-init))
```

Images are automatically scaled when created based on the **image-scaling-factor** variable. The value is either a floating point number (where numbers higher than 1 means to increase the size and lower means to shrink the size), or the symbol **auto**, which will compute a scaling factor based on the font pixel size.

### 41.17.9 Showing Images

You can use an image descriptor by setting up the **display** property yourself, but it is easier to use the functions in this section.

**insert-image** *image &optional string area slice inhibit-isearch* [Function]

This function inserts *image* in the current buffer at point. The value *image* should be an image descriptor; it could be a value returned by **create-image**, or the value of a symbol defined with **defimage**. The argument *string* specifies the text to put in the buffer to hold the image. If it is omitted or **nil**, **insert-image** uses " " by default.

The argument *area* specifies whether to put the image in a margin. If it is **left-margin**, the image appears in the left margin; **right-margin** specifies the right margin. If *area* is **nil** or omitted, the image is displayed at point within the buffer's text.

The argument *slice* specifies a slice of the image to insert. If *slice* is **nil** or omitted the whole image is inserted. (However, note that images are chopped on display at the window's right edge, because wrapping images is not supported.) Otherwise, *slice* is a list (*x y width height*) which specifies the *x* and *y* positions and *width* and *height* of the image area to insert. Integer values are in units of pixels. A floating-point number in the range 0.0–1.0 stands for that fraction of the width or height of the entire image.

Internally, this function inserts *string* in the buffer, and gives it a `display` property which specifies *image*. See Section 41.16 [Display Property], page 1198. By default, doing interactive searches in the buffer will consider *string* when searching. If `inhibit-isearch` is non-`nil`, this is inhibited.

**insert-sliced-image** *image &optional string area rows cols* [Function]

This function inserts *image* in the current buffer at point, like `insert-image`, but splits the image into *rows**cols* equally sized slices.

Emacs displays each slice as a separate image, and allows more intuitive scrolling up/down, instead of jumping up/down the entire image when paging through a buffer that displays (large) images.

**put-image** *image pos &optional string area* [Function]

This function puts *image* in front of *pos* in the current buffer. The argument *pos* should be an integer or a marker. It specifies the buffer position where the image should appear. The argument *string* specifies the text that should hold the image as an alternative to the default ‘x’.

The argument *image* must be an image descriptor, perhaps returned by `create-image` or stored by `defimage`.

The argument *area* specifies whether to put the image in a margin. If it is `left-margin`, the image appears in the left margin; `right-margin` specifies the right margin. If *area* is `nil` or omitted, the image is displayed at point within the buffer’s text.

Internally, this function creates an overlay, and gives it a `before-string` property containing text that has a `display` property whose value is the image. (Whew! that was a mouthful...)

**remove-images** *start end &optional buffer* [Function]

This function removes images in *buffer* between positions *start* and *end*. If *buffer* is omitted or `nil`, images are removed from the current buffer.

This removes only images that were put into *buffer* the way `put-image` does it, not images that were inserted with `insert-image` or in other ways.

**image-size** *spec &optional pixels frame* [Function]

This function returns the size of an image as a pair (`width . height`). *spec* is an image specification. `pixels non-nil` means return sizes measured in pixels, otherwise return sizes measured in the default character size of *frame* (see Section 30.3.2 [Frame Font], page 797). *frame* is the frame on which the image will be displayed. *frame nil* or omitted means use the selected frame (see Section 30.10 [Input Focus], page 824).

**max-image-size** [Variable]

This variable is used to define the maximum size of image that Emacs will load. Emacs will refuse to load (and display) any image that is larger than this limit.

If the value is an integer, it directly specifies the maximum image height and width, measured in pixels. If it is floating point, it specifies the maximum image height and width as a ratio to the frame height and width. If the value is non-numeric, there is no explicit limit on the size of images.

The purpose of this variable is to prevent unreasonably large images from accidentally being loaded into Emacs. It only takes effect the first time an image is loaded. Once an image is placed in the image cache, it can always be displayed, even if the value of `max-image-size` is subsequently changed (see Section 41.17.11 [Image Cache], page 1225).

**image-at-point-p** [Function]

This function returns `t` if point is on an image, and `nil` otherwise.

Images inserted with the insertion functions above also get a local keymap installed in the text properties (or overlays) that span the displayed image. This keymap defines the following commands:

|                  |                                                                          |
|------------------|--------------------------------------------------------------------------|
| <code>i +</code> | Increase the image size ( <code>image-increase-size</code> ).            |
| <code>i -</code> | Decrease the image size ( <code>image-decrease-size</code> ).            |
| <code>i r</code> | Rotate the image ( <code>image-rotate</code> ).                          |
| <code>i h</code> | Flip the image horizontally ( <code>image-flip-horizontally</code> ).    |
| <code>i v</code> | Flip the image vertically ( <code>image-flip-vertically</code> ).        |
| <code>i o</code> | Save the image to a file ( <code>image-save</code> ).                    |
| <code>i c</code> | Interactively crop the image ( <code>image-crop</code> ).                |
| <code>i x</code> | Interactively cut a rectangle from the image ( <code>image-cut</code> ). |

See Section “Image Mode” in *The GNU Emacs Manual*, for more details about these image-specific key bindings.

### 41.17.10 Multi-Frame Images

Some image files can contain more than one image. We say that there are multiple “frames” in the image. At present, Emacs supports multiple frames for GIF, TIFF, and certain ImageMagick formats such as DJVM.

The frames can be used either to represent multiple pages (this is usually the case with multi-frame TIFF files, for example), or to create animation (usually the case with multi-frame GIF files).

A multi-frame image has a property `:index`, whose value is an integer (counting from 0) that specifies which frame is being displayed.

**image-multi-frame-p *image*** [Function]

This function returns non-`nil` if *image* contains more than one frame. The actual return value is a cons (`nimages . delay`), where *nimages* is the number of frames and *delay* is the delay in seconds between them, or `nil` if the image does not specify a delay. Images that are intended to be animated usually specify a frame delay, whereas ones that are intended to be treated as multiple pages do not.

**image-current-frame *image*** [Function]

This function returns the index of the current frame number for *image*, counting from 0.

**image-show-frame** *image n &optional nocheck* [Function]

This function switches *image* to frame number *n*. It replaces a frame number outside the valid range with that of the end of the range, unless *nocheck* is non-*nil*. If *image* does not contain a frame with the specified number, the image displays as a hollow box.

**image-animate** *image &optional index limit* [Function]

This function animates *image*. The optional integer *index* specifies the frame from which to start (default 0). The optional argument *limit* controls the length of the animation. If omitted or *nil*, the image animates once only; if *t* it loops forever; if a number animation stops after that many seconds.

Animation operates by means of a timer. Note that Emacs imposes a minimum frame delay of 0.01 (`(image-minimum-frame-delay)`) seconds. If the image itself does not specify a delay, Emacs uses `image-default-frame-delay`.

**image-animate-timer** *image* [Function]

This function returns the timer responsible for animating *image*, if there is one.

### 41.17.11 Image Cache

Emacs caches images so that it can display them again more efficiently. When Emacs displays an image, it searches the image cache for an existing image specification `equal` to the desired specification. If a match is found, the image is displayed from the cache. Otherwise, Emacs loads the image normally.

**image-flush** *spec &optional frame* [Function]

This function removes the image with specification *spec* from the image cache of frame *frame*. Image specifications are compared using `equal`. If *frame* is *nil*, it defaults to the selected frame. If *frame* is *t*, the image is flushed on all existing frames.

In Emacs's current implementation, each graphical terminal possesses an image cache, which is shared by all the frames on that terminal (see Section 30.2 [Multiple Terminals], page 787). Thus, refreshing an image in one frame also refreshes it in all other frames on the same terminal.

One use for `image-flush` is to tell Emacs about a change in an image file. If an image specification contains a `:file` property, the image is cached based on the file's contents when the image is first displayed. Even if the file subsequently changes, Emacs continues displaying the old version of the image. Calling `image-flush` flushes the image from the cache, forcing Emacs to re-read the file the next time it needs to display that image.

Another use for `image-flush` is for memory conservation. If your Lisp program creates a large number of temporary images over a period much shorter than `image-cache-eviction-delay` (see below), you can opt to flush unused images yourself, instead of waiting for Emacs to do it automatically.

**clear-image-cache** *&optional filter* [Function]

This function clears an image cache, removing all the images stored in it. If *filter* is omitted or *nil*, it clears the cache for the selected frame. If *filter* is a frame, it clears the cache for that frame. If *filter* is *t*, all image caches are cleared. Otherwise, *filter*

is taken to be a file name, and all images associated with that file name are removed from all image caches.

If an image in the image cache has not been displayed for a specified period of time, Emacs removes it from the cache and frees the associated memory.

### **image-cache-eviction-delay**

[Variable]

This variable specifies the number of seconds an image can remain in the cache without being displayed. When an image is not displayed for this length of time, Emacs removes it from the image cache.

Under some circumstances, if the number of images in the cache grows too large, the actual eviction delay may be shorter than this.

If the value is `nil`, Emacs does not remove images from the cache except when you explicitly clear it. This mode can be useful for debugging.

### **image-cache-size**

[Function]

This function returns the total size of the current image cache, in bytes. An image of size 200x100 with 24 bits per color will have a cache size of 60000 bytes, for instance.

## 41.18 Icons

Emacs sometimes uses buttons (for clicking on) or small graphics (to illustrate something). Since Emacs is available on a wide variety of systems with different capabilities, and users have different preferences, Emacs provides a facility to handle this in a convenient way, allowing customization, graceful degradation, accessibility, as well as themability: *Icons*.

The central macro here is `define-icon`, and here's a simple example:

```
(define-icon outline-open button
 '((image "right.svg" "open.xpm" "open.pbm" :height line)
 (emoji ""))
 (symbol ""))
 (text "open" :face icon-button))
"Icon used for buttons for opening a section in outline buffers."
:version "29.1"
:help-echo "Open this section")
```

Which alternative will actually be displayed depends on the value of the user option `icon-preference` (see Section “Icons” in *The GNU Emacs Manual*) and on the results of run-time checks for what the current frame’s terminal can actually display.

The macro in the example above defines `outline-open` as an icon, and inherits properties from the icon called `button` (so this is meant as a clickable button to be inserted in a buffer). It is followed by a list of `icon` types along with the actual icon shapes themselves. In addition, there’s a doc string and various keywords that contain additional information and properties.

To instantiate an icon, you use `icon-string`, which will consult the current Customize theming, and the `icon-preference` user option, and finally what the Emacs is able to actually display. If `icon-preference` is `(image emoji symbol text)` (i.e., allowing all of these forms of icons), in this case, `icon-string` will first check that Emacs is able to display images at all, and then whether it has support for each of those different image formats. If that fails, Emacs will check whether Emacs can display emojis (in the current frame). If

that fails, it'll check whether it can display the symbol in question. If that fails, it'll use the plain text version.

For instance, if `icon-preference` doesn't contain `image` or `emoji`, it'll skip those entries.

Code can confidently call `icon-string` in all circumstances and be sure that something readable will appear on the screen, no matter whether the user is on a graphical terminal or a text terminal, and no matter which features Emacs was built with.

**define-icon** *name parent specs doc &rest keywords* [Macro]

Define an icon *name*, a symbol, with the display alternatives in *spec*, that can be later instantiated using `icon-string`. The *name* is the name of the resulting keyword.

The resulting icon will inherit specs from *parent*, and from their parent's parents, and so on, and the lowest descendent element wins.

*specs* is a list of icon specifications. The first element of each specification is the type, and the rest is something that can be used as an icon of that type, and then optionally followed by a keyword list. The following icon types are available:

- |                     |                                                                                                                                                                                                                                                                                                                                   |
|---------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>image</code>  | In this case, there may be many images listed as candidates. Emacs will choose the first one that the current Emacs instance can show. If an image is listed as an absolute file name, it's used as is, but it's otherwise looked up in the list <code>image-load-path</code> (see Section 41.17.8 [Defining Images], page 1220). |
| <code>emoji</code>  | This should be a (possibly colorful) emoji.                                                                                                                                                                                                                                                                                       |
| <code>symbol</code> | This should be a (monochrome) symbol character.                                                                                                                                                                                                                                                                                   |
| <code>text</code>   | Icons should also have a textual fallback. This can also be used for the visually impaired: if <code>icon-preference</code> is just ( <code>text</code> ), all icons will be replaced by text.                                                                                                                                    |

Various keywords may follow the list of icon specifications. For instance:

```
(symbol "" "" :face icon-button)
```

Unknown keywords are ignored. The following keywords are allowed:

- |                      |                                                                                                                                                                                                                                    |
|----------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>:face</code>   | The face to be used for the icon.                                                                                                                                                                                                  |
| <code>:height</code> | This is only valid for <code>image</code> icons, and can be either a number (which specifies the height in pixels), or the symbol <code>line</code> , which will use the default line height in the currently selected window.     |
| <code>:width</code>  | This is only valid for <code>image</code> icons, and can be either a number (which specifies the width in pixels), or the symbol <code>font</code> , which will use the width in pixels of the current buffer's default face font. |

*doc* should be a doc string.

*keywords* is a list of keyword/value pairs. The following keywords are allowed:

- |                         |                                                                                          |
|-------------------------|------------------------------------------------------------------------------------------|
| <code>:version</code>   | The (approximate) Emacs version this button first appeared. (This keyword is mandatory.) |
| <code>:group</code>     | The customization group this icon belongs in. If not present, it is inferred.            |
| <code>:help-echo</code> | The help string shown when hovering over the icon with the mouse pointer.                |

**icon-string icon** [Function]

This function returns a string suitable for display in the current buffer for *icon*.

**icon-elements icon** [Function]

Alternatively, you can get a “deconstructed” version of *icon* with this function. It returns a plist (see Section 5.9 [Property Lists], page 99) where the keys are `string`, `face` and `image`. (The latter is only present if the icon is represented by an image.) This can be useful if the icon isn’t to be inserted directly in the buffer, but needs some sort of pre-processing first.

Icons can be customized with `M-x customize-icon`. Themes can specify changes to icons with, for instance:

```
(custom-theme-set-icons
 'my-theme
 '(outline-open ((image :height 100)
 (text " OPEN ")))
 '(outline-close ((image :height 100)
 (text " CLOSE " :face warning))))
```

## 41.19 Embedded Native Widgets

Emacs is able to display native widgets, such as GTK+ WebKit widgets, in Emacs buffers when it was built with the necessary support libraries and is running on a graphical terminal. To test whether Emacs supports display of embedded widgets, check that the `xwidget-internal` feature is available (see Section 16.7 [Named Features], page 309).

To display an embedded widget in a buffer, you must first create an `xwidget` object, and then use that object as the display specifier in a `display` text or overlay property (see Section 41.16 [Display Property], page 1198).

Embedded widgets can send events notifying Lisp code about changes occurring within them. (see Section 22.7.11 [Xwidget Events], page 449).

**make-xwidget type title width height arguments &optional buffer related** [Function]

This creates and returns an `xwidget` object. If *buffer* is omitted or `nil`, it defaults to the current buffer. If *buffer* names a buffer that doesn’t exist, it will be created. The *type* identifies the type of the `xwidget` component, it can be one of the following:

**webkit** The WebKit component.

The *width* and *height* arguments specify the widget size in pixels, and *title*, a string, specifies its title. *related* is used internally by the WebKit widget, and specifies another WebKit widget that the newly created widget should share settings and subprocesses with.

The `xwidget` that is returned will be killed alongside its buffer (see Section 28.10 [Killing Buffers], page 685). You can also kill it using `kill-xwidget`. Once it is killed, the `xwidget` may continue to exist as a Lisp object and act as a `display` property until all references to it are gone, but most actions that can be performed on live `xwidgets` will no longer be available.

**xwidgetp** *object* [Function]

This function returns `t` if *object* is an xwidget, `nil` otherwise.

**xwidget-live-p** *object* [Function]

This function returns `t` if *object* is an xwidget that hasn't been killed, and `nil` otherwise.

**kill-xwidget** *xwidget* [Function]

This function kills *xwidget*, by removing it from its buffer and releasing window system resources it holds.

**xwidget plist** *xwidget* [Function]

This function returns the property list of *xwidget*.

**set-xwidget-plist** *xwidget plist* [Function]

This function replaces the property list of *xwidget* with a new property list given by *plist*.

**xwidget-buffer** *xwidget* [Function]

This function returns the buffer of *xwidget*. If *xwidget* has been killed, it returns `nil`.

**set-xwidget-buffer** *xwidget buffer* [Function]

This function sets the buffer of *xwidget* to *buffer*.

**get-buffer-xwidgets** *buffer* [Function]

This function returns a list of xwidget objects associated with the *buffer*, which can be specified as a buffer object or a name of an existing buffer, a string. The value is `nil` if *buffer* contains no xwidgets.

**xwidget-webkit-goto-uri** *xwidget uri* [Function]

This function browses the specified *uri* in the given *xwidget*. The *uri* is a string that specifies the name of a file or a URL.

**xwidget-webkit-execute-script** *xwidget script* [Function]

This function causes the browser widget specified by *xwidget* to execute the specified JavaScript *script*.

**xwidget-webkit-execute-script-rv** *xwidget script &optional default* [Function]

This function executes the specified *script* like **xwidget-webkit-execute-script** does, but it also returns the script's return value as a string. If *script* doesn't return a value, this function returns *default*, or `nil` if *default* was omitted.

**xwidget-webkit-get-title** *xwidget* [Function]

This function returns the title of *xwidget* as a string.

**xwidget-resize** *xwidget width height* [Function]

This function resizes the specified *xwidget* to the size *widthxheight* pixels.

**xwidget-size-request** *xwidget* [Function]

This function returns the desired size of *xwidget* as a list of the form (*width height*). The dimensions are in pixels.

**xwidget-info** *xwidget* [Function]

This function returns the attributes of *xwidget* as a vector of the form [*type title width height*]. The attributes are usually determined by `make-xwidget` when the *xwidget* is created.

**set-xwidget-query-on-exit-flag** *xwidget flag* [Function]

This function allows you to arrange that Emacs will ask the user for confirmation before exiting or before killing a buffer that has *xwidget* associated with it. If *flag* is non-*nil*, Emacs will query the user, otherwise it will not.

**xwidget-query-on-exit-flag** *xwidget* [Function]

This function returns the current setting of *xwidget*'s query-on-exit flag, either *t* or *nil*.

**xwidget-perform-lispy-event** *xwidget event frame* [Function]

Send an input event *event* to *xwidget*. The precise action performed is platform-specific. See Section 22.7 [Input Events], page 440.

You can optionally pass the frame on which the event was generated via *frame*. On X11, modifier keys in key events will not be considered if *frame* is *nil*, and the selected frame is not an X-Windows frame.

On GTK, only keyboard and function key events are supported. Mouse, motion, and click events are dispatched to the *xwidget* without going through Lisp code, and as such shouldn't require this function to be called.

**xwidget-webkit-search** *query xwidget &optional case-insensitive backwards wrap-around* [Function]

Start an incremental search on the WebKit widget *xwidget* with the string *query* as the query. *case-insensitive* denotes whether or not the search is case-insensitive, *backwards* determines if the search is performed backwards towards the start of the document, and *wrap-around* determines whether or not the search terminates at the end of the document.

If the function is called while a search query is already present, then the query specified here will replace the existing query.

To stop a search query, use `xwidget-webkit-finish-search`.

**xwidget-webkit-next-result** *xwidget* [Function]

Display the next search result in *xwidget*. This function will signal an error if a search query has not been already started in *xwidget* through `xwidget-webkit-search`.

If *wrap-around* was non-*nil* when `xwidget-webkit-search` was called, then the search will restart from the beginning of the document when its end is reached.

**xwidget-webkit-previous-result** *xwidget* [Function]

Display the previous search result in *xwidget*. This function signals an error if a search query has not been already started in *xwidget* through `xwidget-webkit-search`.

If *wrap-around* was non-*nil* when `xwidget-webkit-search` was called, then the search will restart from the end of the document when its beginning is reached.

**xwidget-webkit-finish-search** *xwidget* [Function]

Finish a search operation started with **xwidget-webkit-search** in *xwidget*. If there is no query currently ongoing, this function signals an error.

**xwidget-webkit-load-html** *xwidget* *text* &optional *base-uri* [Function]

Load *text*, a string, into *xwidget*, which should be a WebKit xwidget. Any HTML markup in *text* will be processed by *xwidget* while rendering the text.

Optional argument *base-uri*, which should be a string, specifies the absolute location of the web resources referenced by *text*, to be used for resolving relative links in *text*.

**xwidget-webkit-goto-history** *xwidget* *rel-pos* [Function]

Make *xwidget*, a WebKit widget, load the *rel-posth* element in its navigation history. If *rel-pos* is zero, the current page will be reloaded instead.

**xwidget-webkit-back-forward-list** *xwidget* &optional *limit* [Function]

Return the navigation history of *xwidget*, up to *limit* items in each direction. If not specified, *limit* defaults to 50.

The returned value is a list of the form (*back here forward*), where *here* is the current navigation item, while *back* is a list of items containing the items recorded by WebKit before the current navigation item, and *forward* is a list of items recorded after the current navigation item. *back*, *here* and *forward* can all be **nil**.

When *here* is **nil**, it means that no items have been recorded yet; if *back* or *forward* are **nil**, it means that there is no history recorded before or after the current item respectively.

Navigation items are themselves lists of the form (*idx title uri*). In these lists, *idx* is an index that can be passed to **xwidget-webkit-goto-history**, *title* is the human-readable title of the item, and *uri* is the URI of the item. The user should normally have no reason to load *uri* manually to reach a specific history item. Instead, *idx* should be passed as an index to **xwidget-webkit-goto-history**.

**xwidget-webkit-estimated-load-progress** *xwidget* [Function]

Return an estimate of how much data is remaining to be transferred before the page displayed by the WebKit widget *xwidget* is fully loaded.

The value returned is a float ranging between 0.0 and 1.0.

**xwidget-webkit-set-cookie-storage-file** *xwidget* *file* [Function]

Make the WebKit widget *xwidget* store cookies in *file*.

*file* must be an absolute file name. The new setting will also affect any *xwidget* that was created with *xwidget* as the **related** argument to **make-xwidget**, and widgets related to those as well.

If this function is not called at least once on *xwidget* or a related widget, *xwidget* will not store cookies on disk at all.

**xwidget-webkit-stop-loading** *xwidget* [Function]

Terminate any data transfer still in progress in the WebKit widget *xwidget* as part of a page-loading operation. If a page is not being loaded, this function does nothing.

## 41.20 Buttons

The Button package defines functions for inserting and manipulating *buttons* that can be activated with the mouse or via keyboard commands. These buttons are typically used for various kinds of hyperlinks.

A button is essentially a set of text or overlay properties, attached to a stretch of text in a buffer. These properties are called *button properties*. One of these properties, the *action* property, specifies a function which is called when the user invokes the button using the keyboard or the mouse. The action function may examine the button and use its other properties as desired.

In some ways, the Button package duplicates the functionality in the Widget package. See Section “Introduction” in *The Emacs Widget Library*. The advantage of the Button package is that it is faster, smaller, and simpler to program. From the point of view of the user, the interfaces produced by the two packages are very similar.

### 41.20.1 Button Properties

Each button has an associated list of properties defining its appearance and behavior, and other arbitrary properties may be used for application specific purposes. The following properties have special meaning to the Button package:

**action**      The function to call when the user invokes the button, which is passed the single argument *button*. By default this is `ignore`, which does nothing.

**mouse-action**      This is similar to **action**, and when present, will be used instead of **action** for button invocations resulting from mouse-clicks (instead of the user hitting RET). If not present, mouse-clicks use **action** instead.

**face**      This is an Emacs face controlling how buttons of this type are displayed; by default this is the **button** face.

**mouse-face**      This is an additional face which controls appearance during mouse-overs (merged with the usual button face); by default this is the usual Emacs **highlight** face.

**keymap**      The button’s keymap, defining bindings active within the button region. By default this is the usual button region keymap, stored in the variable **button-map**, which defines RET and **mouse-2** to invoke the button.

**type**      The button type. See Section 41.20.2 [Button Types], page 1233.

**help-echo**      A string displayed by the Emacs tooltip help system; by default, "mouse-2,  
RET: Push this button". Alternatively, a function that returns, or a form that evaluates to, a string to be displayed or `nil`. For details see [Text help-echo], page 926.

The function is called with three arguments, *window*, *object*, and *pos*. The second argument, *object*, is either the overlay that had the property (for overlay buttons), or the buffer containing the button (for text property buttons). The other arguments have the same meaning as for the special text property **help-echo**.

**follow-link**

The `follow-link` property, defining how a `mouse-1` click behaves on this button,  
See Section 33.19.8 [Clickable Text], page 934.

**button**

All buttons have a `non-nil button` property, which may be useful in finding regions of text that comprise buttons (which is what the standard button functions do).

There are other properties defined for the regions of text in a button, but these are not generally interesting for typical uses.

### 41.20.2 Button Types

Every button has a *button type*, which defines default values for the button's properties. Button types are arranged in a hierarchy, with specialized types inheriting from more general types, so that it's easy to define special-purpose types of buttons for specific tasks.

**define-button-type name &rest properties**

[Function]

Define a button type called `name` (a symbol). The remaining arguments form a sequence of *property value* pairs, specifying default property values for buttons with this type (a button's type may be set by giving it a `:type` property when creating the button, using the `:type` keyword argument).

In addition, the keyword argument `:supertype` may be used to specify a button-type from which `name` inherits its default property values. Note that this inheritance happens only when `name` is defined; subsequent changes to a supertype are not reflected in its subtypes.

Using `define-button-type` to define default properties for buttons is not necessary—buttons without any specified type use the built-in button-type `button`—but it is encouraged, since doing so usually makes the resulting code clearer and more efficient.

### 41.20.3 Making Buttons

Buttons are associated with a region of text, using an overlay or text properties to hold button-specific information, all of which are initialized from the button's type (which defaults to the built-in button type `button`). Like all Emacs text, the appearance of the button is governed by the `face` property; by default (via the `face` property inherited from the `button` button-type) this is a simple underline, like a typical web-page link.

For convenience, there are two sorts of button-creation functions, those that add button properties to an existing region of a buffer, called `make-...button`, and those that also insert the button text, called `insert-...button`.

The button-creation functions all take the `&rest` argument `properties`, which should be a sequence of *property value* pairs, specifying properties to add to the button; see Section 41.20.1 [Button Properties], page 1232. In addition, the keyword argument `:type` may be used to specify a button-type from which to inherit other properties; see Section 41.20.2 [Button Types], page 1233. Any properties not explicitly specified during creation will be inherited from the button's type (if the type defines such a property).

The following functions add a button using an overlay (see Section 41.9 [Overlays], page 1150) to hold the button properties:

**make-button** *beg end &rest properties* [Function]

This makes a button from *beg* to *end* in the current buffer, and returns it.

**insert-button** *label &rest properties* [Function]

This inserts a button with the label *label* at point, and returns it.

The following functions are similar, but using text properties (see Section 33.19 [Text Properties], page 917) to hold the button properties. Such buttons do not add markers to the buffer, so editing in the buffer does not slow down if there is an extremely large numbers of buttons. However, if there is an existing face text property on the text (e.g., a face assigned by Font Lock mode), the button face may not be visible. Both of these functions return the starting position of the new button.

**make-text-button** *beg end &rest properties* [Function]

This makes a button from *beg* to *end* in the current buffer, using text properties.

**insert-text-button** *label &rest properties* [Function]

This inserts a button with the label *label* at point, using text properties.

**buttonize** *string callback &optional data* [Function]

Sometimes it's more convenient to make a string into a button without inserting it into a buffer immediately, for instance when creating data structures that may then, later, be inserted into a buffer. This function makes *string* into such a string, and *callback* will be called when the user clicks on the button. The optional *data* parameter will be used as the parameter when *callback* is called. If *nil*, the button is used as the parameter instead.

#### 41.20.4 Manipulating Buttons

These are functions for getting and setting properties of buttons. Often these are used by a button's invocation function to determine what to do.

Where a *button* parameter is specified, it means an object referring to a specific button, either an overlay (for overlay buttons), or a buffer-position or marker (for text property buttons). Such an object is passed as the first argument to a button's invocation function when it is invoked.

**button-start** *button* [Function]

Return the position at which *button* starts.

**button-end** *button* [Function]

Return the position at which *button* ends.

**button-get** *button prop* [Function]

Get the property of button *button* named *prop*.

**button-put** *button prop val* [Function]

Set *button*'s *prop* property to *val*.

**button-activate** *button &optional use-mouse-action* [Function]

Call *button*'s *action* property (i.e., invoke the function that is the value of that property, passing it the single argument *button*). If *use-mouse-action* is non-*nil*, try

to invoke the button's `mouse-action` property instead of `action`; if the button has no `mouse-action` property, use `action` as normal. If the `button-data` property is present in `button`, use that as the argument for the `action` function instead of `button`.

**button-label** *button* [Function]  
Return *button*'s text label.

**button-type** *button* [Function]  
Return *button*'s button-type.

**button-has-type-p** *button type* [Function]  
Return `t` if *button* has button-type *type*, or one of *type*'s subtypes.

**button-at** *pos* [Function]  
Return the button at position *pos* in the current buffer, or `nil`. If the button at *pos* is a text property button, the return value is a marker pointing to *pos*.

**button-type-put** *type prop val* [Function]  
Set the button-type *type*'s *prop* property to *val*.

**button-type-get** *type prop* [Function]  
Get the property of button-type *type* named *prop*.

**button-type-subtype-p** *type supertype* [Function]  
Return `t` if button-type *type* is a subtype of *supertype*.

#### 41.20.5 Button Buffer Commands

These are commands and functions for locating and operating on buttons in an Emacs buffer.

`push-button` is the command that a user uses to actually push a button, and is bound by default in the button itself to RET and to `mouse-2` using a local keymap in the button's overlay or text properties. Commands that are useful outside the buttons itself, such as `forward-button` and `backward-button` are additionally available in the keymap stored in `button-buffer-map`; a mode which uses buttons may want to use `button-buffer-map` as a parent keymap for its keymap. Alternatively, the `button-mode` can be switched on for much the same effect: It's a minor mode that does nothing else than install `button-buffer-map` as a minor mode keymap.

If the button has a non-`nil` `follow-link` property, and `mouse-1-click-follows-link` is set, a quick `mouse-1` click will also activate the `push-button` command. See Section 33.19.8 [Clickable Text], page 934.

**push-button** &optional *pos use-mouse-action* [Command]  
Perform the action specified by a button at location *pos*. *pos* may be either a buffer position or a mouse-event. If `use-mouse-action` is non-`nil`, or *pos* is a mouse-event (see Section 22.7.3 [Mouse Events], page 442), try to invoke the button's `mouse-action` property instead of `action`; if the button has no `mouse-action` property, use `action` as normal. *pos* defaults to point, except when `push-button` is invoked interactively as the result of a mouse-event, in which case, the mouse event's position is used. If there's no button at *pos*, do nothing and return `nil`, otherwise return `t`.

**forward-button** *n* &optional *wrap display-message no-error* [Command]

Move to the *n*th next button, or *n*th previous button if *n* is negative. If *n* is zero, move to the start of any button at point. If *wrap* is non-nil, moving past either end of the buffer continues from the other end. If *display-message* is non-nil, the button's help-echo string is displayed. Any button with a non-nil *skip* property is skipped over. Returns the button found, and signals an error if no buttons can be found. If *no-error* is non-nil, return nil instead of signaling the error.

**backward-button** *n* &optional *wrap display-message no-error* [Command]

Move to the *n*th previous button, or *n*th next button if *n* is negative. If *n* is zero, move to the start of any button at point. If *wrap* is non-nil, moving past either end of the buffer continues from the other end. If *display-message* is non-nil, the button's help-echo string is displayed. Any button with a non-nil *skip* property is skipped over. Returns the button found, and signals an error if no buttons can be found. If *no-error* is non-nil, return nil instead of signaling the error.

**next-button** *pos* &optional *count-current* [Function]

**previous-button** *pos* &optional *count-current* [Function]

Return the next button after (for **next-button**) or before (for **previous-button**) position *pos* in the current buffer. If *count-current* is non-nil, count any button at *pos* in the search, instead of starting at the next button.

## 41.21 Abstract Display

The Ewoc package constructs buffer text that represents a structure of Lisp objects, and updates the text to follow changes in that structure. This is like the “view” component in the “model–view–controller” design paradigm. Ewoc means “Emacs’s Widget for Object Collections”.

An ewoc is a structure that organizes information required to construct buffer text that represents certain Lisp data. The buffer text of the ewoc has three parts, in order: first, fixed *header* text; next, textual descriptions of a series of data elements (Lisp objects that you specify); and last, fixed *footer* text. Specifically, an ewoc contains information on:

- The buffer which its text is generated in.
- The text's start position in the buffer.
- The header and footer strings.
- A doubly-linked chain of *nodes*, each of which contains:
  - A *data element*, a single Lisp object.
  - Links to the preceding and following nodes in the chain.
- A *pretty-printer* function which is responsible for inserting the textual representation of a data element value into the current buffer.

Typically, you define an ewoc with **ewoc-create**, and then pass the resulting ewoc structure to other functions in the Ewoc package to build nodes within it, and display it in the buffer. Once it is displayed in the buffer, other functions determine the correspondence between buffer positions and nodes, move point from one node's textual representation to another, and so forth. See Section 41.21.1 [Abstract Display Functions], page 1237.

A node *encapsulates* a data element much the way a variable holds a value. Normally, encapsulation occurs as a part of adding a node to the ewoc. You can retrieve the data element value and place a new value in its place, like so:

```
(ewoc-data node)
⇒ value

(ewoc-set-data node new-value)
⇒ new-value
```

You can also use, as the data element value, a Lisp object (list or vector) that is a container for the real value, or an index into some other structure. The example (see Section 41.21.2 [Abstract Display Example], page 1239) uses the latter approach.

When the data changes, you will want to update the text in the buffer. You can update all nodes by calling `ewoc-refresh`, or just specific nodes using `ewoc-invalidate`, or all nodes satisfying a predicate using `ewoc-map`. Alternatively, you can delete invalid nodes using `ewoc-delete` or `ewoc-filter`, and add new nodes in their place. Deleting a node from an ewoc deletes its associated textual description from buffer, as well.

### 41.21.1 Abstract Display Functions

In this subsection, `ewoc` and `node` stand for the structures described above (see Section 41.21 [Abstract Display], page 1236), while `data` stands for an arbitrary Lisp object used as a data element.

**ewoc-create** *pretty-printer* &optional *header* *footer* *nosep* [Function]

This constructs and returns a new ewoc, with no nodes (and thus no data elements). *pretty-printer* should be a function that takes one argument, a data element of the sort you plan to use in this ewoc, and inserts its textual description at point using `insert` (and never `insert-before-markers`, because that would interfere with the Ewoc package's internal mechanisms).

Normally, a newline is automatically inserted after the header, the footer and every node's textual description. If *nosep* is non-`nil`, no newline is inserted. This may be useful for displaying an entire ewoc on a single line, for example, or for making nodes invisible by arranging for *pretty-printer* to do nothing for those nodes.

An ewoc maintains its text in the buffer that is current when you create it, so switch to the intended buffer before calling `ewoc-create`.

**ewoc-buffer** *ewoc* [Function]

This returns the buffer where *ewoc* maintains its text.

**ewoc-get-hf** *ewoc* [Function]

This returns a cons cell (*header* . *footer*) made from *ewoc*'s header and footer.

**ewoc-set-hf** *ewoc* *header* *footer* [Function]

This sets the header and footer of *ewoc* to the strings *header* and *footer*, respectively.

**ewoc-enter-first** *ewoc* *data* [Function]

**ewoc-enter-last** *ewoc* *data* [Function]

These add a new node encapsulating *data*, putting it, respectively, at the beginning or end of *ewoc*'s chain of nodes.

|                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |            |
|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|------------|
| <b>ewoc-enter-before</b> <i>ewoc node data</i>                                                                                                                                                                                                                                                                                                                                                                                                                          | [Function] |
| <b>ewoc-enter-after</b> <i>ewoc node data</i>                                                                                                                                                                                                                                                                                                                                                                                                                           | [Function] |
| These add a new node encapsulating <i>data</i> , adding it to <i>ewoc</i> before or after <i>node</i> , respectively.                                                                                                                                                                                                                                                                                                                                                   |            |
| <b>ewoc-prev</b> <i>ewoc node</i>                                                                                                                                                                                                                                                                                                                                                                                                                                       | [Function] |
| <b>ewoc-next</b> <i>ewoc node</i>                                                                                                                                                                                                                                                                                                                                                                                                                                       | [Function] |
| These return, respectively, the previous node and the next node of <i>node</i> in <i>ewoc</i> .                                                                                                                                                                                                                                                                                                                                                                         |            |
| <b>ewoc-nth</b> <i>ewoc n</i>                                                                                                                                                                                                                                                                                                                                                                                                                                           | [Function] |
| This returns the node in <i>ewoc</i> found at zero-based index <i>n</i> . A negative <i>n</i> means count from the end. <b>ewoc-nth</b> returns <b>nil</b> if <i>n</i> is out of range.                                                                                                                                                                                                                                                                                 |            |
| <b>ewoc-data</b> <i>node</i>                                                                                                                                                                                                                                                                                                                                                                                                                                            | [Function] |
| This extracts the data encapsulated by <i>node</i> and returns it.                                                                                                                                                                                                                                                                                                                                                                                                      |            |
| <b>ewoc-set-data</b> <i>node data</i>                                                                                                                                                                                                                                                                                                                                                                                                                                   | [Function] |
| This sets the data encapsulated by <i>node</i> to <i>data</i> .                                                                                                                                                                                                                                                                                                                                                                                                         |            |
| <b>ewoc-locate</b> <i>ewoc &amp;optional pos guess</i>                                                                                                                                                                                                                                                                                                                                                                                                                  | [Function] |
| This determines the node in <i>ewoc</i> which contains point (or <i>pos</i> if specified), and returns that node. If <i>ewoc</i> has no nodes, it returns <b>nil</b> . If <i>pos</i> is before the first node, it returns the first node; if <i>pos</i> is after the last node, it returns the last node. The optional third arg <i>guess</i> should be a node that is likely to be near <i>pos</i> ; this doesn't alter the result, but makes the function run faster. |            |
| <b>ewoc-location</b> <i>node</i>                                                                                                                                                                                                                                                                                                                                                                                                                                        | [Function] |
| This returns the start position of <i>node</i> .                                                                                                                                                                                                                                                                                                                                                                                                                        |            |
| <b>ewoc-goto-prev</b> <i>ewoc arg</i>                                                                                                                                                                                                                                                                                                                                                                                                                                   | [Function] |
| <b>ewoc-goto-next</b> <i>ewoc arg</i>                                                                                                                                                                                                                                                                                                                                                                                                                                   | [Function] |
| These move point to the previous or next, respectively, argth node in <i>ewoc</i> . <b>ewoc-goto-prev</b> does not move if it is already at the first node or if <i>ewoc</i> is empty, whereas <b>ewoc-goto-next</b> moves past the last node, returning <b>nil</b> . Excepting this special case, these functions return the node moved to.                                                                                                                            |            |
| <b>ewoc-goto-node</b> <i>ewoc node</i>                                                                                                                                                                                                                                                                                                                                                                                                                                  | [Function] |
| This moves point to the start of <i>node</i> in <i>ewoc</i> .                                                                                                                                                                                                                                                                                                                                                                                                           |            |
| <b>ewoc-refresh</b> <i>ewoc</i>                                                                                                                                                                                                                                                                                                                                                                                                                                         | [Function] |
| This function regenerates the text of <i>ewoc</i> . It works by deleting the text between the header and the footer, i.e., all the data elements' representations, and then calling the pretty-printer function for each node, one by one, in order.                                                                                                                                                                                                                    |            |
| <b>ewoc-invalidate</b> <i>ewoc &amp;rest nodes</i>                                                                                                                                                                                                                                                                                                                                                                                                                      | [Function] |
| This is similar to <b>ewoc-refresh</b> , except that only <i>nodes</i> in <i>ewoc</i> are updated instead of the entire set.                                                                                                                                                                                                                                                                                                                                            |            |
| <b>ewoc-delete</b> <i>ewoc &amp;rest nodes</i>                                                                                                                                                                                                                                                                                                                                                                                                                          | [Function] |
| This deletes each node in <i>nodes</i> from <i>ewoc</i> .                                                                                                                                                                                                                                                                                                                                                                                                               |            |

**ewoc-filter** *ewoc predicate &rest args* [Function]

This calls *predicate* for each data element in *ewoc* and deletes those nodes for which *predicate* returns `nil`. Any *args* are passed to *predicate*.

**ewoc-collect** *ewoc predicate &rest args* [Function]

This calls *predicate* for each data element in *ewoc* and returns a list of those elements for which *predicate* returns non-`nil`. The elements in the list are ordered as in the buffer. Any *args* are passed to *predicate*.

**ewoc-map** *map-function ewoc &rest args* [Function]

This calls *map-function* for each data element in *ewoc* and updates those nodes for which *map-function* returns non-`nil`. Any *args* are passed to *map-function*.

### 41.21.2 Abstract Display Example

Here is a simple example using functions of the *ewoc* package to implement a *color components* display, an area in a buffer that represents a vector of three integers (itself representing a 24-bit RGB value) in various ways.

```
(setq colorcomp-ewoc nil
 colorcomp-data nil
 colorcomp-mode-map nil
 colorcomp-labels ["Red" "Green" "Blue"])

(defun colorcomp-pp (data)
 (if data
 (let ((comp (aref colorcomp-data data)))
 (insert (aref colorcomp-labels data) "\t: #x"
 (format "%02X" comp) " "
 (make-string (ash comp -2) ?#) "\n"))
 (let ((cstr (format "#%02X%02X%02X"
 (aref colorcomp-data 0)
 (aref colorcomp-data 1)
 (aref colorcomp-data 2)))
 (samp " (sample text) "))
 (insert "Color\t: "
 (propertize samp 'face
 `'(foreground-color . ,cstr))
 (propertize samp 'face
 `'(background-color . ,cstr))
 "\n")))

(defun colorcomp (color)
 "Allow fiddling with COLOR in a new buffer.
The buffer is in Color Components mode."
 (interactive "sColor (name or #RGB or #RRGGBB): ")
 (when (string= "" color)
 (setq color "green"))
 (unless (color-values color)
```

```

(error "No such color: %S" color))
(switch-to-buffer
 (generate-new-buffer (format "originally: %s" color)))
(kill-all-local-variables)
(setq major-mode 'colorcomp-mode
 mode-name "Color Components")
(use-local-map colorcomp-mode-map)
(erase-buffer)
(buffer-disable-undo)
(let ((data (apply 'vector (mapcar (lambda (n) (ash n -8))
 (color-values color)))))
 (ewoc (ewoc-create 'colorcomp-pp
 "\nColor Components\n\n"
 (substitute-command-keys
 "\n\\{colorcomp-mode-map}")))))
 (set (make-local-variable 'colorcomp-data) data)
 (set (make-local-variable 'colorcomp-ewoc) ewoc)
 (ewoc-enter-last ewoc 0)
 (ewoc-enter-last ewoc 1)
 (ewoc-enter-last ewoc 2)
 (ewoc-enter-last ewoc nil)))

```

This example can be extended to be a color selection widget (in other words, the “controller” part of the “model–view–controller” design paradigm) by defining commands to modify `colorcomp-data` and to finish the selection process, and a keymap to tie it all together conveniently.

```

(defun colorcomp-mod (index limit delta)
 (let ((cur (aref colorcomp-data index)))
 (unless (= limit cur)
 (aset colorcomp-data index (+ cur delta)))
 (ewoc-invalidate
 colorcomp-ewoc
 (ewoc-nth colorcomp-ewoc index)
 (ewoc-nth colorcomp-ewoc -1)))))

(defun colorcomp-R-more () (interactive) (colorcomp-mod 0 255 1))
(defun colorcomp-G-more () (interactive) (colorcomp-mod 1 255 1))
(defun colorcomp-B-more () (interactive) (colorcomp-mod 2 255 1))
(defun colorcomp-R-less () (interactive) (colorcomp-mod 0 0 -1))
(defun colorcomp-G-less () (interactive) (colorcomp-mod 1 0 -1))
(defun colorcomp-B-less () (interactive) (colorcomp-mod 2 0 -1))

(defun colorcomp-copy-as-kill-and-exit ()
 "Copy the color components into the kill ring and kill the buffer.
The string is formatted #RRGGBB (hash followed by six hex digits)."
 (interactive)
 (kill-new (format "#%02X%02X%02X"
 (aref colorcomp-data 0)
 (aref colorcomp-data 1)
 (aref colorcomp-data 2)))
 (kill-buffer nil))

(setq colorcomp-mode-map

```

```
(define-keymap :suppress t
 "i" 'colorcomp-R-less
 "o" 'colorcomp-R-more
 "k" 'colorcomp-G-less
 "l" 'colorcomp-G-more
 "," 'colorcomp-B-less
 ";" 'colorcomp-B-more
 "SPC" 'colorcomp-copy-as-kill-and-exit))
```

Note that we never modify the data in each node, which is fixed when the ewoc is created to be either `nil` or an index into the vector `colorcomp-data`, the actual color components.

## 41.22 Blinking Parentheses

This section describes the mechanism by which Emacs shows a matching open parenthesis when the user inserts a close parenthesis.

### `blink-paren-function`

[Variable]

The value of this variable should be a function (of no arguments) to be called whenever a character with close parenthesis syntax is inserted. The value of `blink-paren-function` may be `nil`, in which case nothing is done.

### `blink-matching-paren`

[User Option]

If this variable is `nil`, then `blink-matching-open` does nothing.

### `blink-matching-paren-distance`

[User Option]

This variable specifies the maximum distance to scan for a matching parenthesis before giving up.

### `blink-matching-delay`

[User Option]

This variable specifies the number of seconds to keep indicating the matching parenthesis. A fraction of a second often gives good results, but the default is 1, which works on all systems.

### `blink-matching-open`

[Command]

This function is the default value of `blink-paren-function`. It assumes that point follows a character with close parenthesis syntax and applies the appropriate effect momentarily to the matching opening character. If that character is not already on the screen, it displays the character's context in the echo area. To avoid long delays, this function does not search farther than `blink-matching-paren-distance` characters.

Here is an example of calling this function explicitly.

```
(defun interactive-blink-matching-open ()
 "Indicate momentarily the start of parenthesized sexp before point."
 (interactive)
 (let ((blink-matching-paren-distance
 (buffer-size))
 (blink-matching-paren t))
 (blink-matching-open)))
```

## 41.23 Character Display

This section describes how characters are actually displayed by Emacs. Typically, a character is displayed as a *glyph* (a graphical symbol which occupies one character position on the screen), whose appearance corresponds to the character itself. For example, the character ‘a’ (character code 97) is displayed as ‘a’. Some characters, however, are displayed specially. For example, the formfeed character (character code 12) is usually displayed as a sequence of two glyphs, ‘^L’, while the newline character (character code 10) starts a new screen line.

You can modify how each character is displayed by defining a *display table*, which maps each character code into a sequence of glyphs. See Section 41.23.2 [Display Tables], page 1243.

### 41.23.1 Usual Display Conventions

Here are the conventions for displaying each character code (in the absence of a display table, which can override these conventions).

- The *printable ASCII characters*, character codes 32 through 126 (consisting of numerals, English letters, and symbols like '#') are displayed literally.
- The tab character (character code 9) displays as whitespace stretching up to the next tab stop column. See Section “Text Display” in *The GNU Emacs Manual*. The variable `tab-width` controls the number of spaces per tab stop (see below).
- The newline character (character code 10) has a special effect: it ends the preceding line and starts a new line.
- The non-printable *ASCII control characters*—character codes 0 through 31, as well as the `DEL` character (character code 127)—display in one of two ways according to the variable `ctl-arrow`. If this variable is `non-nil` (the default), these characters are displayed as sequences of two glyphs, where the first glyph is ‘^’ (a display table can specify a glyph to use instead of ‘^’); e.g., the `DEL` character is displayed as ‘^?’.

If `ctl-arrow` is `nil`, these characters are displayed as octal escapes (see below).

This rule also applies to carriage return (character code 13), if that character appears in the buffer. But carriage returns usually do not appear in buffer text; they are eliminated as part of end-of-line conversion (see Section 34.10.1 [Coding System Basics], page 977).

- Raw bytes are non-ASCII characters with codes 128 through 255 (see Section 34.1 [Text Representations], page 963). These characters display as *octal escapes*: sequences of four glyphs, where the first glyph is the ASCII code for ‘\’, and the others are digit characters representing the character code in octal. (A display table can specify a glyph to use instead of ‘\’.)
- Each non-ASCII character with code above 255 is displayed literally, if the terminal supports it. If the terminal does not support it, the character is said to be *glyphless*, and it is usually displayed using a placeholder glyph. For example, if a graphical terminal has no font for a character, Emacs usually displays a box containing the character code in hexadecimal. See Section 41.23.5 [Glyphless Chars], page 1245.

The above display conventions apply even when there is a display table, for any character whose entry in the active display table is `nil`. Thus, when you set up a display table, you need only specify the characters for which you want special display behavior.

The following variables affect how certain characters are displayed on the screen. Since they change the number of columns the characters occupy, they also affect the indentation functions. They also affect how the mode line is displayed; if you want to force redisplay of the mode line using the new values, call the function `force-mode-line-update` (see Section 24.4 [Mode Line Format], page 550).

**ctl-arrow**

[User Option]

This buffer-local variable controls how control characters are displayed. If it is non-`nil`, they are displayed as a caret followed by the character: ‘^A’. If it is `nil`, they are displayed as octal escapes: a backslash followed by three octal digits, as in ‘\001’.

**tab-width**

[User Option]

The value of this buffer-local variable is the spacing between tab stops used for displaying tab characters in Emacs buffers. The value is in units of columns, and the default is 8. Note that this feature is completely independent of the user-settable tab stops used by the command `tab-to-tab-stop`. See Section 33.17.5 [Indent Tabs], page 915.

### 41.23.2 Display Tables

A display table is a special-purpose char-table (see Section 6.6 [Char-Tables], page 119), with `display-table` as its subtype, which is used to override the usual character display conventions. This section describes how to make, inspect, and assign elements to a display table object. The next section (see Section 41.23.3 [Active Display Table], page 1244) describes the various standard display tables and their precedence.

**make-display-table**

[Function]

This creates and returns a display table. The table initially has `nil` in all elements.

The ordinary elements of the display table are indexed by character codes; the element at index `c` says how to display the character code `c`. The value should be `nil` (which means to display the character `c` according to the usual display conventions; see Section 41.23.1 [Usual Display], page 1242), or a vector of glyph codes (which means to display the character `c` as those glyphs; see Section 41.23.4 [Glyphs], page 1245).

**Warning:** if you use the display table to change the display of newline characters, the whole buffer will be displayed as one long line.

The display table also has six extra slots which serve special purposes. Here is a table of their meanings; `nil` in any slot means to use the default for that slot, as stated below.

- |   |                                                                                                                                                                                                                                                                                                                                                          |
|---|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0 | The glyph for the end of a truncated screen line (the default for this is ‘\$’). See Section 41.23.4 [Glyphs], page 1245. On graphical terminals, Emacs by default uses arrows in the fringes to indicate truncation, so the display table has no effect, unless you disable the fringes (see Section “Window Fringes” in <i>the GNU Emacs Manual</i> ). |
| 1 | The glyph for the end of a continued line (the default is ‘\’). On graphical terminals, Emacs by default uses curved arrows in the fringes to indicate continuation, so the display table has no effect, unless you disable the fringes.                                                                                                                 |
| 2 | The glyph for indicating a character displayed as an octal character code (the default is ‘\’).                                                                                                                                                                                                                                                          |

- 3 The glyph for indicating a control character (the default is ‘^’).
- 4 A vector of glyphs for indicating the presence of invisible lines (the default is ‘...’). See Section 41.7 [Selective Display], page 1145.
- 5 The glyph used to draw the border between side-by-side windows (the default is ‘|’). See Section 29.7 [Splitting Windows], page 708. This currently has effect only on text terminals; on graphical terminals, if vertical scroll bars are supported and in use, a scroll bar separates the two windows, and if there are no vertical scroll bars and no dividers (see Section 41.15 [Window Dividers], page 1198), Emacs uses a thin line to indicate the border.

For example, here is how to construct a display table that mimics the effect of setting `ctl-arrow` to a non-nil value (see Section 41.23.4 [Glyphs], page 1245, for the function `make-glyph-code`):

```
(setq disptab (make-display-table))
(dotimes (i 32)
 (or (= i ?\t)
 (= i ?\n)
 (aset disptab i
 (vector (make-glyph-code ?^ 'escape-glyph)
 (make-glyph-code (+ i 64) 'escape-glyph)))))

(aset disptab 127
 (vector (make-glyph-code ?^ 'escape-glyph)
 (make-glyph-code ?? 'escape-glyph)))
```

**display-table-slot** *display-table slot* [Function]

This function returns the value of the extra slot *slot* of *display-table*. The argument *slot* may be a number from 0 to 5 inclusive, or a slot name (symbol). Valid symbols are `truncation`, `wrap`, `escape`, `control`, `selective-display`, and `vertical-border`.

**set-display-table-slot** *display-table slot value* [Function]

This function stores *value* in the extra slot *slot* of *display-table*. The argument *slot* may be a number from 0 to 5 inclusive, or a slot name (symbol). Valid symbols are `truncation`, `wrap`, `escape`, `control`, `selective-display`, and `vertical-border`.

**describe-display-table** *display-table* [Function]

This function displays a description of the display table *display-table* in a help buffer.

**describe-current-display-table** [Command]

This command displays a description of the current display table in a help buffer.

### 41.23.3 Active Display Table

Each window can specify a display table, and so can each buffer. The window’s display table, if there is one, takes precedence over the buffer’s display table. If neither exists, Emacs tries to use the standard display table; if that is `nil`, Emacs uses the usual character display conventions (see Section 41.23.1 [Usual Display], page 1242). (Emacs does not “merge” display tables: For instance, if the window has a display table, the buffer’s display table and the standard display table are completely ignored.)

Note that display tables affect how the mode line is displayed, so if you want to force redisplay of the mode line using a new display table, call `force-mode-line-update` (see Section 24.4 [Mode Line Format], page 550).

**window-display-table** &optional `window` [Function]

This function returns `window`'s display table, or `nil` if there is none. The default for `window` is the selected window.

**set-window-display-table** `window table` [Function]

This function sets the display table of `window` to `table`. The argument `table` should be either a display table or `nil`.

**buffer-display-table** [Variable]

This variable is automatically buffer-local in all buffers; its value specifies the buffer's display table. If it is `nil`, there is no buffer display table.

**standard-display-table** [Variable]

The value of this variable is the standard display table, which is used when Emacs is displaying a buffer in a window with neither a window display table nor a buffer display table defined, or when Emacs is outputting text to the standard output or error streams. Although its default is typically `nil`, in an interactive session if the terminal cannot display curved quotes, its default maps curved quotes to ASCII approximations. See Section 25.4 [Text Quoting Style], page 600.

The `disp-table` library defines several functions for changing the standard display table.

#### 41.23.4 Glyphs

A *glyph* is a graphical symbol which occupies a single character position on the screen. Each glyph is represented in Lisp as a *glyph code*, which specifies a character and optionally a face to display it in (see Section 41.12 [Faces], page 1164). The main use of glyph codes is as the entries of display tables (see Section 41.23.2 [Display Tables], page 1243). The following functions are used to manipulate glyph codes:

**make-glyph-code** `char &optional face` [Function]

This function returns a glyph code representing `char` `char` with face `face`. If `face` is omitted or `nil`, the glyph uses the default face; in that case, the glyph code is an integer. If `face` is non-`nil`, the glyph code is not necessarily an integer object.

**glyph-char** `glyph` [Function]

This function returns the character of glyph code `glyph`.

**glyph-face** `glyph` [Function]

This function returns face of glyph code `glyph`, or `nil` if `glyph` uses the default face.

#### 41.23.5 Glyphless Character Display

*Glyphless characters* are characters which are displayed in a special way, e.g., as a box containing a hexadecimal code, instead of being displayed literally. These include characters which are explicitly defined to be glyphless, as well as characters for which there is no available font (on a graphical display), and characters which cannot be encoded by the terminal's coding system (on a text terminal).

The `glyphless-display-mode` minor mode can be used to toggle displaying glyphless characters in a convenient manner in the current buffer. If this mode is enabled, all the glyphless characters are displayed as boxes that display acronyms of their character names.

### `glyphless-char-display`

[Variable]

For more fine-grained (and global) control, this variable can be used. The value of this variable is a char-table which defines glyphless characters and how they are displayed. Each entry must be one of the following display methods:

`nil` Display the character in the usual way.

#### `zero-width`

Don't display the character.

#### `thin-space`

Display a thin space, 1-pixel wide on graphical displays, or 1-character wide on text terminals.

#### `empty-box`

Display an empty box.

`hex-code` Display a box containing the Unicode codepoint of the character, in hexadecimal notation.

#### an ASCII string

Display a box containing that string. The string should contain at most 6 ASCII characters. As an exception, if the string includes just one character, on text-mode terminals that character will be displayed without a box; this allows to handle such “acronyms” as a replacement character for characters that cannot be displayed by the terminal.

#### a cons cell (*graphical* . *text*)

Display with *graphical* on graphical displays, and with *text* on text terminals. Both *graphical* and *text* must be one of the display methods described above.

The `thin-space`, `empty-box`, `hex-code`, and ASCII string display methods are drawn with the `glyphless-char` face. On text terminals, a box is emulated by square brackets, ‘[]’.

The char-table has one extra slot, which determines how to display any character that cannot be displayed with any available font, or cannot be encoded by the terminal's coding system. Its value should be one of the above display methods, except `zero-width`.

If a character has a non-`nil` entry in an active display table, the display table takes effect; in this case, Emacs does not consult `glyphless-char-display` at all.

### `glyphless-char-display-control`

[User Option]

This user option provides a convenient way to set `glyphless-char-display` for groups of similar characters. Do not set its value directly from Lisp code; the value takes effect only via a custom `:set` function (see Section 15.3 [Variable Definitions], page 280), which updates `glyphless-char-display`.

Its value should be an alist of elements (*group . method*), where *group* is a symbol specifying a group of characters, and *method* is a symbol specifying how to display them.

*group* should be one of the following:

**c0-control**

ASCII control characters U+0000 to U+001F, excluding the newline and tab characters (normally displayed as escape sequences like ‘^A’; see Section “How Text Is Displayed” in *The GNU Emacs Manual*).

**c1-control**

Non-ASCII, non-printing characters U+0080 to U+009F (normally displayed as octal escape sequences like ‘\230’).

**format-control**

Characters of Unicode General Category [Cf], such as U+200E LEFT-TO-RIGHT MARK, but excluding characters that have graphic images, such as U+00AD SOFT HYPHEN.

**bidi-control**

This is a subset of **format-control**, but only includes characters that are related to bidirectional formatting control, like U+2069 POP DIRECTIONAL ISOLATE and U+202A LEFT-TO-RIGHT EMBEDDING. See Section 41.27 [Bidirectional Display], page 1250.

Characters of Unicode General Category [Cf], such as U+200E LEFT-TO-RIGHT MARK, but excluding characters that have graphic images, such as U+00AD SOFT HYPHEN.

**variation-selectors**

Unicode VS-1 through VS-256 (U+FE00 through U+FE0F and U+E0100 through U+E01EF), which are used to select between different glyphs for the same codepoints (typically emojis).

**no-font**

Characters for which there is no suitable font, or which cannot be encoded by the terminal’s coding system, or those for which the text-mode terminal has no glyphs.

The *method* symbol should be one of **zero-width**, **thin-space**, **empty-box**, or **hex-code**. These have the same meanings as in **glyphless-char-display**, above.

## 41.24 Beeping

This section describes how to make Emacs ring the bell (or blink the screen) to attract the user’s attention. Be conservative about how often you do this; frequent bells can become irritating. Also be careful not to use just beeping when signaling an error is more appropriate (see Section 11.7.3 [Errors], page 179).

**ding &optional do-not-terminate**

[Function]

This function beeps, or flashes the screen (see **visible-bell** below). It also terminates any keyboard macro currently executing unless *do-not-terminate* is non-*nil*.

**beep** &optional do-not-terminate [Function]  
 This is a synonym for `ding`.

**visible-bell** [User Option]  
 This variable determines whether Emacs should flash the screen to represent a bell. Non-`nil` means yes, `nil` means no. This is effective on graphical displays, and on text terminals provided the terminal's Termcap entry defines the visible bell capability ('vb').

**ring-bell-function** [User Option]  
 If this is non-`nil`, it specifies how Emacs should ring the bell. Its value should be a function of no arguments. If this is non-`nil`, it takes precedence over the `visible-bell` variable.

## 41.25 Window Systems

Emacs works with several window systems, most notably the X Window System. Both Emacs and X use the term “window”, but use it differently. An Emacs frame is a single window as far as X is concerned; the individual Emacs windows are not known to X at all.

**window-system** [Variable]  
 This terminal-local variable tells Lisp programs what window system Emacs is using for displaying the frame. The possible values are

- x Emacs is displaying the frame using X.
- w32 Emacs is displaying the frame using native MS-Windows GUI.
- ns Emacs is displaying the frame using the Nextstep interface (used on GNUstep and macOS).
- pc Emacs is displaying the frame using MS-DOS direct screen writes.
- haiku Emacs is displaying the frame using the Application Kit on Haiku.
- pgtk Emacs is displaying the frame using pure GTK facilities.
- nil Emacs is displaying the frame on a character-based terminal.

**initial-window-system** [Variable]  
 This variable holds the value of `window-system` used for the first frame created by Emacs during startup. (When Emacs is invoked as a daemon, it does not create any initial frames, so `initial-window-system` is `nil`, except on MS-Windows, where it is still `w32`. See Section “Initial Options” in *The GNU Emacs Manual*.)

**window-system** &optional frame [Function]  
 This function returns a symbol whose name tells what window system is used for displaying `frame` (which defaults to the currently selected frame). The list of possible symbols it returns is the same one documented for the variable `window-system` above.

Do *not* use `window-system` and `initial-window-system` as predicates or boolean flag variables, if you want to write code that works differently on text terminals and graphic displays. That is because `window-system` is not a good indicator of Emacs capabilities on a given display type. Instead, use `display-graphic-p` or any of the other `display-*-p` predicates described in Section 30.26 [Display Feature Testing], page 849.

## 41.26 Tooltips

*Tooltips* are special frames (see Chapter 30 [Frames], page 785) that are used to display helpful hints (a.k.a. “tips”) related to the current position of the mouse pointer. Emacs uses tooltips to display help strings about active portions of text (see Section 33.19.4 [Special Properties], page 924) and about various UI elements, such as menu items (see Section 23.18.1.2 [Extended Menu Items], page 511) and tool-bar buttons (see Section 23.18.6 [Tool Bar], page 517).

**tooltip-mode** [Function]

Tooltip Mode is a minor mode that enables display of tooltips. Turning off this mode causes the tooltips be displayed in the echo area. On text-mode (a.k.a. “TTY”) frames, tooltips are always displayed in the echo area.

When Emacs is built with the GTK+ toolkit or Haiku windowing support, it by default displays tooltips using toolkit functions, and the appearance of the tooltips is then controlled by the toolkit’s settings. Toolkit-provided tooltips can be disabled by changing the value of the variable `use-system-tooltips` to `nil`. The rest of this subsection describes how to control non-toolkit tooltips, which are presented by Emacs itself.

Tooltips are displayed in special frames called tooltip frames, which have their own frame parameters (see Section 30.4 [Frame Parameters], page 802). Unlike other frames, the default parameters for tooltip frames are stored in a special variable.

**tooltip-frame-parameters** [User Option]

This customizable option holds the default frame parameters used for displaying tooltips. Any font and color parameters are ignored, and the corresponding attributes of the `tooltip` face are used instead. If `left` or `top` parameters are included, they are used as absolute frame-relative coordinates where the tooltip should be shown. (Mouse-relative position of the tooltip can be customized using the variables described in Section “Tooltips” in *The GNU Emacs Manual*.) Note that the `left` and `top` parameters, if present, override the values of mouse-relative offsets.

The `tooltip` face determines the appearance of text shown in tooltips. It should generally use a variable-pitch font of size that is preferably smaller than the default frame font.

**tooltip-functions** [Variable]

This abnormal hook is a list of functions to call when Emacs needs to display a tooltip. Each function is called with a single argument `event` which is a copy of the last mouse movement event. If a function on this list actually displays the tooltip, it should return `non-nil`, and then the rest of the functions will not be called. The default value of this variable is a single function `tooltip-help-tips`.

If you write your own function to be put on the `tooltip-functions` list, you may need to know the buffer of the mouse event that triggered the tooltip display. The following function provides that information.

**tooltip-event-buffer** `event` [Function]

This function returns the buffer over which `event` occurred. Call it with the argument of the function from `tooltip-functions` to obtain the buffer whose text triggered the tooltip. Note that the event might occur not over a buffer (e.g., over the tool bar), in which case this function will return `nil`.

Other aspects of tooltip display are controlled by several customizable settings; see Section “Tooltips” in *The GNU Emacs Manual*.

## 41.27 Bidirectional Display

Emacs can display text written in scripts, such as Arabic, Farsi, and Hebrew, whose natural ordering for horizontal text display runs from right to left. Furthermore, segments of Latin script and digits embedded in right-to-left text are displayed left-to-right, while segments of right-to-left script embedded in left-to-right text (e.g., Arabic or Hebrew text in comments or strings in a program source file) are appropriately displayed right-to-left. We call such mixtures of left-to-right and right-to-left text *bidirectional text*. This section describes the facilities and options for editing and displaying bidirectional text.

Text is stored in Emacs buffers and strings in *logical* (or *reading*) order, i.e., the order in which a human would read each character. In right-to-left and bidirectional text, the order in which characters are displayed on the screen (called *visual order*) is not the same as logical order; the characters’ screen positions do not increase monotonically with string or buffer position. In performing this *bidirectional reordering*, Emacs follows the Unicode Bidirectional Algorithm (a.k.a. UBA), which is described in Annex #9 of the Unicode standard (<https://www.unicode.org/reports/tr9/>). Emacs provides a “Full Bidirectionality” class implementation of the UBA, consistent with the requirements of the Unicode Standard v9.0. Note, however, that the way Emacs displays continuation lines when text direction is opposite to the base paragraph direction deviates from the UBA, which requires to perform line wrapping before reordering text for display.

### `bidi-display-reordering`

[Variable]

If the value of this buffer-local variable is `non-nil` (the default), Emacs performs bidirectional reordering for display. The reordering affects buffer text, as well as display strings and overlay strings from text and overlay properties in the buffer (see Section 41.9.2 [Overlay Properties], page 1153, and see Section 41.16 [Display Property], page 1198). If the value is `nil`, Emacs does not perform bidirectional reordering in the buffer.

The default value of `bidi-display-reordering` controls the reordering of strings which are not directly supplied by a buffer, including the text displayed in mode lines (see Section 24.4 [Mode Line Format], page 550) and header lines (see Section 24.4.7 [Header Lines], page 559).

Emacs never reorders the text of a unibyte buffer, even if `bidi-display-reordering` is `non-nil` in the buffer. This is because unibyte buffers contain raw bytes, not characters, and thus lack the directionality properties required for reordering. Therefore, to test whether text in a buffer will be reordered for display, it is not enough to test the value of `bidi-display-reordering` alone. The correct test is this:

```
(if (and enable-multibyte-characters
 bidi-display-reordering)
 ;; Buffer is being reordered for display
)
```

However, unibyte display and overlay strings *are* reordered if their parent buffer is reordered. This is because plain-ASCII strings are stored by Emacs as unibyte strings. If a

unibyte display or overlay string includes non-ASCII characters, these characters are assumed to have left-to-right direction.

Text covered by `display` text properties, by overlays with `display` properties whose value is a string, and by any other properties that replace buffer text, is treated as a single unit when it is reordered for display. That is, the entire chunk of text covered by these properties is reordered together. Moreover, the bidirectional properties of the characters in such a chunk of text are ignored, and Emacs reorders them as if they were replaced with a single character U+FFFC, known as the *Object Replacement Character*. This means that placing a display property over a portion of text may change the way that the surrounding text is reordered for display. To prevent this unexpected effect, always place such properties on text whose directionality is identical with text that surrounds it.

Each paragraph of bidirectional text has a *base direction*, either right-to-left or left-to-right. Left-to-right paragraphs are displayed beginning at the left margin of the window, and are truncated or continued when the text reaches the right margin. Right-to-left paragraphs are displayed beginning at the right margin, and are continued or truncated at the left margin.

Where exactly paragraphs start and end, for the purpose of the Emacs UBA implementation, is determined by the following two buffer-local variables (note that `paragraph-start` and `paragraph-separate` have no influence on this). By default both of these variables are `nil`, and paragraphs are bounded by empty lines, i.e., lines that consist entirely of zero or more whitespace characters followed by a newline.

#### `bidi-paragraph-start-re`

[Variable]

If non-`nil`, this variable's value should be a regular expression matching a line that starts or separates two paragraphs. The regular expression is always matched after a newline, so it is best to anchor it, i.e., begin it with a "^".

#### `bidi-paragraph-separate-re`

[Variable]

If non-`nil`, this variable's value should be a regular expression matching a line separates two paragraphs. The regular expression is always matched after a newline, so it is best to anchor it, i.e., begin it with a "^".

If you modify any of these two variables, you should normally modify both, to make sure they describe paragraphs consistently. For example, to have each new line start a new paragraph for bidi-reordering purposes, set both variables to "^".

By default, Emacs determines the base direction of each paragraph by looking at the text at its beginning. The precise method of determining the base direction is specified by the UBA; in a nutshell, the first character in a paragraph that has an explicit directionality determines the base direction of the paragraph. However, sometimes a buffer may need to force a certain base direction for its paragraphs. For example, buffers containing program source code should force all paragraphs to be displayed left-to-right. You can use following variable to do this:

#### `bidi-paragraph-direction`

[User Option]

If the value of this buffer-local variable is the symbol `right-to-left` or `left-to-right`, all paragraphs in the buffer are assumed to have that specified direction. Any other value is equivalent to `nil` (the default), which means to determine the base direction of each paragraph from its contents.

Modes for program source code should set this to `left-to-right`. Prog mode does this by default, so modes derived from Prog mode do not need to set this explicitly (see Section 24.2.5 [Basic Major Modes], page 536).

**current-bidi-paragraph-direction** &**optional buffer** [Function]

This function returns the paragraph direction at point in the named *buffer*. The returned value is a symbol, either `left-to-right` or `right-to-left`. If *buffer* is omitted or `nil`, it defaults to the current buffer. If the buffer-local value of the variable `bidi-paragraph-direction` is non-`nil`, the returned value will be identical to that value; otherwise, the returned value reflects the paragraph direction determined dynamically by Emacs. For buffers whose value of `bidi-display-reordering` is `nil` as well as unibyte buffers, this function always returns `left-to-right`.

Sometimes there's a need to move point in strict visual order, either to the left or to the right of its current screen position. Emacs provides a primitive to do that.

**move-point-visually** *direction* [Function]

This function moves point of the currently selected window to the buffer position that appears immediately to the right or to the left of point on the screen. If *direction* is positive, point will move one screen position to the right, otherwise it will move one screen position to the left. Note that, depending on the surrounding bidirectional context, this could potentially move point many buffer positions away. If invoked at the end of a screen line, the function moves point to the rightmost or leftmost screen position of the next or previous screen line, as appropriate for the value of *direction*.

The function returns the new buffer position as its value.

Bidirectional reordering can have surprising and unpleasant effects when two strings with bidirectional content are juxtaposed in a buffer, or otherwise programmatically concatenated into a string of text. A typical problematic case is when a buffer consists of sequences of text fields separated by whitespace or punctuation characters, like Buffer Menu mode or Rmail Summary Mode. Because the punctuation characters used as separators have *weak directionality*, they take on the directionality of surrounding text. As result, a numeric field that follows a field with bidirectional content can be displayed *to the left* of the preceding field, messing up the expected layout. There are several ways to avoid this problem:

- Append the special character U+200E LEFT-TO-RIGHT MARK, or LRM, to the end of each field that may have bidirectional content, or prepend it to the beginning of the following field. The function `bidi-string-mark-left-to-right`, described below, comes in handy for this purpose. (In a right-to-left paragraph, use U+200F RIGHT-TO-LEFT MARK, or RLM, instead.) This is one of the solutions recommended by the UBA.
- Include the tab character in the field separator. The tab character plays the role of *segment separator* in bidirectional reordering, causing the text on either side to be reordered separately.
- Separate fields with a `display` property or overlay with a property value of the form `(space . PROPS)` (see Section 41.16.2 [Specified Space], page 1200). Emacs treats this display specification as a *paragraph separator*, and reorders the text on either side separately.

**bidi-string-mark-left-to-right** *string* [Function]

This function returns its argument *string*, possibly modified, such that the result can be safely concatenated with another string, or juxtaposed with another string in a buffer, without disrupting the relative layout of this string and the next one on display. If the string returned by this function is displayed as part of a left-to-right paragraph, it will always appear on display to the left of the text that follows it. The function works by examining the characters of its argument, and if any of those characters could cause reordering on display, the function appends the LRM character to the string. The appended LRM character is made invisible by giving it an `invisible` text property of `t` (see Section 41.6 [Invisible Text], page 1142).

The reordering algorithm uses the bidirectional properties of the characters stored as their `bidi-class` property (see Section 34.6 [Character Properties], page 968). Lisp programs can change these properties by calling the `put-char-code-property` function. However, doing this requires a thorough understanding of the UBA, and is therefore not recommended. Any changes to the bidirectional properties of a character have global effect: they affect all Emacs frames and windows.

Similarly, the `mirroring` property is used to display the appropriate mirrored character in the reordered text. Lisp programs can affect the mirrored display by changing this property. Again, any such changes affect all of Emacs display.

The bidirectional properties of characters can be overridden by inserting into the text special directional control characters, LEFT-TO-RIGHT OVERRIDE (LRO) and RIGHT-TO-LEFT OVERRIDE (RLO). Any characters between a RLO and the following newline or POP DIRECTIONAL FORMATTING (PDF) control character, whichever comes first, will be displayed as if they were strong right-to-left characters, i.e. they will be reversed on display. Similarly, any characters between LRO and PDF or newline will display as if they were strong left-to-right, and will *not* be reversed even if they are strong right-to-left characters.

These overrides are useful when you want to make some text unaffected by the reordering algorithm, and instead directly control the display order. But they can also be used for malicious purposes, known as *phishing*. Specifically, a URL on a Web page or a link in an email message can be manipulated to make its visual appearance unrecognizable, or similar to some popular benign location, while the real location, interpreted by a browser in the logical order, is very different.

Emacs provides a primitive that applications can use to detect instances of text whose bidirectional properties were overridden so as to make a left-to-right character display as if it were a right-to-left character, or vice versa.

**bidi-find-overridden-directionality** *from to &optional object* [Function]

This function looks at the text of the specified *object* between positions *from* (inclusive) and *to* (exclusive), and returns the first position where it finds a strong left-to-right character whose directional properties were forced to display the character as right-to-left, or for a strong right-to-left character that was forced to display as left-to-right. If it finds no such characters in the specified region of text, it returns `nil`.

The optional argument *object* specifies which text to search, and defaults to the current buffer. If *object* is non-`nil`, it can be some other buffer, or it can be a string

or a window. If it is a string, the function searches that string. If it is a window, the function searches the buffer displayed in that window. If a buffer whose text you want to examine is displayed in some window, we recommend to specify it by that window, rather than pass the buffer to the function. This is because telling the function about the window allows it to correctly account for window-specific overlays, which might change the result of the function if some text in the buffer is covered by overlays.

When text that includes mixed right-to-left and left-to-right characters and bidirectional controls is copied into a different location, it can change its visual appearance, and also can affect the visual appearance of the surrounding text at destination. This is because reordering of bidirectional text specified by the UBA has non-trivial context-dependent effects both on the copied text and on the text at copy destination that will surround it.

Sometimes, a Lisp program may need to preserve the exact visual appearance of the copied text at destination, and of the text that surrounds the copy. Lisp programs can use the following function to achieve that effect.

**buffer-substring-with-bidi-context** *start end &optional no-properties* [Function]

This function works similar to **buffer-substring** (see Section 33.2 [Buffer Contents], page 879), but it prepends and appends to the copied text bidi directional control characters necessary to preserve the visual appearance of the text when it is inserted at another place. Optional argument *no-properties*, if non-**nil**, means remove the text properties from the copy of the text.

## 42 Operating System Interface

This chapter is about starting and getting out of Emacs, access to values in the operating system environment, and terminal input, output.

See Section E.1 [Building Emacs], page 1346, for related information. See Chapter 41 [Display], page 1129, for additional operating system status information pertaining to the terminal and the screen.

### 42.1 Starting Up Emacs

This section describes what Emacs does when it is started, and how you can customize these actions.

#### 42.1.1 Summary: Sequence of Actions at Startup

When Emacs is started up, it performs the following operations (see `normal-top-level` in `startup.el`):

1. It adds subdirectories to `load-path`, by running the file named `subdirs.el` in each directory in the list. Normally, this file adds the directory's subdirectories to the list, and those are scanned in their turn. The files `subdirs.el` are normally generated automatically when Emacs is installed.
2. It loads any `leim-list.el` that it finds in the `load-path` directories. This file is intended for registering input methods. The search is only for any personal `leim-list.el` files that you may have created; it skips the directories containing the standard Emacs libraries (these should contain only a single `leim-list.el` file, which is compiled into the Emacs executable).
3. It sets the variable `before-init-time` to the value of `current-time` (see Section 42.5 [Time of Day], page 1270). It also sets `after-init-time` to `nil`, which signals to Lisp programs that Emacs is being initialized.
4. It sets the language environment and the terminal coding system, if requested by environment variables such as `LANG`.
5. It does some basic parsing of the command-line arguments.
6. It loads your early init file (see Section “Early Init File” in *The GNU Emacs Manual*). This is not done if the options ‘`-q`’, ‘`-Q`’, or ‘`--batch`’ were specified. If the ‘`-u`’ option was specified, Emacs looks for the init file in that user’s home directory instead.
7. It calls the function `package-activate-all` to activate any optional Emacs Lisp package that has been installed. See Section 43.1 [Packaging Basics], page 1303. However, Emacs doesn’t activate the packages when `package-enable-at-startup` is `nil` or when it’s started with one of the options ‘`-q`’, ‘`-Q`’, or ‘`--batch`’. To activate the packages in the latter case, `package-activate-all` should be called explicitly (e.g., via the ‘`--funcall`’ option).
8. If not running in batch mode, it initializes the window system that the variable `initial-window-system` specifies (see Section 41.25 [Window Systems], page 1248). The initialization function, `window-system-initialization`, is a generic function (see Section 13.8 [Generic Functions], page 245) whose actual implementation is different for each supported window system. If the value of `initial-window-system` is

`windowsystem`, then the appropriate implementation of the initialization function is defined in the file `term/windowsystem-win.el`. This file should have been compiled into the Emacs executable when it was built.

9. It runs the normal hook `before-init-hook`.
10. If appropriate, it creates a graphical frame. As part of creating the graphical frame, it initializes the window system specified by `initial-frame-alist` and `default-frame-alist` (see Section 30.4.2 [Initial Parameters], page 804) for the graphical frame, by calling the `window-system-initialization` function for that window system. This is not done in batch (noninteractive) or daemon mode.
11. It initializes the initial frame's faces, and sets up the menu bar and tool bar if needed. If graphical frames are supported, it sets up the tool bar even if the current frame is not a graphical one, since a graphical frame may be created later on.
12. It uses `custom-reevaluate-setting` to re-initialize the members of the list `custom-delayed-init-variables`. These are any pre-loaded user options whose default value depends on the run-time, rather than build-time, context. See Section E.1 [Building Emacs], page 1346.
13. It loads the library `site-start`, if it exists. This is not done if the options '`-Q`' or '`--no-site-file`' were specified.
14. It loads your init file (see Section 42.1.2 [Init File], page 1258). This is not done if the options '`-q`', '`-Q`', or '`--batch`' were specified. If the '`-u`' option was specified, Emacs looks for the init file in that user's home directory instead.
15. It loads the library `default`, if it exists. This is not done if `inhibit-default-init` is `non-nil`, nor if the options '`-q`', '`-Q`', or '`--batch`' were specified.
16. It loads your abbrevs from the file specified by `abbrev-file-name`, if that file exists and can be read (see Section 38.3 [Abbrev Files], page 1068). This is not done if the option '`--batch`' was specified.
17. It sets the variable `after-init-time` to the value of `current-time`. This variable was set to `nil` earlier; setting it to the current time signals that the initialization phase is over, and, together with `before-init-time`, provides the measurement of how long it took.
18. It runs the normal hooks `after-init-hook` and `delayed-warnings-hook`. The latter shows any warnings emitted during previous stages of startup, which are automatically delayed.
19. If the buffer `*scratch*` exists and is still in Fundamental mode (as it should be by default), it sets its major mode according to `initial-major-mode`.
20. If started on a text terminal, it loads the terminal-specific Lisp library (see Section 42.1.3 [Terminal-Specific], page 1260), and runs the hook `tty-setup-hook`. This is not done in `--batch` mode, nor if `term-file-prefix` is `nil`.
21. It displays the initial echo area message, unless you have suppressed that with `inhibit-startup-echo-area-message`.
22. It processes any command-line options that were not handled earlier.
23. It now exits if the option `--batch` was specified.
24. If the `*scratch*` buffer exists and is empty, it inserts (`substitute-command-keys initial-scratch-message`) into that buffer.

25. If `initial-buffer-choice` is a string, it visits the file (or directory) with that name. If it is a function, it calls the function with no arguments and selects the buffer that it returns. If one file is given as a command line argument, that file is visited and its buffer displayed alongside `initial-buffer-choice`. If more than one file is given, all of the files are visited and the `*Buffer List*` buffer is displayed alongside `initial-buffer-choice`.
26. It runs `emacs-startup-hook`.
27. It calls `frame-notice-user-settings`, which modifies the parameters of the selected frame according to whatever the init files specify.
28. It runs `window-setup-hook`. The only difference between this hook and `emacs-startup-hook` is that this one runs after the previously mentioned modifications to the frame parameters.
29. It displays the *startup screen*, which is a special buffer that contains information about copyleft and basic Emacs usage. This is not done if `inhibit-startup-screen` or `initial-buffer-choice` are non-nil, or if the ‘`--no-splash`’ or ‘`-Q`’ command-line options were specified.
30. If a daemon was requested, it calls `server-start`. (On POSIX systems, if a background daemon was requested, it then detaches from the controlling terminal.) See Section “Emacs Server” in *The GNU Emacs Manual*.
31. If started by the X session manager, it calls `emacs-session-restore` passing it as argument the ID of the previous session. See Section 42.18 [Session Management], page 1290.

The following options affect some aspects of the startup sequence.

#### `inhibit-startup-screen`

[User Option]

This variable, if non-nil, inhibits the startup screen. In that case, Emacs typically displays the `*scratch*` buffer; but see `initial-buffer-choice`, below.

Do not set this variable in the init file of a new user, or in a way that affects more than one user, as that would prevent new users from receiving information about copyleft and basic Emacs usage.

`inhibit-startup-message` and `inhibit-splash-screen` are aliases for this variable.

#### `initial-buffer-choice`

[User Option]

If non-nil, this variable is a string that specifies a file or directory for Emacs to display after starting up, instead of the startup screen. If its value is a function, Emacs calls that function which must return a buffer which is then displayed. If its value is t, Emacs displays the `*scratch*` buffer.

#### `inhibit-startup-echo-area-message`

[User Option]

This variable controls the display of the startup echo area message. You can suppress the startup echo area message by adding text with this form to your init file:

```
(setq inhibit-startup-echo-area-message
 "your-login-name")
```

Emacs explicitly checks for an expression as shown above in your init file; your login name must appear in the expression as a Lisp string constant. You can also use

the Customize interface. Other methods of setting `inhibit-startup-echo-area-message` to the same value do not inhibit the startup message. This way, you can easily inhibit the message for yourself if you wish, but thoughtless copying of your init file will not inhibit the message for someone else.

**initial-scratch-message** [User Option]

This variable, if non-`nil`, should be a string, which is treated as documentation to be inserted into the `*scratch*` buffer when Emacs starts up or when that buffer is recreated. If it is `nil`, the `*scratch*` buffer is empty.

The following command-line options affect some aspects of the startup sequence. See Section “Initial Options” in *The GNU Emacs Manual*.

**--no-splash**

Do not display a splash screen.

**--batch** Run without an interactive terminal. See Section 42.17 [Batch Mode], page 1289.

**--daemon**

**--bg-daemon**

**--fg-daemon**

Do not initialize any display; just start a server. (A “background” daemon automatically runs in the background.)

**--no-init-file**

**-q** Do not load either the init file, or the `default` library.

**--no-site-file**

Do not load the `site-start` library.

**--quick**

**-Q** Equivalent to ‘`-q --no-site-file --no-splash`’.

**--init-directory**

Specify the directory to use when finding the Emacs init files.

### 42.1.2 The Init File

When you start Emacs, it normally attempts to load your *init file*. This is either a file named `.emacs` or `.emacs.el` in your home directory, or a file named `init.el` in a subdirectory named `.emacs.d` in your home directory.

The command-line switches ‘`-q`’, ‘`-Q`’, and ‘`-u`’ control whether and where to find the init file; ‘`-q`’ (and the stronger ‘`-Q`’) says not to load an init file, while ‘`-u user`’ says to load *user*’s init file instead of yours. See Section “Entering Emacs” in *The GNU Emacs Manual*. If neither option is specified, Emacs uses the `LOGNAME` environment variable, or the `USER` (most systems) or `USERNAME` (MS systems) variable, to find your home directory and thus your init file; this way, even if you have su’d, Emacs still loads your own init file. If those environment variables are absent, though, Emacs uses your user-id to find your home directory.

Emacs also attempts to load a second init file, called the *early init file*, if it exists. This is a file named `early-init.el` in your `~/.emacs.d` directory. The difference between the early init file and the regular init file is that the early init file is loaded much earlier during

the startup process, so you can use it to customize some things that are initialized before loading the regular init file. For example, you can customize the process of initializing the package system, by setting variables such as `package-load-list` or `package-enable-at-startup`. See Section “Package Installation” in *The GNU Emacs Manual*.

An Emacs installation may have a *default init file*, which is a Lisp library named `default.el`. Emacs finds this file through the standard search path for libraries (see Section 16.1 [How Programs Do Loading], page 298). The Emacs distribution does not come with this file; it is intended for local customizations. If the default init file exists, it is loaded whenever you start Emacs. But your own personal init file, if any, is loaded first; if it sets `inhibit-default-init` to a non-`nil` value, then Emacs does not subsequently load the `default.el` file. In batch mode, or if you specify ‘`-q`’ (or ‘`-Q`’), Emacs loads neither your personal init file nor the default init file.

Another file for site-customization is `site-start.el`. Emacs loads this *before* the user’s init file. You can inhibit the loading of this file with the option ‘`--no-site-file`’.

**site-run-file**

[User Option]

This variable specifies the site-customization file to load before the user’s init file. Its normal value is “`site-start`”. The only way you can change it with real effect is to do so before dumping Emacs.

See Section “Init File Examples” in *The GNU Emacs Manual*, for examples of how to make various commonly desired customizations in your `.emacs` file.

**inhibit-default-init**

[User Option]

If this variable is non-`nil`, it prevents Emacs from loading the default initialization library file. The default value is `nil`.

**before-init-hook**

[Variable]

This normal hook is run, once, just before loading all the init files (`site-start.el`, your init file, and `default.el`). (The only way to change it with real effect is before dumping Emacs.)

**after-init-hook**

[Variable]

This normal hook is run, once, just after loading all the init files (`site-start.el`, your init file, and `default.el`), before loading the terminal-specific library (if started on a text terminal) and processing the command-line action arguments.

**emacs-startup-hook**

[Variable]

This normal hook is run, once, just after handling the command line arguments. In batch mode, Emacs does not run this hook.

**window-setup-hook**

[Variable]

This normal hook is very similar to `emacs-startup-hook`. The only difference is that it runs slightly later, after setting of the frame parameters. See Section 42.1.1 [Startup Summary], page 1255.

**user-init-file**

[Variable]

This variable holds the absolute file name of the user’s init file. If the actual init file loaded is a compiled file, such as `.emacs.elc`, the value refers to the corresponding source file.

**user-emacs-directory**

[Variable]

This variable holds the name of the Emacs default directory. It defaults to `$(XDG_CONFIG_HOME-'~/.config')/emacs/` if that directory exists and `~/emacs.d/` and `~/.emacs` do not exist, otherwise to `~/emacs.d/` on all platforms but MS-DOS. Here, `$(XDG_CONFIG_HOME-'~/.config')` stands for the value of the environment variable `XDG_CONFIG_HOME` if that variable is set, and for `~/config` otherwise. See Section “How Emacs Finds Your Init File” in *The GNU Emacs Manual*.

### 42.1.3 Terminal-Specific Initialization

Each terminal type can have its own Lisp library that Emacs loads when run on that type of terminal. The library’s name is constructed by concatenating the value of the variable `term-file-prefix` and the terminal type (specified by the environment variable `TERM`). Normally, `term-file-prefix` has the value `"term/"`; changing this is not recommended. If there is an entry matching `TERM` in the `term-file-aliases` association list, Emacs uses the associated value in place of `TERM`. Emacs finds the file in the normal manner, by searching the `load-path` directories, and trying the `'.elc'` and `'.el'` suffixes.

The usual role of a terminal-specific library is to enable special keys to send sequences that Emacs can recognize. It may also need to set or add to `input-decode-map` if the Termcap or Terminfo entry does not specify all the terminal’s function keys. See Section 42.13 [Terminal Input], page 1285.

When the name of the terminal type contains a hyphen or underscore, and no library is found whose name is identical to the terminal’s name, Emacs strips from the terminal’s name the last hyphen or underscore and everything that follows it, and tries again. This process is repeated until Emacs finds a matching library, or until there are no more hyphens or underscores in the name (i.e., there is no terminal-specific library). For example, if the terminal name is `‘xterm-256color’` and there is no `term/xterm-256color.el` library, Emacs tries to load `term/xterm.el`. If necessary, the terminal library can evaluate `(getenv "TERM")` to find the full name of the terminal type.

Your init file can prevent the loading of the terminal-specific library by setting the variable `term-file-prefix` to `nil`.

You can also arrange to override some of the actions of the terminal-specific library by using `tty-setup-hook`. This is a normal hook that Emacs runs after initializing a new text terminal. You could use this hook to define initializations for terminals that do not have their own libraries. See Section 24.1 [Hooks], page 524.

**term-file-prefix**

[User Option]

If the value of this variable is `non-nil`, Emacs loads a terminal-specific initialization file as follows:

```
(load (concat term-file-prefix (getenv "TERM")))
```

You may set the `term-file-prefix` variable to `nil` in your init file if you do not wish to load the terminal-initialization file.

On MS-DOS, Emacs sets the `TERM` environment variable to ‘internal’.

**term-file-aliases**

[User Option]

This variable is an association list mapping terminal types to their aliases. For example, an element of the form `("vt102" . "vt100")` means to treat a terminal of type ‘`vt102`’ like one of type ‘`vt100`’.

**tty-setup-hook**

[Variable]

This variable is a normal hook that Emacs runs after initializing a new text terminal. (This applies when Emacs starts up in non-windowed mode, and when making a `tty emacsclient` connection.) The hook runs after loading your init file (if applicable) and the terminal-specific Lisp file, so you can use it to adjust the definitions made by that file.

For a related feature, see Section 42.1.2 [Init File], page 1258.

#### 42.1.4 Command-Line Arguments

You can use command-line arguments to request various actions when you start Emacs. Note that the recommended way of using Emacs is to start it just once, after logging in, and then do all editing in the same Emacs session (see Section “Entering Emacs” in *The GNU Emacs Manual*). For this reason, you might not use command-line arguments very often; nonetheless, they can be useful when invoking Emacs from session scripts or debugging Emacs. This section describes how Emacs processes command-line arguments.

**command-line**

[Function]

This function parses the command line that Emacs was called with, processes it, and (amongst other things) loads the user’s init file and displays the startup messages.

**command-line-processed**

[Variable]

The value of this variable is `t` once the command line has been processed.

If you redump Emacs by calling `dump-emacs` (see Section E.1 [Building Emacs], page 1346), you may wish to set this variable to `nil` first in order to cause the new dumped Emacs to process its new command-line arguments.

**command-switch-alist**

[Variable]

This variable is an alist of user-defined command-line options and associated handler functions. By default it is empty, but you can add elements if you wish.

A *command-line option* is an argument on the command line, which has the form:

*-option*

The elements of the `command-switch-alist` look like this:

*(option . handler-function)*

The CAR, *option*, is a string, the name of a command-line option (including the initial hyphen). The *handler-function* is called to handle *option*, and receives the option name as its sole argument.

In some cases, the option is followed in the command line by an argument. In these cases, the *handler-function* can find all the remaining command-line arguments in the variable `command-line-args-left` (see below). (The entire list of command-line arguments is in `command-line-args`.)

Note that the handling of `command-switch-alist` doesn’t treat equals signs in *option* specially. That is, if there’s an option like `--name=value` on the command line, then only a `command-switch-alist` member whose car is literally `--name=value` will match this option. If you want to parse such options, you need to use `command-line-functions` instead (see below).

The command-line arguments are parsed by the `command-line-1` function in the `startup.el` file. See also Section “Command Line Arguments for Emacs Invocation” in *The GNU Emacs Manual*.

**command-line-args** [Variable]

The value of this variable is the list of command-line arguments passed to Emacs.

**command-line-args-left** [Variable]

The value of this variable is the list of command-line arguments that have not yet been processed.

**command-line-functions** [Variable]

This variable’s value is a list of functions for handling an unrecognized command-line argument. Each time the next argument to be processed has no special meaning, the functions in this list are called, in order of appearance, until one of them returns a non-`nil` value.

These functions are called with no arguments. They can access the command-line argument under consideration through the variable `argi`, which is bound temporarily at this point. The remaining arguments (not including the current one) are in the variable `command-line-args-left`.

When a function recognizes and processes the argument in `argi`, it should return a non-`nil` value to say it has dealt with that argument. If it has also dealt with some of the following arguments, it can indicate that by deleting them from `command-line-args-left`.

If all of these functions return `nil`, then the argument is treated as a file name to visit.

## 42.2 Getting Out of Emacs

There are two ways to get out of Emacs: you can kill the Emacs job, which exits permanently, or you can suspend it, which permits you to reenter the Emacs process later. (In a graphical environment, you can of course simply switch to another application without doing anything special to Emacs, then switch back to Emacs when you want.)

### 42.2.1 Killing Emacs

Killing Emacs means ending the execution of the Emacs process. If you started Emacs from a terminal, the parent process normally resumes control. The low-level primitive for killing Emacs is `kill-emacs`.

**kill-emacs &optional exit-data restart** [Command]

This command calls the hook `kill-emacs-hook`, then exits the Emacs process and kills it.

If `exit-data` is an integer, that is used as the exit status of the Emacs process. (This is useful primarily in batch operation; see Section 42.17 [Batch Mode], page 1289.)

If `exit-data` is a string, its contents are stuffed into the terminal input buffer so that the shell (or whatever program next reads input) can read them.

If `exit-data` is neither an integer nor a string, or is omitted, that means to use the (system-specific) exit status which indicates successful program termination.

If `restart` is non-`nil`, instead of just exiting at the end, start a new Emacs process, using the same command line arguments as the currently running Emacs process.

The `kill-emacs` function is normally called via the higher-level command `C-x C-c` (`save-buffers-kill-terminal`). See Section “Exiting” in *The GNU Emacs Manual*. It is also called automatically if Emacs receives a `SIGTERM` or `SIGHUP` operating system signal (e.g., when the controlling terminal is disconnected), or if it receives a `SIGINT` signal while running in batch mode (see Section 42.17 [Batch Mode], page 1289).

**kill-emacs-hook** [Variable]

This normal hook is run by `kill-emacs`, before it kills Emacs.

Because `kill-emacs` can be called in situations where user interaction is impossible (e.g., when the terminal is disconnected), functions on this hook should not attempt to interact with the user. If you want to interact with the user when Emacs is shutting down, use `kill-emacs-query-functions`, described below.

When Emacs is killed, all the information in the Emacs process, aside from files that have been saved, is lost. Because killing Emacs inadvertently can lose a lot of work, the `save-buffers-kill-terminal` command queries for confirmation if you have buffers that need saving or subprocesses that are running. It also runs the abnormal hook `kill-emacs-query-functions`:

**kill-emacs-query-functions** [User Option]

When `save-buffers-kill-terminal` is killing Emacs, it calls the functions in this hook, after asking the standard questions and before calling `kill-emacs`. The functions are called in order of appearance, with no arguments. Each function can ask for additional confirmation from the user. If any of them returns `nil`, `save-buffers-kill-emacs` does not kill Emacs, and does not run the remaining functions in this hook. Calling `kill-emacs` directly does not run this hook.

**restart-emacs** [Command]

This command does the same as `save-buffers-kill-emacs`, but instead of just killing the current Emacs process at the end, it’ll restart a new Emacs process, using the same command line arguments as the currently running Emacs process.

### 42.2.2 Suspending Emacs

On text terminals, it is possible to *suspend Emacs*, which means stopping Emacs temporarily and returning control to its superior process, which is usually the shell. This allows you to resume editing later in the same Emacs process, with the same buffers, the same kill ring, the same undo history, and so on. To resume Emacs, use the appropriate command in the parent shell—most likely `fg`.

Suspending works only on a terminal device from which the Emacs session was started. We call that device the *controlling terminal* of the session. Suspending is not allowed if the controlling terminal is a graphical terminal. Suspending is usually not relevant in graphical environments, since you can simply switch to another application without doing anything special to Emacs.

Some operating systems (those without `SIGTSTP`, or MS-DOS) do not support suspension of jobs; on these systems, suspension actually creates a new shell temporarily as a subprocess of Emacs. Then you would exit the shell to return to Emacs.

**suspend-emacs** &optional *string*

[Command]

This function stops Emacs and returns control to the superior process. If and when the superior process resumes Emacs, **suspend-emacs** returns **nil** to its caller in Lisp. This function works only on the controlling terminal of the Emacs session; to relinquish control of other tty devices, use **suspend-tty** (see below). If the Emacs session uses more than one terminal, you must delete the frames on all the other terminals before suspending Emacs, or this function signals an error. See Section 30.2 [Multiple Terminals], page 787.

If *string* is non-**nil**, its characters are sent to Emacs's superior shell, to be read as terminal input. The characters in *string* are not echoed by the superior shell; only the results appear.

Before suspending, **suspend-emacs** runs the normal hook **suspend-hook**. After the user resumes Emacs, **suspend-emacs** runs the normal hook **suspend-resume-hook**. See Section 24.1 [Hooks], page 524.

The next redisplay after resumption will redraw the entire screen, unless the variable **no-redraw-on-reenter** is non-**nil**. See Section 41.1 [Refresh Screen], page 1129.

Here is an example of how you could use these hooks:

```
(add-hook 'suspend-hook
 (lambda () (or (y-or-n-p "Really suspend?")
 (error "Suspend canceled"))))
(add-hook 'suspend-resume-hook (lambda () (message "Resumed!")
 (sit-for 2)))
```

Here is what you would see upon evaluating (**suspend-emacs "pwd"**):

```
----- Buffer: Minibuffer -----
Really suspend? y
----- Buffer: Minibuffer -----
```

```
----- Parent Shell -----
bash$ /home/username
bash$ fg
```

```
----- Echo Area -----
Resumed!
```

Note that ‘**pwd**’ is not echoed after Emacs is suspended. But it is read and executed by the shell.

**suspend-hook**

[Variable]

This variable is a normal hook that Emacs runs before suspending.

**suspend-resume-hook**

[Variable]

This variable is a normal hook that Emacs runs on resuming after a suspension.

**suspend-tty** &optional *tty*

[Function]

If *tty* specifies a terminal device used by Emacs, this function relinquishes the device and restores it to its prior state. Frames that used the device continue to exist, but are not updated and Emacs doesn't read input from them. *tty* can be a terminal object, a frame (meaning the terminal for that frame), or **nil** (meaning the terminal for the selected frame). See Section 30.2 [Multiple Terminals], page 787.

If *tty* is already suspended, this function does nothing.

This function runs the hook `suspend-tty-functions`, passing the terminal object as an argument to each function.

**resume-tty &optional tty** [Function]

This function resumes the previously suspended terminal device `tty`; where `tty` has the same possible values as it does for `suspend-tty`.

This function reopens the terminal device, re-initializes it, and redraws it with that terminal's selected frame. It then runs the hook `resume-tty-functions`, passing the terminal object as an argument to each function.

If the same device is already used by another Emacs terminal, this function signals an error. If `tty` is not suspended, this function does nothing.

**controlling-tty-p &optional tty** [Function]

This function returns `non-nil` if `tty` is the controlling terminal of the Emacs session; `tty` can be a terminal object, a frame (meaning the terminal for that frame), or `nil` (meaning the terminal for the selected frame).

**suspend-frame** [Command]

This command *suspends* a frame. For GUI frames, it calls `iconify-frame` (see Section 30.11 [Visibility of Frames], page 828); for frames on text terminals, it calls either `suspend-emacs` or `suspend-tty`, depending on whether the frame is displayed on the controlling terminal device or not.

## 42.3 Operating System Environment

Emacs provides access to variables in the operating system environment through various functions. These variables include the name of the system, the user's UID, and so on.

**system-configuration** [Variable]

This variable holds the standard GNU configuration name for the hardware/software configuration of your system, as a string. For example, a typical value for a 64-bit GNU/Linux system is "`"x86_64-unknown-linux-gnu"`".

**system-type** [Variable]

The value of this variable is a symbol indicating the type of operating system Emacs is running on. The possible values are:

`aix` IBM's AIX.

`berkeley-unix`

Berkeley BSD and its variants.

`cygwin` Cygwin, a POSIX layer on top of MS-Windows.

`darwin` Darwin (macOS).

`gnu` The GNU system (using the GNU kernel, which consists of the HURD and Mach).

`gnu/linux`

A GNU/Linux system—that is, a variant GNU system, using the Linux kernel. (These systems are the ones people often call “Linux”, but actually Linux is just the kernel, not the whole system.)

|                     |                                                                                                                                     |
|---------------------|-------------------------------------------------------------------------------------------------------------------------------------|
| <b>gnu/kfreebsd</b> | A GNU (glibc-based) system with a FreeBSD kernel.                                                                                   |
| <b>haiku</b>        | The Haiku operating system, a derivative of the Be Operating System.                                                                |
| <b>hpx</b>          | Hewlett-Packard HPUX operating system.                                                                                              |
| <b>nacl</b>         | Google Native Client (NaCl) sandboxing system.                                                                                      |
| <b>ms-dos</b>       | Microsoft's DOS. Emacs compiled with DJGPP for MS-DOS binds <b>system-type</b> to <b>ms-dos</b> even when you run it on MS-Windows. |
| <b>usg-unix-v</b>   | AT&T Unix System V.                                                                                                                 |
| <b>windows-nt</b>   | Microsoft Windows NT, 9X and later. The value of <b>system-type</b> is always <b>windows-nt</b> , e.g., even on Windows 10.         |

We do not wish to add new symbols to make finer distinctions unless it is absolutely necessary! In fact, we hope to eliminate some of these alternatives in the future. If you need to make a finer distinction than **system-type** allows for, you can test **system-configuration**, e.g., against a regexp.

**system-name** [Function]  
 This function returns the name of the machine you are running on, as a string.

**mail-host-address** [User Option]  
 If this variable is non-*nil*, it is used instead of **system-name** for purposes of generating email addresses. For example, it is used when constructing the default value of **user-mail-address**. See Section 42.4 [User Identification], page 1269.

**getenv var &optional frame** [Command]  
 This function returns the value of the environment variable *var*, as a string. *var* should be a string. If *var* is undefined in the environment, **getenv** returns *nil*. It returns “” if *var* is set but null. Within Emacs, a list of environment variables and their values is kept in the variable **process-environment**.

```
(getenv "USER")
⇒ "lewis"
```

The shell command **printenv** prints all or part of the environment:

```
bash$ printenv
PATH=/usr/local/bin:/usr/bin:/bin
USER=lewis
TERM=xterm
SHELL=/bin/bash
HOME=/home/lewis
...
```

**setenv variable &optional value substitute** [Command]  
 This command sets the value of the environment variable named *variable* to *value*. *variable* should be a string. Internally, Emacs Lisp can handle any string. However,

normally *variable* should be a valid shell identifier, that is, a sequence of letters, digits and underscores, starting with a letter or underscore. Otherwise, errors may occur if subprocesses of Emacs try to access the value of *variable*. If *value* is omitted or *nil* (or, interactively, with a prefix argument), `setenv` removes *variable* from the environment. Otherwise, *value* should be a string.

If the optional argument *substitute* is *non-nil*, Emacs calls the function `substitute-env-vars` to expand any environment variables in *value*.

`setenv` works by modifying `process-environment`; binding that variable with `let` is also reasonable practice.

`setenv` returns the new value of *variable*, or *nil* if it removed *variable* from the environment.

#### **with-environment-variables** *variables* *body*... [Macro]

This macro sets the environment variables according to *variables* temporarily when executing *body*. The previous values are restored when the form finishes. The argument *variables* should be a list of pairs of strings of the form (*var* *value*), where *var* is the name of the environment variable and *value* is that variable's value.

```
(with-environment-variables (("LANG" "C")
 ("LANGUAGE" "en_US:en"))
 (call-process "ls" nil t))
```

#### **process-environment** [Variable]

This variable is a list of strings, each describing one environment variable. The functions `getenv` and `setenv` work by means of this variable.

```
process-environment
⇒ ("PATH=/usr/local/bin:/usr/bin:/bin"
 "USER=lewis"
 "TERM=xterm"
 "SHELL=/bin/bash"
 "HOME=/home/lewis"
 ...)
```

If `process-environment` contains multiple elements that specify the same environment variable, the first of these elements specifies the variable, and the others are ignored.

#### **initial-environment** [Variable]

This variable holds the list of environment variables Emacs inherited from its parent process when Emacs started.

#### **path-separator** [Variable]

This variable holds a string that says which character separates directories in a search path (as found in an environment variable). Its value is ":" for Unix and GNU systems, and ";" for MS systems.

#### **path-separator** [Function]

This function returns the connection-local value of variable `path-separator`. That is ";" for MS systems and a local `default-directory`, and ":" for Unix and GNU systems, or a remote `default-directory`.

**parse-colon-path** *path*

[Function]

This function takes a search path string such as the value of the PATH environment variable, and splits it at the separators, returning a list of directories. `nil` in this list means the current directory. Although the function's name says “colon”, it actually uses the value of variable `path-separator`.

```
(parse-colon-path ":/foo:/bar")
⇒ (nil "/foo/" "/bar/")
```

**invocation-name**

[Variable]

This variable holds the program name under which Emacs was invoked. The value is a string, and does not include a directory name.

**invocation-directory**

[Variable]

This variable holds the directory in which the Emacs executable was located when it was run, or `nil` if that directory cannot be determined.

**installation-directory**

[Variable]

If non-`nil`, this is a directory within which to look for the `lib-src` and `etc` sub-directories. In an installed Emacs, it is normally `nil`. It is non-`nil` when Emacs can't find those directories in their standard installed locations, but can find them in a directory related somehow to the one containing the Emacs executable (i.e., `invocation-directory`).

**load-average &optional** *use-float*

[Function]

This function returns the current 1-minute, 5-minute, and 15-minute system load averages, in a list. The load average indicates the number of processes trying to run on the system.

By default, the values are integers that are 100 times the system load averages, but if `use-float` is non-`nil`, then they are returned as floating-point numbers without multiplying by 100.

If it is impossible to obtain the load average, this function signals an error. On some platforms, access to load averages requires installing Emacs as setuid or setgid so that it can read kernel information, and that usually isn't advisable.

If the 1-minute load average is available, but the 5- or 15-minute averages are not, this function returns a shortened list containing the available averages.

```
(load-average)
⇒ (169 48 36)
(load-average t)
⇒ (1.69 0.48 0.36)
```

The shell command `uptime` returns similar information.

**emacs-pid**

[Function]

This function returns the process ID of the Emacs process, as an integer.

**tty-erase-char**

[Variable]

This variable holds the erase character that was selected in the system's terminal driver, before Emacs was started.

**null-device** [Variable]

This variable holds the system null device. Its value is "/dev/null" for Unix and GNU systems, and "NUL" for MS systems.

**null-device** [Function]

This function returns the connection-local value of variable `null-device`. That is "NUL" for MS systems and a local `default-directory`, and "/dev/null" for Unix and GNU systems, or a remote `default-directory`.

## 42.4 User Identification

**init-file-user** [Variable]

This variable says which user's init files should be used by Emacs—or `nil` if none. "" stands for the user who originally logged in. The value reflects command-line options such as '-q' or '-u *user*'.

Lisp packages that load files of customizations, or any other sort of user profile, should obey this variable in deciding where to find it. They should load the profile of the user name found in this variable. If `init-file-user` is `nil`, meaning that the '-q', '-Q', or '-batch' option was used, then Lisp packages should not load any customization files or user profile.

**user-mail-address** [User Option]

This holds the email address of the user who is using Emacs.

**user-login-name &optional uid** [Function]

This function returns the name under which the user is logged in. It uses the environment variables `LOGNAME` or `USER` if either is set. Otherwise, the value is based on the effective UID, not the real UID.

If you specify *uid* (a number), the result is the user name that corresponds to *uid*, or `nil` if there is no such user.

**user-real-login-name** [Function]

This function returns the user name corresponding to Emacs's real UID. This ignores the effective UID, and the environment variables `LOGNAME` and `USER`.

**user-full-name &optional uid** [Function]

This function returns the full name of the logged-in user—or the value of the environment variable `NAME`, if that is set.

If the Emacs process's user-id does not correspond to any known user (and provided `NAME` is not set), the result is "unknown".

If *uid* is non-`nil`, then it should be a number (a user-id) or a string (a login name). Then `user-full-name` returns the full name corresponding to that user-id or login name. If you specify a user-id or login name that isn't defined, it returns `nil`.

The symbols `user-login-name`, `user-real-login-name` and `user-full-name` are variables as well as functions. The functions return the same values that the variables hold. These variables allow you to fake out Emacs by telling the functions what to return. The variables are also useful for constructing frame titles (see Section 30.6 [Frame Titles], page 821).

|                                                                                                                                                                                                                       |            |
|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|------------|
| <b>user-real-uid</b>                                                                                                                                                                                                  | [Function] |
| This function returns the real UID of the user.                                                                                                                                                                       |            |
| <b>user-uid</b>                                                                                                                                                                                                       | [Function] |
| This function returns the effective UID of the user.                                                                                                                                                                  |            |
| <b>group-gid</b>                                                                                                                                                                                                      | [Function] |
| This function returns the effective GID of the Emacs process.                                                                                                                                                         |            |
| <b>group-real-gid</b>                                                                                                                                                                                                 | [Function] |
| This function returns the real GID of the Emacs process.                                                                                                                                                              |            |
| <b>system-users</b>                                                                                                                                                                                                   | [Function] |
| This function returns a list of strings, listing the user names on the system. If Emacs cannot retrieve this information, the return value is a list containing just the value of <code>user-real-login-name</code> . |            |
| <b>system-groups</b>                                                                                                                                                                                                  | [Function] |
| This function returns a list of strings, listing the names of user groups on the system. If Emacs cannot retrieve this information, the return value is <code>nil</code> .                                            |            |
| <b>group-name</b> <i>gid</i>                                                                                                                                                                                          | [Function] |
| This function returns the group name that corresponds to the numeric group ID <i>gid</i> , or <code>nil</code> if there is no such group.                                                                             |            |

## 42.5 Time of Day

This section explains how to determine the current time and time zone.

Many functions like `current-time` and `file-attributes` return *Lisp timestamp* values that count seconds, and that can represent absolute time by counting seconds since the epoch of 1970-01-01 00:00:00 UTC (Coordinated Universal Time). Typically these counts ignore leap seconds; however, GNU and some other operating systems can be configured to count leap seconds.

Although traditionally Lisp timestamps were integer pairs, their form has evolved and programs ordinarily should not depend on the current default form. If your program needs a particular timestamp form, you can use the `time-convert` function to convert it to the needed form. See Section 42.7 [Time Conversion], page 1273.

There are currently three forms of Lisp timestamps, each of which represents a number of seconds:

- An integer. Although this is the simplest form, it cannot represent subsecond timestamps.
- A pair of integers (*ticks . hz*), where *hz* is positive. This represents *ticks/hz* seconds, which is the same time as plain *ticks* if *hz* is 1. A common value for *hz* is 1000000000, for a nanosecond-resolution clock.
- A list of four integers (*high low micro pico*), where  $0 \leq low < 65536$ ,  $0 \leq micro < 1000000$ , and  $0 \leq pico < 1000000$ . This represents the number of seconds using the formula:  $high \times 2^{16} + low + micro \times 10^{-6} + pico \times 10^{-12}$ . If `current-time-list` is *t*, some functions may default to returning two- or three-element lists, with omitted *micro* and *pico*.

components defaulting to zero. On all current machines *pico* is a multiple of 1000, but this may change as higher-resolution clocks become available.

Function arguments, e.g., the *time* argument to `format-time-string`, accept a more-general *time value* format, which can be a Lisp timestamp, `nil` for the current time, a finite floating-point number for seconds, or a list (*high low micro*) or (*high low*) that is a truncated list timestamp with missing elements taken to be zero.

Time values can be converted to and from calendrical and other forms. Some of these conversions rely on operating system functions that limit the range of possible time values, and signal an error such as ‘‘Specified time is not representable’’ if the limits are exceeded. For instance, a system might not support timestamps before the epoch, or years far in the future. You can convert a time value into a human-readable string using `format-time-string`, into a Lisp timestamp using `time-convert`, and into other forms using `decode-time` and `float-time`. These functions are described in the following sections.

### `current-time-string` &optional *time zone*

[Function]

This function returns the current time and date as a human-readable string. The format does not vary for the initial part of the string, which contains the day of week, month, day of month, and time of day in that order: the number of characters used for these fields is always the same, although (unless you require English weekday or month abbreviations regardless of locale) it is typically more convenient to use `format-time-string` than to extract fields from the output of `current-time-string`, as the year might not have exactly four digits, and additional information may some day be added at the end.

The argument *time*, if given, specifies a time to format, instead of the current time. The optional argument *zone* defaults to the current time zone rule. See Section 42.6 [Time Zone Rules], page 1272. The operating system limits the range of time and zone values.

```
(current-time-string)
⇒ "Fri Nov 1 15:59:49 2019"
```

### `current-time-list`

[Variable]

This boolean variable is a transition aid. If `t`, `current-time` and related functions return timestamps in list form, typically (*high low micro pico*); otherwise, they use (*ticks . hz*) form. Currently this variable defaults to `t`, for behavior compatible with previous Emacs versions. Developers are encouraged to test timestamp-related code with this variable set to `nil`, as it will default to `nil` in a future Emacs version, and will be removed in some version after that.

### `current-time`

[Function]

This function returns the current time as a Lisp timestamp. If `current-time-list` is `nil`, the timestamp has the form (*ticks . hz*) where *ticks* counts clock ticks and *hz* is the clock ticks per second. Otherwise, the timestamp has the list form (*high low usec psec*). You can use (`time-convert nil t`) or (`time-convert nil 'list`) to obtain a particular form regardless of the value of `current-time-list`. See Section 42.7 [Time Conversion], page 1273.

**float-time &optional time**

[Function]

This function returns the current time as a floating-point number of seconds since the epoch. The optional argument *time*, if given, specifies a time to convert instead of the current time.

*Warning:* Since the result is floating point, it may not be exact. Do not use this function if precise time stamps are required. For example, on typical systems (`float-time '(1 . 10)`) displays as ‘0.1’ but is slightly greater than 1/10.

`time-to-seconds` is an alias for this function.

**current-cpu-time**

[Function]

Return the current CPU time along with its resolution. The return value is a pair (`CPU-TICKS . TICKS-PER-SEC`). The *CPU-TICKS* counter can wrap around, so values cannot be meaningfully compared if too much time has passed between them.

## 42.6 Time Zone Rules

The default time zone is determined by the `TZ` environment variable. See Section 42.3 [System Environment], page 1265. For example, you can tell Emacs to default to Universal Time with (`(setenv "TZ" "UTC0")`). If `TZ` is not in the environment, Emacs uses system wall clock time, which is a platform-dependent default time zone.

The set of supported `TZ` strings is system-dependent. GNU and many other systems support TZDB timezones, e.g., ‘“America/New\_York”’ specifies the time zone and daylight saving time history for locations near New York City. GNU and most other systems support POSIX-style `TZ` strings, e.g., ‘“EST5EDT,M4.1.0,M10.5.0”’ specifies the rules used in New York from 1987 through 2006. All systems support the string ‘“UTC0”’ meaning Universal Time.

Functions that convert to and from local time accept an optional *time zone rule* argument, which specifies the conversion’s time zone and daylight saving time history. If the time zone rule is omitted or `nil`, the conversion uses Emacs’s default time zone. If it is `t`, the conversion uses Universal Time. If it is `wall`, the conversion uses the system wall clock time. If it is a string, the conversion uses the time zone rule equivalent to setting `TZ` to that string. If it is a list (`offset abbr`), where `offset` is an integer number of seconds east of Universal Time and `abbr` is a string, the conversion uses a fixed time zone with the given offset and abbreviation. An integer `offset` is treated as if it were (`offset abbr`), where `abbr` is a numeric abbreviation on POSIX-compatible platforms and is unspecified on MS-Windows.

**current-time-zone &optional time zone**

[Function]

This function returns a list describing the time zone that the user is in.

The value has the form (`offset abbr`). Here `offset` is an integer giving the number of seconds ahead of Universal Time (east of Greenwich). A negative value means west of Greenwich. The second element, `abbr`, is a string giving an abbreviation for the time zone, e.g., ‘“CST”’ for China Standard Time or for U.S. Central Standard Time. Both elements can change when daylight saving time begins or ends; if the user has specified a time zone that does not use a seasonal time adjustment, then the value is constant through time.

If the operating system doesn’t supply all the information necessary to compute the value, the unknown elements of the list are `nil`.

The argument *time*, if given, specifies a time value to analyze instead of the current time. The optional argument *zone* defaults to the current time zone rule. The operating system limits the range of time and zone values.

## 42.7 Time Conversion

These functions convert time values (see Section 42.5 [Time of Day], page 1270) to Lisp timestamps, or into calendrical information and vice versa.

Many operating systems use 64-bit signed integers to count seconds, and can represent times far in the past or future. However, some are more limited. For example, old-fashioned operating systems that use 32-bit signed integers typically handle only times from 1901-12-13 20:45:52 through 2038-01-19 03:14:07 Universal Time.

Calendrical conversion functions use the Gregorian calendar even for dates before the Gregorian calendar was introduced, and for dates in the far distant past or future for which the Gregorian calendar is wildly inaccurate and disagrees with common practice in scientific fields like astronomy and paleontology, which use Julian-calendar year lengths. Year numbers count since the year 1 BCE, and do not skip zero as traditional Gregorian years do; for example, the year number –37 represents the Gregorian year 38 BCE.

### `time-convert time form`

[Function]

This function converts a time value into a Lisp timestamp.

The *form* argument specifies the timestamp form to be returned. If *form* is the symbol `integer`, this function returns an integer count of seconds. If *form* is a positive integer, it specifies a clock frequency and this function returns an integer-pair timestamp (`ticks . form`). If *form* is `t`, this function treats it as a positive integer suitable for representing the timestamp; for example, it is treated as 1000000000 if *time* is `nil` and the platform timestamp has nanosecond resolution. If *form* is `list`, this function returns an integer list (`high low micro pico`). Although a `nil` *form* currently acts like `list`, this is planned to change in a future Emacs version, so callers requiring list timestamps should pass `list` explicitly.

If *time* is not a time value, this function signals an error. Otherwise, if *time* cannot be represented exactly, conversion truncates it toward minus infinity. When *form* is `t`, conversion is always exact so no truncation occurs, and the returned clock resolution is no less than that of *time*. By way of contrast, although `float-time` can also convert any time value without signaling an error, the result might not be exact. See Section 42.5 [Time of Day], page 1270.

For efficiency this function might return a value that is `eq` to *time*, or that otherwise shares structure with *time*.

Although `(time-convert nil nil)` is equivalent to `(current-time)`, the latter may be a bit faster.

```
(setq a (time-convert nil t))
⇒ (1564826753904873156 . 1000000000)
(time-convert a 100000)
⇒ (156482675390487 . 100000)
(time-convert a 'integer)
⇒ 1564826753
```

```
(time-convert a 'list)
⇒ (23877 23681 904873 156000)
```

**decode-time &optional time zone form**

[Function]

This function converts a time value into calendrical information. If you don't specify *time*, it decodes the current time, and similarly *zone* defaults to the current time zone rule. See Section 42.6 [Time Zone Rules], page 1272. The operating system limits the range of time and zone values.

The *form* argument controls the form of the returned *seconds* element, as described below. The return value is a list of nine elements, as follows:

```
(seconds minutes hour day month year dow dst utcoff)
```

Here is what the elements mean:

|                |                                                                                                                                    |
|----------------|------------------------------------------------------------------------------------------------------------------------------------|
| <i>seconds</i> | The number of seconds past the minute, with form described below.                                                                  |
| <i>minutes</i> | The number of minutes past the hour, as an integer between 0 and 59.                                                               |
| <i>hour</i>    | The hour of the day, as an integer between 0 and 23.                                                                               |
| <i>day</i>     | The day of the month, as an integer between 1 and 31.                                                                              |
| <i>month</i>   | The month of the year, as an integer between 1 and 12.                                                                             |
| <i>year</i>    | The year, an integer typically greater than 1900.                                                                                  |
| <i>dow</i>     | The day of week, as an integer between 0 and 6, where 0 stands for Sunday.                                                         |
| <i>dst</i>     | <i>t</i> if daylight saving time is effect, <i>nil</i> if it is not in effect, and <i>-1</i> if this information is not available. |
| <i>utcoff</i>  | An integer indicating the Universal Time offset in seconds, i.e., the number of seconds east of Greenwich.                         |

The *seconds* element is a Lisp timestamp that is nonnegative and less than 61; it is less than 60 except during positive leap seconds (assuming the operating system supports leap seconds). If the optional *form* argument is *t*, *seconds* uses the same precision as *time*; if *form* is *integer*, *seconds* is truncated to an integer. For example, if *time* is the timestamp (1566009571321 . 1000), which represents 2019-08-17 02:39:31.321 UTC on typical systems that lack leap seconds, then (*decode-time time t t*) returns ((31321 . 1000) 39 2 17 8 2019 6 *nil* 0), whereas (*decode-time time t 'integer*) returns (31 39 2 17 8 2019 6 *nil* 0). If *form* is omitted or *nil*, it currently defaults to *integer* but this default may change in future Emacs releases, so callers requiring a particular form should specify *form*.

**Common Lisp Note:** Common Lisp has different meanings for *dow*, *dst* and *utcoff*, and its *second* is an integer between 0 and 59 inclusive.

To access (or alter) the elements in the calendrical information, the *decoded-time-second*, *decoded-time-minute*, *decoded-time-hour*, *decoded-time-day*, *decoded-time-month*, *decoded-time-year*, *decoded-time-weekday*, *decoded-time-dst* and *decoded-time-zone* accessors can be used.

**encode-time** *time* &rest obsolescent-arguments [Function]

This function converts *time* to a Lisp timestamp. It can act as the inverse of **decode-time**.

Ordinarily the first argument is a list (*second minute hour day month year ignored dst zone*) that specifies a decoded time in the style of **decode-time**. For the meanings of these list elements, see the table under **decode-time**. In particular, *dst* says how to interpret timestamps during a daylight saving fallback when timestamps are repeated. If *dst* is  $-1$ , the DST value is guessed; if it is *t* or *nil* the timestamp with that DST value is returned, with an error signaled if no such timestamp exists. Unfortunately a *dst* value of *t* or *nil* does not disambiguate timestamps duplicated when a TZDB-based timezone moves further west of Greenwich, such as disambiguating the two standard-time timestamps 2020-12-27 01:30 when *zone* is "Europe/Volgograd", which at 02:00 that day changed standard time from 4 to 3 hours east of Greenwich; if you need to handle situations like this you can use a numeric zone to disambiguate instead.

The first argument can also be a list (*second minute hour day month year*), which is treated like the list (*second minute hour day month year nil -1 nil*).

As an obsolescent calling convention, this function can be given six or more arguments. The first six arguments *second*, *minute*, *hour*, *day*, *month*, and *year* specify most of the components of a decoded time. If there are more than six arguments the *last* argument is used as *zone* and any other extra arguments are ignored, so that (*apply #'encode-time (decode-time ...)*) works. In this obsolescent convention, *dst* is  $-1$  and *zone* defaults to the current time zone rule (see Section 42.6 [Time Zone Rules], page 1272). When modernizing an obsolescent caller, ensure that the more-modern list equivalent contains 9 elements with a *dst* element that is  $-1$ , not *nil*.

Year numbers less than 100 are not treated specially. If you want them to stand for years above 1900, or years above 2000, you must alter them yourself before you call **encode-time**. The operating system limits the range of time and zone values. However, timestamps ranging from the epoch to the near future are always supported. The **encode-time** function acts as a rough inverse to **decode-time**. For example, you can pass the output of the latter to the former as follows:

```
(encode-time (decode-time ...))
```

You can perform simple date arithmetic by using out-of-range values for *seconds*, *minutes*, *hour*, *day*, and *month*; for example, *day 0* means the day preceding the given month. Take care when doing so, as it is common for this to fail in some cases. For example:

```
;; Try to compute the time one month from now.
;; Watch out; this might not work as expected.
(let ((time (decode-time)))
 (setf (decoded-time-month time)
 (+ (decoded-time-month time) 1))
 time)
```

Unfortunately, this code might not work as expected if the resulting time is invalid due to month length differences, daylight saving transitions, time zone changes, or missing leap days or leap seconds. For example, if executed on January 30 this code yields a nonexistent date February 30, which **encode-time** would adjust to early March.

Similarly, adding four years to February 29, 2096 would yield the nonexistent date February 29, 2100; and adding one hour to 01:30 on March 13, 2022 in New York would yield a timestamp 02:30 that does not exist because clocks sprang forward from 02:00 to 03:00 that day. To avoid some (though not all) of the problem, you can base calculations on the middle of the affected unit, e.g., start at the 15th of the month when adding months. Alternatively, you can use the `calendar` and `time-date` libraries.

## 42.8 Parsing and Formatting Times

These functions convert time values to text in a string, and vice versa. Time values are either represented as a Lisp timestamp (see Section 42.5 [Time of Day], page 1270) or a decoded time structure (see Section 42.7 [Time Conversion], page 1273).

### `date-to-time` *string*

[Function]

This function parses the time-string *string* and returns the corresponding Lisp timestamp. The argument *string* should represent a date-time, and should be in one of the forms recognized by `parse-time-string` (see below). This function assumes Universal Time if *string* lacks explicit time zone information, and assumes earliest values if *string* lacks month, day, or time. The operating system limits the range of time and zone values.

### `parse-time-string` *string*

[Function]

This function parses the time-string *string* into a decoded time structure (see Section 42.7 [Time Conversion], page 1273). The argument *string* should resemble an RFC 822 (or later) or ISO 8601 string, like “Fri, 25 Mar 2016 16:24:56 +0100” or “1998-09-12T12:21:54-0200”, but this function will attempt to parse less well-formed time strings as well.

### `iso8601-parse` *string*

[Function]

For a more strict function (that will error out upon invalid input), this function can be used instead. It can parse all variants of the ISO 8601 standard, so in addition to the formats mentioned above, it also parses things like “1998W45-3” (week number) and “1998-245” (ordinal day number). To parse durations, there’s `iso8601-parse-duration`, and to parse intervals, there’s `iso8601-parse-interval`. All these functions return decoded time structures, except the final one, which returns three of them (the start, the end, and the duration).

### `format-time-string` *format-string* &*optional time zone*

[Function]

This function converts *time* (which should be a Lisp timestamp, and defaults to the current time if *time* is omitted or `nil`) to a string according to *format-string*. The conversion uses the time zone rule *zone*, which defaults to the current time zone rule. See Section 42.6 [Time Zone Rules], page 1272. The argument *format-string* may contain ‘%’-sequences which say to substitute parts of the time. Here is a table of what the ‘%’-sequences mean:

‘%a’ This stands for the abbreviated name of the day of week.

‘%A’ This stands for the full name of the day of week.

|      |                                                                                                                                                                                                                                                                                                                                                                                                      |
|------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| '%b' | This stands for the abbreviated name of the month.                                                                                                                                                                                                                                                                                                                                                   |
| '%B' | This stands for the full name of the month.                                                                                                                                                                                                                                                                                                                                                          |
| '%c' | This is a synonym for '%x %X'.                                                                                                                                                                                                                                                                                                                                                                       |
| '%C' | This stands for the century, that is, the year divided by 100, truncated toward zero. The default field width is 2.                                                                                                                                                                                                                                                                                  |
| '%d' | This stands for the day of month, zero-padded.                                                                                                                                                                                                                                                                                                                                                       |
| '%D' | This is a synonym for '%m/%d/%y'.                                                                                                                                                                                                                                                                                                                                                                    |
| '%e' | This stands for the day of month, blank-padded.                                                                                                                                                                                                                                                                                                                                                      |
| '%F' | This stands for the ISO 8601 date format, which is like '+4Y-%m-%d' except that any flags or field width override the '+' and (after subtracting 6) the '4'.                                                                                                                                                                                                                                         |
| '%g' | This stands for the year without century (00–99) corresponding to the current ISO week number. ISO weeks start on Monday and end on Sunday. If an ISO week begins in one year and ends in another, the rules regarding which year '%g' will produce are complex and will not be described here; however, in general, if most of the week's days are in the ending year, '%g' will produce that year. |
| '%G' | This stands for the year with century corresponding to the current ISO week number.                                                                                                                                                                                                                                                                                                                  |
| '%h' | This is a synonym for '%b'.                                                                                                                                                                                                                                                                                                                                                                          |
| '%H' | This stands for the hour (00–23).                                                                                                                                                                                                                                                                                                                                                                    |
| '%I' | This stands for the hour (01–12).                                                                                                                                                                                                                                                                                                                                                                    |
| '%j' | This stands for the day of the year (001–366).                                                                                                                                                                                                                                                                                                                                                       |
| '%k' | This stands for the hour (0–23), blank padded.                                                                                                                                                                                                                                                                                                                                                       |
| '%l' | This stands for the hour (1–12), blank padded.                                                                                                                                                                                                                                                                                                                                                       |
| '%m' | This stands for the month (01–12).                                                                                                                                                                                                                                                                                                                                                                   |
| '%M' | This stands for the minute (00–59).                                                                                                                                                                                                                                                                                                                                                                  |
| '%n' | This stands for a newline.                                                                                                                                                                                                                                                                                                                                                                           |
| '%N' | This stands for the nanoseconds (000000000–999999999). To ask for fewer digits, use '%3N' for milliseconds, '%6N' for microseconds, etc. Any excess digits are discarded, without rounding.                                                                                                                                                                                                          |
| '%p' | This stands for 'AM' or 'PM', as appropriate.                                                                                                                                                                                                                                                                                                                                                        |
| '%q' | This stands for the calendar quarter (1–4).                                                                                                                                                                                                                                                                                                                                                          |
| '%r' | This is a synonym for '%I:%M:%S %p'.                                                                                                                                                                                                                                                                                                                                                                 |
| '%R' | This is a synonym for '%H:%M'.                                                                                                                                                                                                                                                                                                                                                                       |
| '%s' | This stands for the integer number of seconds since the epoch.                                                                                                                                                                                                                                                                                                                                       |

|      |                                                                                                                                                                                                                                                                                                                                |
|------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| '%S' | This stands for the second (00–59, or 00–60 on platforms that support leap seconds).                                                                                                                                                                                                                                           |
| '%t' | This stands for a tab character.                                                                                                                                                                                                                                                                                               |
| '%T' | This is a synonym for '%H:%M:%S'.                                                                                                                                                                                                                                                                                              |
| '%u' | This stands for the numeric day of week (1–7). Monday is day 1.                                                                                                                                                                                                                                                                |
| '%U' | This stands for the week of the year (01–52), assuming that weeks start on Sunday.                                                                                                                                                                                                                                             |
| '%V' | This stands for the week of the year according to ISO 8601.                                                                                                                                                                                                                                                                    |
| '%w' | This stands for the numeric day of week (0–6). Sunday is day 0.                                                                                                                                                                                                                                                                |
| '%W' | This stands for the week of the year (01–52), assuming that weeks start on Monday.                                                                                                                                                                                                                                             |
| '%x' | This has a locale-specific meaning. In the default locale (named 'C'), it is equivalent to '%D'.                                                                                                                                                                                                                               |
| '%X' | This has a locale-specific meaning. In the default locale (named 'C'), it is equivalent to '%T'.                                                                                                                                                                                                                               |
| '%y' | This stands for the year without century (00–99).                                                                                                                                                                                                                                                                              |
| '%Y' | This stands for the year with century.                                                                                                                                                                                                                                                                                         |
| '%Z' | This stands for the time zone abbreviation (e.g., 'EST').                                                                                                                                                                                                                                                                      |
| '%z' | This stands for the time zone numerical offset. The 'z' can be preceded by one, two, or three colons; if plain '%z' stands for '-0500', then '%:z' stands for '-05:00', '%::z' stands for '-05:00:00', and '%:::z' is like '%::z' except it suppresses trailing instances of ':00' so it stands for '-05' in the same example. |
| '%%' | This stands for a single '%'.                                                                                                                                                                                                                                                                                                  |

One or more flag characters can appear immediately after the '%'. '0' pads with zeros, '+' pads with zeros and also puts '+' before nonnegative year numbers with more than four digits, '\_' pads with blanks, '-' suppresses padding, '^' upper-cases letters, and '#' reverses the case of letters.

You can also specify the field width and type of padding for any of these '%' -sequences. This works as in `printf`: you write the field width as digits in a '%' -sequence, after any flags. For example, '%S' specifies the number of seconds since the minute; '%03S' means to pad this with zeros to 3 positions, '%\_3S' to pad with spaces to 3 positions. Plain '%3S' pads with zeros, because that is how '%S' normally pads to two positions. The characters 'E' and 'O' act as modifiers when used after any flags and field widths in a '%' -sequence. 'E' specifies using the current locale's alternative version of the date and time. In a Japanese locale, for example, %Ex might yield a date format based on the Japanese Emperors' reigns. 'E' is allowed in '%Ec', '%EC', '%Ex', '%EX', '%Ey', and '%EY'.

'O' means to use the current locale's alternative representation of numbers, instead of the ordinary decimal digits. This is allowed with most letters, all the ones that output numbers.

To help debug programs, unrecognized ‘%’-sequences stand for themselves and are output as-is. Programs should not rely on this behavior, as future versions of Emacs may recognize new ‘%’-sequences as extensions.

This function uses the C library function `strftime` (see Section “Formatting Calendar Time” in *The GNU C Library Reference Manual*) to do most of the work. In order to communicate with that function, it first converts *time* and *zone* to internal form; the operating system limits the range of time and zone values. This function also encodes *format-string* using the coding system specified by `locale-coding-system` (see Section 34.12 [Locales], page 991); after `strftime` returns the resulting string, this function decodes the string using that same coding system.

**format-seconds** *format-string* *seconds* [Function]

This function converts its argument *seconds* into a string of years, days, hours, etc., according to *format-string*. The argument *format-string* may contain ‘%’-sequences which control the conversion. Here is a table of what the ‘%’-sequences mean:

|      |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
|------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| ‘%y’ |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
| ‘%Y’ | The integer number of 365-day years.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| ‘%d’ |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
| ‘%D’ | The integer number of days.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| ‘%h’ |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
| ‘%H’ | The integer number of hours.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| ‘%m’ |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
| ‘%M’ | The integer number of minutes.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |
| ‘%s’ |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
| ‘%S’ | The number of seconds. If the optional ‘,’ parameter is used, it’s a floating point number, and the number after the ‘,’ specifies how many decimals to be used. ‘%,2s’ means “use two decimals”.                                                                                                                                                                                                                                                                                                                                                                        |
| ‘%z’ | Non-printing control flag. When it is used, other specifiers must be given in the order of decreasing size, i.e., years before days, hours before minutes, etc. Nothing will be produced in the result string to the left of ‘%z’ until the first non-zero conversion is encountered. For example, the default format used by <code>emacs-uptime</code> (see Section 42.9 [Processor Run Time], page 1280) “%Y, %D, %H, %M, %z%S” means that the number of seconds will always be produced, but years, days, hours, and minutes will only be shown if they are non-zero. |
| ‘%x’ | Non-printing control flag that works along the same lines as ‘%z’, but instead suppresses printing of trailing zero-value time elements.                                                                                                                                                                                                                                                                                                                                                                                                                                 |
| ‘%%’ | Produces a literal ‘%’.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |

Upper-case format sequences produce the units in addition to the numbers, lower-case formats produce only the numbers.

You can also specify the field width by following the ‘%’ with a number; shorter numbers will be padded with blanks. An optional period before the width requests zero-padding instead. For example, “%.3Y” might produce “004 years”.

## 42.9 Processor Run time

Emacs provides several functions and primitives that return time, both elapsed and processor time, used by the Emacs process.

### `emacs-uptime &optional format`

[Command]

This function returns a string representing the Emacs *uptime*—the elapsed wall-clock time this instance of Emacs is running. The string is formatted by `format-seconds` according to the optional argument *format*. For the available format descriptors, see Section 42.8 [Time Parsing], page 1276. If *format* is `nil` or omitted, it defaults to `"%Y, %D, %H, %M, %z%S"`.

When called interactively, it prints the uptime in the echo area.

### `get-internal-run-time`

[Function]

This function returns the processor run time used by Emacs, as a Lisp timestamp (see Section 42.5 [Time of Day], page 1270).

Note that the time returned by this function excludes the time Emacs was not using the processor, and if the Emacs process has several threads, the returned value is the sum of the processor times used up by all Emacs threads.

If the system doesn't provide a way to determine the processor run time, `get-internal-run-time` returns the same time as `current-time`.

### `emacs-init-time`

[Command]

This function returns the duration of the Emacs initialization (see Section 42.1.1 [Startup Summary], page 1255) in seconds, as a string. When called interactively, it prints the duration in the echo area.

## 42.10 Time Calculations

These functions perform calendrical computations using time values (see Section 42.5 [Time of Day], page 1270). As with any time value, a value of `nil` for any of their time-value arguments stands for the current system time, and a finite number stands for the number of seconds since the epoch.

### `time-less-p t1 t2`

[Function]

This returns `t` if the time value *t1* is less than the time value *t2*.

### `time-equal-p t1 t2`

[Function]

This returns `t` if the two time values *t1* and *t2* are equal. The result is `nil` if either argument is a NaN. For the purpose of comparison, a `nil` argument represents the current time with infinite resolution, so this function returns `nil` if one argument is `nil` and the other is not, and callers can therefore use `nil` to represent an unknown time value that does not equal any timestamp.

### `time-subtract t1 t2`

[Function]

This returns the time difference  $t1 - t2$  between two time values, as a Lisp timestamp. The result is exact and its clock resolution is no worse than the worse of its two arguments' resolutions. If you need the difference in units of elapsed seconds, you can convert it with `time-convert` or `float-time`. See Section 42.7 [Time Conversion], page 1273.

**time-add** *t1 t2*

[Function]

This returns the sum of two time values, using the same conversion rules as **time-subtract**. One argument should represent a time difference rather than a point in time, as a time value that is often just a single number of elapsed seconds. Here is how to add a number of seconds to a time value:

```
(time-add time seconds)
```

**time-to-days** *time-value*

[Function]

This function returns the number of days between the beginning of year 1 and *time-value*, assuming the default time zone. The operating system limits the range of time and zone values.

**days-to-time** *days*

[Function]

This is not quite the inverse of the **time-to-days** function, as it uses the Emacs epoch (instead of the year 1) for historical reasons. To get the inverse, subtract **(time-to-days 0)** from *days*, in which case **days-to-time** may return **nil** if *days* is negative.

**time-to-day-in-year** *time-value*

[Function]

This returns the day number within the year corresponding to *time-value*, assuming the default time zone. The operating system limits the range of time and zone values.

**date-leap-year-p** *year*

[Function]

This function returns **t** if *year* is a leap year.

**date-days-in-month** *year month*

[Function]

Return the number of days in *month* in *year*. For instance, February 2020 has 29 days.

**date-ordinal-to-time** *year ordinal*

[Function]

Return the date of *ordinal* in *year* as a decoded time structure. For instance, the 120th day in 2004 is April 29th.

## 42.11 Timers for Delayed Execution

You can set up a *timer* to call a function at a specified future time or after a certain length of idleness. A timer is a special object that stores the information about the next invocation times and the function to invoke.

**timerp** *object*

[Function]

This predicate function returns **non-nil** if *object* is a timer.

Emacs cannot run timers at any arbitrary point in a Lisp program; it can run them only when Emacs could accept output from a subprocess: namely, while waiting or inside certain primitive functions such as **sit-for** or **read-event** which *can* wait. Therefore, a timer's execution may be delayed if Emacs is busy. However, the time of execution is very precise if Emacs is idle.

Emacs binds **inhibit-quit** to **t** before calling the timer function, because quitting out of many timer functions can leave things in an inconsistent state. This is normally unproblematical because most timer functions don't do a lot of work. Indeed, for a timer

to call a function that takes substantial time to run is likely to be annoying. If a timer function needs to allow quitting, it should use `with-local-quit` (see Section 22.11 [Quitting], page 471). For example, if a timer function calls `accept-process-output` to receive output from an external process, that call should be wrapped inside `with-local-quit`, to ensure that `C-g` works if the external process hangs.

It is usually a bad idea for timer functions to alter buffer contents. When they do, they usually should call `undo-boundary` both before and after changing the buffer, to separate the timer's changes from user commands' changes and prevent a single undo entry from growing to be quite large.

Timer functions should also avoid calling functions that cause Emacs to wait, such as `sit-for` (see Section 22.10 [Waiting], page 470). This can lead to unpredictable effects, since other timers (or even the same timer) can run while waiting. If a timer function needs to perform an action after a certain time has elapsed, it can do this by scheduling a new timer.

If a timer function performs a remote file operation, it can be in conflict with an already running remote file operation of the same connection. Such conflicts are detected, and they result in a `remote-file-error` error (see Appendix F [Standard Errors], page 1390). This should be protected by wrapping the timer function body with

```
(ignore-error 'remote-file-error
 ...)
```

If a timer function calls functions that can change the match data, it should save and restore the match data. See Section 35.6.4 [Saving Match Data], page 1016.

**run-at-time** *time repeat function &rest args* [Command]

This sets up a timer that calls the function *function* with arguments *args* at time *time*. If *repeat* is a number (integer or floating point), the timer is scheduled to run again every *repeat* seconds after *time*. If *repeat* is `nil`, the timer runs only once.

*time* may specify an absolute or a relative time.

Absolute times may be specified using a string with a limited variety of formats, and are taken to be times *today*, even if already in the past. The recognized forms are ‘*xxxx*’, ‘*x:xx*’, or ‘*xx:xx*’ (military time), and ‘*xxam*’, ‘*xxAM*’, ‘*xxpm*’, ‘*xxPM*’, ‘*xx:xxam*’, ‘*xx:xxAM*’, ‘*xx:xxpm*’, or ‘*xx:xxPM*’. A period can be used instead of a colon to separate the hour and minute parts.

To specify a relative time as a string, use numbers followed by units. For example:

‘1 min’ denotes 1 minute from now.

‘1 min 5 sec’  
denotes 65 seconds from now.

‘1 min 2 sec 3 hour 4 day 5 week 6 fortnight 7 month 8 year’  
denotes exactly 103 months, 123 days, and 10862 seconds from now.

For relative time values, Emacs considers a month to be exactly thirty days, and a year to be exactly 365.25 days.

Not all convenient formats are strings. If *time* is a number (integer or floating point), that specifies a relative time measured in seconds. The result of `encode-time` can also be used to specify an absolute value for *time*.

In most cases, *repeat* has no effect on when *first* call takes place—*time* alone specifies that. There is one exception: if *time* is *t*, then the timer runs whenever the time is a multiple of *repeat* seconds after the epoch. This is useful for functions like `display-time`. For instance, the following will make *function* run at every “whole” minute (e.g., ‘11:03:00’, ‘11:04:00’, etc):

```
(run-at-time t 60 function)
```

If Emacs didn’t get any CPU time when the timer would have run (for example if the system was busy running another process or if the computer was sleeping or in a suspended state), the timer will run as soon as Emacs resumes and is idle.

The function `run-at-time` returns a timer value that identifies the particular scheduled future action. You can use this value to call `cancel-timer` (see below).

**run-with-timer** *secs repeat function &rest args* [Command]

This is exactly the same as `run-at-time` (so see that definition for an explanation of the parameters; *secs* is passed as *time* to that function), but is meant to be used when the delay is specified in seconds.

A repeating timer nominally ought to run every *repeat* seconds, but remember that any invocation of a timer can be late. Lateness of one repetition has no effect on the scheduled time of the next repetition. For instance, if Emacs is busy computing for long enough to cover three scheduled repetitions of the timer, and then starts to wait, it will immediately call the timer function three times in immediate succession (presuming no other timers trigger before or between them). If you want a timer to run again no less than *n* seconds after the last invocation, don’t use the *repeat* argument. Instead, the timer function should explicitly reschedule the timer.

**timer-max-repeats** [User Option]

This variable’s value specifies the maximum number of times to repeat calling a timer function in a row, when many previously scheduled calls were unavoidably delayed.

**with-timeout** (*seconds timeout-forms...*) *body...* [Macro]

Execute *body*, but give up after *seconds* seconds. If *body* finishes before the time is up, `with-timeout` returns the value of the last form in *body*. If, however, the execution of *body* is cut short by the timeout, then `with-timeout` executes all the *timeout-forms* and returns the value of the last of them.

This macro works by setting a timer to run after *seconds* seconds. If *body* finishes before that time, it cancels the timer. If the timer actually runs, it terminates execution of *body*, then executes *timeout-forms*.

Since timers can run within a Lisp program only when the program calls a primitive that can wait, `with-timeout` cannot stop executing *body* while it is in the midst of a computation—only when it calls one of those primitives. So use `with-timeout` only with a *body* that waits for input, not one that does a long computation.

The function `y-or-n-p-with-timeout` provides a simple way to use a timer to avoid waiting too long for an answer. See Section 21.7 [Yes-or-No Queries], page 413.

**cancel-timer** *timer*

[Function]

This cancels the requested action for *timer*, which should be a timer—usually, one previously returned by `run-at-time` or `run-with-idle-timer`. This cancels the effect of that call to one of these functions; the arrival of the specified time will not cause anything special to happen.

The `list-timers` command lists all the currently active timers. The command `c` (`timer-list-cancel`) will cancel the timer on the line under point. You can sort the list by column using the command `S` (`tabulated-list-sort`).

## 42.12 Idle Timers

Here is how to set up a timer that runs when Emacs is idle for a certain length of time. Aside from how to set them up, idle timers work just like ordinary timers.

**run-with-idle-timer** *secs* *repeat* *function &rest args*

[Command]

Set up a timer which runs the next time Emacs is idle for *secs* seconds. The value of *secs* may be a number or a value of the type returned by `current-idle-time`.

If *repeat* is `nil`, the timer runs just once, the first time Emacs remains idle for a long enough time. More often *repeat* is non-`nil`, which means to run the timer *each time* Emacs remains idle for *secs* seconds.

The function `run-with-idle-timer` returns a timer value which you can use in calling `cancel-timer` (see Section 42.11 [Timers], page 1281).

Emacs becomes *idle* when it starts waiting for user input (unless it waits for input with a timeout, see Section 22.8.2 [Reading One Event], page 462), and it remains idle until the user provides some input. If a timer is set for five seconds of idleness, it runs approximately five seconds after Emacs first becomes idle. Even if *repeat* is non-`nil`, this timer will not run again as long as Emacs remains idle, because the duration of idleness will continue to increase and will not go down to five seconds again.

Emacs can do various things while idle: garbage collect, autosave or handle data from a subprocess. But these interludes during idleness do not interfere with idle timers, because they do not reset the clock of idleness to zero. An idle timer set for 600 seconds will run when ten minutes have elapsed since the last user command was finished, even if subprocess output has been accepted thousands of times within those ten minutes, and even if there have been garbage collections and autosaves.

When the user supplies input, Emacs becomes non-idle while executing the input. Then it becomes idle again, and all the idle timers that are set up to repeat will subsequently run another time, one by one.

Do not write an idle timer function containing a loop which does a certain amount of processing each time around, and exits when (`input-pending-p`) is non-`nil`. This approach seems very natural but has two problems:

- It blocks out all process output (since Emacs accepts process output only while waiting).
- It blocks out any idle timers that ought to run during that time.

Similarly, do not write an idle timer function that sets up another idle timer (including the same idle timer) with *secs* argument less than or equal to the current idleness time.

Such a timer will run almost immediately, and continue running again and again, instead of waiting for the next time Emacs becomes idle. The correct approach is to reschedule with an appropriate increment of the current value of the idleness time, as described below.

**current-idle-time** [Function]

If Emacs is idle, this function returns the length of time Emacs has been idle, using the same format as `current-time` (see Section 42.5 [Time of Day], page 1270).

When Emacs is not idle, `current-idle-time` returns `nil`. This is a convenient way to test whether Emacs is idle.

The main use of `current-idle-time` is when an idle timer function wants to “take a break” for a while. It can set up another idle timer to call the same function again, after a few seconds more idleness. Here’s an example:

```
(defvar my-resume-timer nil
 "Timer for `my-timer-function' to reschedule itself, or nil.")

(defun my-timer-function ()
 ;; If the user types a command while my-resume-timer
 ;; is active, the next time this function is called from
 ;; its main idle timer, deactivate my-resume-timer.
 (when my-resume-timer
 (cancel-timer my-resume-timer))
 ...do the work for a while...
 (when taking-a-break
 (setq my-resume-timer
 (run-with-idle-timer
 ;; Compute an idle time break-length
 ;; more than the current value.
 (time-add (current-idle-time) break-length)
 nil
 'my-timer-function))))
```

## 42.13 Terminal Input

This section describes functions and variables for recording or manipulating terminal input. See Chapter 41 [Display], page 1129, for related functions.

### 42.13.1 Input Modes

**set-input-mode** *interrupt flow meta &optional quit-char* [Function]

This function sets the mode for reading keyboard input. If *interrupt* is non-`nil`, then Emacs uses input interrupts. If it is `nil`, then it uses CBREAK mode. The default setting is system-dependent. Some systems always use CBREAK mode regardless of what is specified.

When Emacs communicates directly with X, it ignores this argument and uses interrupts if that is the way it knows how to communicate.

If *flow* is non-`nil`, then Emacs uses XON/XOFF (*C-q*, *C-s*) flow control for output to the terminal. This has no effect except in CBREAK mode.

The argument *meta* controls support for input character codes above 127. If *meta* is `t`, Emacs converts characters with the 8th bit set into Meta characters, before it decodes them as needed (see Section 34.10.8 [Terminal I/O Encoding], page 990). If *meta* is `nil`, Emacs disregards the 8th bit; this is necessary when the terminal uses it as a parity bit. If *meta* is the symbol `encoded`, Emacs first decodes the characters using all the 8 bits of each byte, and then converts the decoded single-byte characters into Meta characters if they have their eighth bit set. Finally, if *meta* is neither `t` nor `nil` nor `encoded`, Emacs uses all 8 bits of input unchanged, both before and after decoding them. This is good for terminals that use 8-bit character sets and don't encode the Meta modifier as the eighth bit.

If *quit-char* is non-`nil`, it specifies the character to use for quitting. Normally this character is `C-g`. See Section 22.11 [Quitting], page 471.

The `current-input-mode` function returns the input mode settings Emacs is currently using.

#### `current-input-mode` [Function]

This function returns the current mode for reading keyboard input. It returns a list, corresponding to the arguments of `set-input-mode`, of the form (*interrupt flow meta quit*) in which:

- |                  |                                                                                                                                                                                                                                                                                                                                                                               |
|------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <i>interrupt</i> | is non- <code>nil</code> when Emacs is using interrupt-driven input. If <code>nil</code> , Emacs is using CBREAK mode.                                                                                                                                                                                                                                                        |
| <i>flow</i>      | is non- <code>nil</code> if Emacs uses XON/XOFF ( <code>C-q</code> , <code>C-s</code> ) flow control for output to the terminal. This value is meaningful only when <i>interrupt</i> is <code>nil</code> .                                                                                                                                                                    |
| <i>meta</i>      | is <code>t</code> if Emacs treats the eighth bit of input characters as the Meta bit before decoding input; <code>encoded</code> if Emacs treats the eighth bit of the decoded single-byte characters as the Meta bit; <code>nil</code> if Emacs clears the eighth bit of every input character; any other value means Emacs uses all eight bits as the basic character code. |
| <i>quit</i>      | is the character Emacs currently uses for quitting, usually <code>C-g</code> .                                                                                                                                                                                                                                                                                                |

### 42.13.2 Recording Input

#### `recent-keys &optional include-cmds` [Function]

This function returns a vector containing the last 300 input events from the keyboard or mouse. All input events are included, whether or not they were used as parts of key sequences. Thus, you always get the last 300 input events, not counting events generated by keyboard macros. (These are excluded because they are less interesting for debugging; it should be enough to see the events that invoked the macros.)

If *include-cmds* is non-`nil`, complete key sequences in the result vector are interleaved with pseudo-events of the form (`nil . COMMAND`), where *COMMAND* is the binding of the key sequence (see Section 22.1 [Command Overview], page 423).

A call to `clear-this-command-keys` (see Section 22.5 [Command Loop Info], page 436) causes this function to return an empty vector immediately afterward.

**open-dribble-file** *filename*

[Command]

This function opens a *dribble file* named *filename*. When a dribble file is open, each input event from the keyboard or mouse (but not those from keyboard macros) is written in that file. A non-character event is expressed using its printed representation surrounded by ‘<...>’. Be aware that sensitive information (such as passwords) may end up recorded in the dribble file.

You close the dribble file by calling this function with an argument of **nil**.

See also the **open-termscript** function (see Section 42.14 [Terminal Output], page 1287).

## 42.14 Terminal Output

The terminal output functions send output to a text terminal, or keep track of output sent to the terminal. The variable **baud-rate** tells you what Emacs thinks is the output speed of the terminal.

**baud-rate**

[User Option]

This variable’s value is the output speed of the terminal, as far as Emacs knows. Setting this variable does not change the speed of actual data transmission, but the value is used for calculations such as padding.

It also affects decisions about whether to scroll part of the screen or repaint on text terminals. See Section 41.2 [Forcing Redisplay], page 1129, for the corresponding functionality on graphical terminals.

The value is measured in baud.

If you are running across a network, and different parts of the network work at different baud rates, the value returned by Emacs may be different from the value used by your local terminal. Some network protocols communicate the local terminal speed to the remote machine, so that Emacs and other programs can get the proper value, but others do not. If Emacs has the wrong value, it makes decisions that are less than optimal. To fix the problem, set **baud-rate**.

**send-string-to-terminal** *string* &**optional** *terminal*

[Function]

This function sends *string* to *terminal* without alteration. Control characters in *string* have terminal-dependent effects. (If you need to display non-ASCII text on the terminal, encode it using one of the functions described in Section 34.10.7 [Explicit Encoding], page 988.) This function operates only on text terminals. *terminal* may be a terminal object, a frame, or **nil** for the selected frame’s terminal. In batch mode, *string* is sent to **stdout** when *terminal* is **nil**.

One use of this function is to define function keys on terminals that have downloadable function key definitions. For example, this is how (on certain terminals) to define function key 4 to move forward four characters (by transmitting the characters **C-u C-f** to the computer):

```
(send-string-to-terminal "\eF4\^U\^F")
⇒ nil
```

**open-termscript** *filename*

[Command]

This function is used to open a *termscript file* that will record all the characters sent by Emacs to the terminal. It returns **nil**. Termscript files are useful for investigating

problems where Emacs garbles the screen, problems that are due to incorrect Termcap entries or to undesirable settings of terminal options more often than to actual Emacs bugs. Once you are certain which characters were actually output, you can determine reliably whether they correspond to the Termcap specifications in use.

```
(open-termscript "../junk/termscript")
⇒ nil
```

You close the termscript file by calling this function with an argument of `nil`.

See also `open-dribble-file` in Section 42.13.2 [Recording Input], page 1286.

## 42.15 Sound Output

To play sound using Emacs, use the function `play-sound`. Only certain systems are supported; if you call `play-sound` on a system which cannot really do the job, it gives an error.

The sound must be stored as a file in RIFF-WAVE format ('`.wav`') or Sun Audio format ('`.au`').

### `play-sound sound`

[Function]

This function plays a specified sound. The argument, `sound`, has the form `(sound properties...)`, where the `properties` consist of alternating keywords (particular symbols recognized specially) and values corresponding to them.

Here is a table of the keywords that are currently meaningful in `sound`, and their meanings:

#### `:file file`

This specifies the file containing the sound to play. If the file name is not absolute, it is expanded against the directory `data-directory`.

#### `:data data`

This specifies the sound to play without need to refer to a file. The value, `data`, should be a string containing the same bytes as a sound file. We recommend using a unibyte string.

#### `:volume volume`

This specifies how loud to play the sound. It should be a number in the range of 0 to 1. The default is to use whatever volume has been specified before.

#### `:device device`

This specifies the system device on which to play the sound, as a string. The default device is system-dependent.

Before actually playing the sound, `play-sound` calls the functions in the list `play-sound-functions`. Each function is called with one argument, `sound`.

### `play-sound-file file &optional volume device`

[Command]

This function is an alternative interface to playing a sound `file` specifying an optional `volume` and `device`.

**play-sound-functions** [Variable]

A list of functions to be called before playing a sound. Each function is called with one argument, a property list that describes the sound.

## 42.16 Operating on X11 Keysyms

To define system-specific X11 keysyms, set the variable **system-key-alist**.

**system-key-alist** [Variable]

This variable's value should be an alist with one element for each system-specific keysym. Each element has the form (*code* . *symbol*), where *code* is the numeric keysym code (not including the vendor-specific bit,  $-2^{28}$ ), and *symbol* is the name for the function key.

For example (168 . *mute-acute*) defines a system-specific key (used by HP X servers) whose numeric code is  $-2^{28} + 168$ .

It is not crucial to exclude from the alist the keysyms of other X servers; those do no harm, as long as they don't conflict with the ones used by the X server actually in use. The variable is always local to the current terminal, and cannot be buffer-local. See Section 30.2 [Multiple Terminals], page 787.

You can specify which keysyms Emacs should use for the Control, Meta, Alt, Hyper, and Super modifiers by setting these variables:

|                       |            |
|-----------------------|------------|
| <b>x-ctrl-keysym</b>  | [Variable] |
| <b>x-alt-keysym</b>   | [Variable] |
| <b>x-meta-keysym</b>  | [Variable] |
| <b>x-hyper-keysym</b> | [Variable] |
| <b>x-super-keysym</b> | [Variable] |

The name of the keysym that should stand for the Control modifier (respectively, for Alt, Meta, Hyper, and Super). For example, here is how to swap the Meta and Alt modifiers within Emacs:

```
(setq x-alt-keysym 'meta)
(setq x-meta-keysym 'alt)
```

## 42.17 Batch Mode

The command-line option '**-batch**' causes Emacs to run noninteractively. In this mode, Emacs does not read commands from the terminal, it does not alter the terminal modes, and it does not expect to be outputting to an erasable screen. The idea is that you specify Lisp programs to run; when they are finished, Emacs should exit. The way to specify the programs to run is with '**-l file**', which loads the library named *file*, or '**-f function**', which calls *function* with no arguments, or '**--eval=form**'.

**noninteractive** [Variable]

This variable is **non-nil** when Emacs is running in batch mode.

If the specified Lisp program signals an unhandled error in batch mode, Emacs exits with a non-zero exit status after invoking the Lisp debugger which shows the Lisp backtrace (see Section 19.1.10 [Invoking the Debugger], page 340) on the standard error stream:

```
$ emacs -Q --batch --eval '(error "foo")'; echo $?

Error: error ("foo")
mapbacktrace(#f(compiled-function (evald func args flags) #<bytecode -0x4f85c5
7c45e2f81>)
debug-early-backtrace()
debug-early(error (error "foo"))
signal(error ("foo"))
error("foo")
eval((error "foo") t)
command-line-1("--eval" "(error \"foo\")")
command-line()
normal-top-level()
foo
255
```

Any Lisp program output that would normally go to the echo area, either using `message`, or using `prin1`, etc., with `t` as the stream (see Section 20.4 [Output Streams], page 375), goes instead to Emacs's standard descriptors when in batch mode: `message` writes to the standard error descriptor, while `prin1` and other print functions write to the standard output. Similarly, input that would normally come from the minibuffer is read from the standard input descriptor. Thus, Emacs behaves much like a noninteractive application program. (The echo area output that Emacs itself normally generates, such as command echoing, is suppressed entirely.)

Non-ASCII text written to the standard output or error descriptors is by default encoded using `locale-coding-system` (see Section 34.12 [Locales], page 991) if it is non-`nil`; this can be overridden by binding `coding-system-for-write` to a coding system of your choice (see Section 34.10.7 [Explicit Encoding], page 988).

In batch mode, Emacs will enlarge the value of the `gc-cons-percentage` variable from the default of ‘0.1’ up to ‘1.0’. Batch jobs that are supposed to run for a long time should adjust the limit back down again, because this means that less garbage collection will be performed by default (and more memory consumed).

## 42.18 Session Management

Emacs supports the X Session Management Protocol, which is used to suspend and restart applications. In the X Window System, a program called the *session manager* is responsible for keeping track of the applications that are running. When the X server shuts down, the session manager asks applications to save their state, and delays the actual shutdown until they respond. An application can also cancel the shutdown.

When the session manager restarts a suspended session, it directs these applications to individually reload their saved state. It does this by specifying a special command-line argument that says what saved session to restore. For Emacs, this argument is ‘`--smid session`’.

`emacs-save-session-functions` [Variable]

Emacs supports saving state via a hook called `emacs-save-session-functions`. Emacs runs this hook when the session manager tells it that the window system is

shutting down. The functions are called with no arguments, and with the current buffer set to a temporary buffer. Each function can use `insert` to add Lisp code to this buffer. At the end, Emacs saves the buffer in a file, called the *session file*.

Subsequently, when the session manager restarts Emacs, it loads the session file automatically (see Chapter 16 [Loading], page 298). This is performed by a function named `emacs-session-restore`, which is called during startup. See Section 42.1.1 [Startup Summary], page 1255.

If a function in `emacs-save-session-functions` returns `non-nil`, Emacs tells the session manager to cancel the shutdown.

Here is an example that just inserts some text into `*scratch*` when Emacs is restarted by the session manager.

```
(add-hook 'emacs-save-session-functions 'save-yourself-test)

(defun save-yourself-test ()
 (insert
 (format "%S" '(with-current-buffer "*scratch*"
 (insert "I am restored"))))
 nil)
```

## 42.19 Desktop Notifications

Emacs is able to send *notifications* on systems that support the freedesktop.org Desktop Notifications Specification and on MS-Windows. In order to use this functionality on POSIX hosts, Emacs must have been compiled with D-Bus support, and the `notifications` library must be loaded. See Section “D-Bus” in *D-Bus integration in Emacs*. The following function is supported when D-Bus support is available:

**notifications-notify &rest params** [Function]

This function sends a notification to the desktop via D-Bus, consisting of the parameters specified by the *params* arguments. These arguments should consist of alternating keyword and value pairs. The supported keywords and values are as follows:

**:bus bus** The D-Bus bus. This argument is needed only if a bus other than `:session` shall be used.

**:title title**  
The notification title.

**:body text**  
The notification body text. Depending on the implementation of the notification server, the text could contain HTML markups, like "`<b>bold text</b>`", hyperlinks, or images. Special HTML characters must be encoded, as "`Contact &lt;postmaster@localhost&gt;!`".

**:app-name name**  
The name of the application sending the notification. The default is `notifications-application-name`.

**:replaces-id id**

The notification *id* that this notification replaces. *id* must be the result of a previous **notifications-notify** call.

**:app-icon icon-file**

The file name of the notification icon. If set to **nil**, no icon is displayed. The default is **notifications-application-icon**.

**:actions (key title key title ...)**

A list of actions to be applied. *key* and *title* are both strings. The default action (usually invoked by clicking the notification) should have a key named "**"default"**". The title can be anything, though implementations are free not to display it.

**:timeout timeout**

The timeout time in milliseconds since the display of the notification at which the notification should automatically close. If **-1**, the notification's expiration time is dependent on the notification server's settings, and may vary for the type of notification. If **0**, the notification never expires. Default value is **-1**.

**:urgency urgency**

The urgency level. It can be **low**, **normal**, or **critical**.

**:action-items**

When this keyword is given, the *title* string of the actions is interpreted as icon name.

**:category category**

The type of notification this is, a string. See the Desktop Notifications Specification (<https://specifications.freedesktop.org/notification-spec/notification-spec-latest.html#categories>) for a list of standard categories.

**:desktop-entry filename**

This specifies the name of the desktop filename representing the calling program, like "**"emacs"**".

**:image-data (width height rowstride has-alpha bits channels data)**

This is a raw data image format that describes the width, height, rowstride, whether there is an alpha channel, bits per sample, channels and image data, respectively.

**:image-path path**

This is represented either as a URI ('**file://**' is the only URI schema supported right now) or a name in a freedesktop.org-compliant icon theme from '**\$XDG\_DATA\_DIRS/icons**'.

**:sound-file filename**

The path to a sound file to play when the notification pops up.

**:sound-name name**

A themable named sound from the freedesktop.org sound naming specification from '**\$XDG\_DATA\_DIRS/sounds**', to play when the notification

pops up. Similar to the icon name, only for sounds. An example would be ‘“message-new-instant”’.

**:suppress-sound**

Causes the server to suppress playing any sounds, if it has that ability.

**:resident**

When set the server will not automatically remove the notification when an action has been invoked. The notification will remain resident in the server until it is explicitly removed by the user or by the sender. This hint is likely only useful when the server has the **:persistence** capability.

**:transient**

When set the server will treat the notification as transient and by-pass the server’s persistence capability, if it should exist.

**:x position**

**:y position**

Specifies the X, Y location on the screen that the notification should point to. Both arguments must be used together.

**:on-action function**

Function to call when an action is invoked. The notification *id* and the key of the action are passed as arguments to the function.

**:on-close function**

Function to call when the notification has been closed by timeout or by the user. The function receive the notification *id* and the closing *reason* as arguments:

- **expired** if the notification has expired
- **dismissed** if the notification was dismissed by the user
- **close-notification** if the notification was closed by a call to **notifications-close-notification**
- **undefined** if the notification server hasn’t provided a reason

Which parameters are accepted by the notification server can be checked via **notifications-get-capabilities**.

This function returns a notification id, an integer, which can be used to manipulate the notification item with **notifications-close-notification** or the **:replaces-id** argument of another **notifications-notify** call. For example:

```
(defun my-on-action-function (id key)
 (message "Message %d, key \'%s\' pressed" id key))
 ⇒ my-on-action-function

(defun my-on-close-function (id reason)
 (message "Message %d, closed due to \'%s\'" id reason))
 ⇒ my-on-close-function
```

```
(notifications-notify
 :title "Title"
 :body "This is important."
 :actions '("Confirm" "I agree" "Refuse" "I disagree")
 :on-action 'my-on-action-function
 :on-close 'my-on-close-function)
 ⇒ 22
```

A message window opens on the desktop. Press ``I agree''.  
 ⇒ Message 22, key "Confirm" pressed  
 Message 22, closed due to "dismissed"

**notifications-close-notification *id* &**optional** *bus*** [Function]

This function closes a notification with identifier *id*. *bus* can be a string denoting a D-Bus connection, the default is :**session**.

**notifications-get-capabilities &**optional** *bus*** [Function]

Returns the capabilities of the notification server, a list of symbols. *bus* can be a string denoting a D-Bus connection, the default is :**session**. The following capabilities can be expected:

- :**actions** The server will provide the specified actions to the user.
  - :**body** Supports body text.
  - :**body-hyperlinks** The server supports hyperlinks in the notifications.
  - :**body-images** The server supports images in the notifications.
  - :**body-markup** Supports markup in the body text.
  - :**icon-multi** The server will render an animation of all the frames in a given image array.
  - :**icon-static** Supports display of exactly 1 frame of any given image array. This value is mutually exclusive with :**icon-multi**.
  - :**persistence** The server supports persistence of notifications.
  - :**sound** The server supports sounds on notifications.
- Further vendor-specific caps start with :**x-vendor**, like :**x-gnome-foo-cap**.

**notifications-get-server-information &**optional** *bus*** [Function]

Return information on the notification server, a list of strings. *bus* can be a string denoting a D-Bus connection, the default is :**session**. The returned list is (*name vendor version spec-version*).

- name** The product name of the server.

`vendor` The vendor name. For example, ““KDE”, ““GNOME””.

`version` The server’s version number.

`spec-version`

The specification version the server is compliant with.

If `spec_version` is `nil`, the server supports a specification prior to ““1.0””.

When Emacs runs on MS-Windows as a GUI session, it supports a small subset of the D-Bus notifications functionality via a native primitive:

**w32-notification-notify &rest params**

[Function]

This function displays an MS-Windows tray notification as specified by `params`. MS-Windows tray notifications are displayed in a balloon from an icon in the notification area of the taskbar.

`Value` is the integer unique ID of the notification that can be used to remove the notification using `w32-notification-close`, described below. If the function fails, the return value is `nil`.

The arguments `params` are specified as keyword/value pairs. All the parameters are optional, but if no parameters are specified, the function will do nothing and return `nil`.

The following parameters are supported:

`:icon icon`

Display `icon` in the system tray. If `icon` is a string, it should specify a file name from which to load the icon; the specified file should be a `.ico` Windows icon file. If `icon` is not a string, or if this parameter is not specified, the standard Emacs icon will be used.

`:tip tip`

Use `tip` as the tooltip for the notification. If `tip` is a string, this is the text of a tooltip that will be shown when the mouse pointer hovers over the tray icon added by the notification. If `tip` is not a string, or if this parameter is not specified, the default tooltip text is ‘‘Emacs notification’’. The tooltip text can be up to 127 characters long (63 on Windows versions before W2K). Longer strings will be truncated.

`:level level`

Notification severity level, one of `info`, `warning`, or `error`. If given, the value determines the icon displayed to the left of the notification title, but only if the `:title` parameter (see below) is also specified and is a string.

`:title title`

The title of the notification. If `title` is a string, it is displayed in a larger font immediately above the body text. The title text can be up to 63 characters long; longer text will be truncated.

`:body body`

The body of the notification. If `body` is a string, it specifies the text of the notification message. Use embedded newlines to control how the text is broken into lines. The body text can be up to 255 characters long, and

will be truncated if it's longer. Unlike with D-Bus, the body text should be plain text, with no markup.

Note that versions of Windows before W2K support only `:icon` and `:tip`. The other parameters can be passed, but they will be ignored on those old systems.

There can be at most one active notification at any given time. An active notification must be removed by calling `w32-notification-close` before a new one can be shown.

To remove the notification and its icon from the taskbar, use the following function:

`w32-notification-close id` [Function]

This function removes the tray notification given by its unique `id`.

## 42.20 Notifications on File Changes

Several operating systems support watching of filesystems for changes to files or their attributes. If configured properly, Emacs links a respective library like `inotify`, `kqueue`, `gfilenotify`, or `w32notify` statically. These libraries enable watching of filesystems on the local machine.

It is also possible to watch filesystems on remote machines, see Section “Remote Files” in *The GNU Emacs Manual*. This does not depend on one of the libraries linked to Emacs.

Since all these libraries emit different events upon notified file changes, Emacs provides a special library `filenotify` which presents a unified interface to applications. Lisp programs that want to receive file notifications should always use this library in preference to the native ones. This section documents the `filenotify` library functions and variables.

`file-notify-add-watch file flags callback` [Function]

Add a watch for filesystem events pertaining to `file`. This arranges for filesystem events pertaining to `file` to be reported to Emacs.

The returned value is a descriptor for the added watch. Its type depends on the underlying library, and in general cannot be assumed to be an integer as in the example below. It should be used for comparison by `equal` only.

If the `file` cannot be watched for some reason, this function signals a `file-notify-error` error.

Sometimes, mounted filesystems cannot be watched for file changes. This is not detected by this function, and so a non-`nil` return value does not guarantee that changes on `file` will be actually notified.

If `file` is a symlink, it doesn't follow that link. Just `file` itself will be watched.

`flags` is a list of conditions to set what will be watched for. It can include the following symbols:

`change` watch for changes in file's contents

`attribute-change` watch for changes in file attributes, like permissions or modification time

If `file` is a directory, `change` watches for file creation and deletion in that directory. Some of the native file notification libraries also report file changes in that case. This does not work recursively.

When any event happens, Emacs will call the *callback* function passing it a single argument *event*, which is of the form

```
(descriptor action file [file1])
```

*descriptor* is the same object as the one returned by this function. *action* is the description of the event. It could be any one of the following symbols:

- created**    *file* was created
- deleted**    *file* was deleted
- changed**    *file*'s contents has changed; with w32notify library, reports attribute changes as well
- renamed**    *file* has been renamed to *file1*
- attribute-changed**  
    a *file* attribute was changed
- stopped**    watching *file* has stopped

Note that the w32notify library does not report **attribute-changed** events. When some file's attribute, like permissions or modification time, has changed, this library reports a **changed** event. Likewise, the kqueue library does not reliably report file attribute changes when watching a directory.

The **stopped** event means that watching the file has been discontinued. This could be because **file-notify-rm-watch** was called (see below), or because the file being watched was deleted, or due to another error reported from the underlying library which makes further watching impossible.

*file* and *file1* are the name of the file(s) whose event is being reported. For example:

```
(require 'filenotify)
⇒ filenotify

(defun my-notify-callback (event)
 (message "Event %S" event))
⇒ my-notify-callback

(file-notify-add-watch
 "/tmp" '(change attribute-change) 'my-notify-callback)
⇒ 35025468

(write-region "foo" nil "/tmp/foo")
⇒ Event (35025468 created "/tmp/.#foo")
Event (35025468 created "/tmp/foo")
Event (35025468 changed "/tmp/foo")
Event (35025468 deleted "/tmp/.#foo")

(write-region "bla" nil "/tmp/foo")
⇒ Event (35025468 created "/tmp/.#foo")
Event (35025468 changed "/tmp/foo")
Event (35025468 deleted "/tmp/.#foo")
```

```
(set-file-modes "/tmp/foo" (default-file-modes) 'nofollow)
 ⇒ Event (35025468 attribute-changed "/tmp/foo")
```

Whether the action `renamed` is returned depends on the used watch library. Otherwise, the actions `deleted` and `created` could be returned in a random order.

```
(rename-file "/tmp/foo" "/tmp/bla")
 ⇒ Event (35025468 renamed "/tmp/foo" "/tmp/bla")
```

```
(delete-file "/tmp/bla")
 ⇒ Event (35025468 deleted "/tmp/bla")
```

#### `file-notify-rm-watch` *descriptor* [Function]

Removes an existing file watch specified by its *descriptor*. *descriptor* should be an object returned by `file-notify-add-watch`.

#### `file-notify-rm-all-watches` [Command]

Removes all existing file notification watches from Emacs.

Use this command with caution, because it could have unexpected side effects on packages relying on file watches. It is intended mainly for debugging purposes, or when Emacs has been stalled.

#### `file-notify-valid-p` *descriptor* [Function]

Checks a watch specified by its *descriptor* for validity. *descriptor* should be an object returned by `file-notify-add-watch`.

A watch can become invalid if the file or directory it watches is deleted, or if the watcher thread exits abnormally for any other reason. Removing the watch by calling `file-notify-rm-watch` also makes it invalid.

```
(make-directory "/tmp/foo")
 ⇒ Event (35025468 created "/tmp/foo")
```

```
(setq desc
 (file-notify-add-watch
 "/tmp/foo" '(change) 'my-notify-callback))
 ⇒ 11359632
```

```
(file-notify-valid-p desc)
 ⇒ t
```

```
(write-region "bla" nil "/tmp/foo/bla")
 ⇒ Event (11359632 created "/tmp/foo/.#bla")
 Event (11359632 created "/tmp/foo/bla")
 Event (11359632 changed "/tmp/foo/bla")
 Event (11359632 deleted "/tmp/foo/.#bla")
```

```
; ; Deleting a file in the directory doesn't invalidate the watch.
(delete-file "/tmp/foo/bla")
 ⇒ Event (11359632 deleted "/tmp/foo/bla")
```

```
(write-region "bla" nil "/tmp/foo/bla")
 ⇒ Event (11359632 created "/tmp/foo/.#bla")
 Event (11359632 created "/tmp/foo/bla")
 Event (11359632 changed "/tmp/foo/bla")
 Event (11359632 deleted "/tmp/foo/.#bla")

;; Deleting the directory invalidates the watch.
;; Events arrive for different watch descriptors.
(delete-directory "/tmp/foo" 'recursive)
 ⇒ Event (35025468 deleted "/tmp/foo")
 Event (11359632 deleted "/tmp/foo/bla")
 Event (11359632 deleted "/tmp/foo")
 Event (11359632 stopped "/tmp/foo")

(file-notify-valid-p desc)
 ⇒ nil
```

## 42.21 Dynamically Loaded Libraries

A *dynamically loaded library* is a library that is loaded on demand, when its facilities are first needed. Emacs supports such on-demand loading of support libraries for some of its features.

### dynamic-library-alist

[Variable]

This is an alist of dynamic libraries and external library files implementing them.

Each element is a list of the form (*library files...*), where the *car* is a symbol representing a supported external library, and the rest are strings giving alternate filenames for that library.

Emacs tries to load the library from the files in the order they appear in the list; if none is found, the Emacs session won't have access to that library, and the features it provides will be unavailable.

Image support on some platforms uses this facility. Here's an example of setting this variable for supporting images on MS-Windows:

```
(setq dynamic-library-alist
 '((xpm "libxpm.dll" "xpm4.dll" "libXpm-nox4.dll")
 (png "libpng12d.dll" "libpng12.dll" "libpng.dll"
 "libpng13d.dll" "libpng13.dll")
 (jpeg "jpeg62.dll" "libjpeg.dll" "jpeg-62.dll"
 "jpeg.dll")
 (tiff "libtiff3.dll" "libtiff.dll")
 (gif "giflib4.dll" "libungif4.dll" "libungif.dll")
 (svg "librsvg-2-2.dll")
 (gdk-pixbuf "libgdk_pixbuf-2.0-0.dll")
 (glib "libglib-2.0-0.dll")
 (gobject "libgobject-2.0-0.dll")))
```

Note that image types `pbm` and `xbm` do not need entries in this variable because they do not depend on external libraries and are always available in Emacs.

Also note that this variable is not meant to be a generic facility for accessing external libraries; only those already known by Emacs can be loaded through it.

This variable is ignored if the given *library* is statically linked into Emacs.

## 42.22 Security Considerations

Like any application, Emacs can be run in a secure environment, where the operating system enforces rules about access and the like. With some care, Emacs-based applications can also be part of a security perimeter that checks such rules. Although the default settings for Emacs work well for a typical software development environment, they may require adjustment in environments containing untrusted users that may include attackers. Here is a compendium of security issues that may be helpful if you are developing such applications. It is by no means complete; it is intended to give you an idea of the security issues involved, rather than to be a security checklist.

### File local variables

A file that Emacs visits can contain variable settings that affect the buffer visiting that file; See Section 12.12 [File Local Variables], page 213. Similarly, a directory can specify local variable values common to all files in that directory; see Section 12.13 [Directory Local Variables], page 217. Although Emacs takes some effort to protect against misuse of these variables, a security hole can be created merely by a package setting `safe-local-variable` too optimistically, a problem that is all too common. To disable this feature for both files and directories, set `enable-local-variables` to `nil`.

### Access control

Although Emacs normally respects access permissions of the underlying operating system, in some cases it handles accesses specially. For example, file names can have handlers that treat the files specially, with their own access checking. See Section 26.12 [Magic File Names], page 649. Also, a buffer can be read-only even if the corresponding file is writable, and vice versa, which can result in messages such as ‘`File passwd is write-protected; try to save anyway? (yes or no)`’. See Section 28.7 [Read Only Buffers], page 680.

### Authentication

Emacs has several functions that deal with passwords, e.g., `read-passwd`. See Section 21.9 [Reading a Password], page 417. Although these functions do not attempt to broadcast passwords to the world, their implementations are not proof against determined attackers with access to Emacs internals. For example, even if Elisp code uses `clear-string` to scrub a password from its memory after using it, remnants of the password may still reside in the garbage-collected free list. See Section 4.4 [Modifying Strings], page 59.

### Code injection

Emacs can send commands to many other applications, and applications should take care that strings sent as operands of these commands are not misinterpreted as directives. For example, when using a shell command to rename a file a to

*b*, do not simply use the string `mv a b`, because either file name might start with ‘-’, or might contain shell metacharacters like ‘;’. Although functions like `shell-quote-argument` can help avoid this sort of problem, they are not panaceas; for example, on a POSIX platform `shell-quote-argument` quotes shell metacharacters but not leading ‘-’. On MS-Windows, quoting for ‘%’ assumes none of the environment variables have ‘^’ in their name. See Section 40.2 [Shell Arguments], page 1080. Typically it is safer to use `call-process` than a subshell. See Section 40.3 [Synchronous Processes], page 1081. And it is safer yet to use builtin Emacs functions; for example, use `(rename-file "a" "b" t)` instead of invoking `mv`. See Section 26.7 [Changing Files], page 629.

#### Coding systems

Emacs attempts to infer the coding systems of the files and network connections it accesses. See Section 34.10 [Coding Systems], page 976. If Emacs infers incorrectly, or if the other parties to the network connection disagree with Emacs’s inferences, the resulting system could be unreliable. Also, even when it infers correctly, Emacs often can use bytes that other programs cannot. For example, although to Emacs the null byte is just a character like any other, many other applications treat it as a string terminator and mishandle strings or files containing null bytes.

#### Environment and configuration variables

POSIX specifies several environment variables that can affect how Emacs behaves. Any environment variable whose name consists entirely of uppercase ASCII letters, digits, and the underscore may affect the internal behavior of Emacs. Emacs uses several such variables, e.g., `EMACSLLOADPATH`. See Section 16.3 [Library Search], page 301. On some platforms some environment variables (e.g., `PATH`, `POSIXLY_CORRECT`, `SHELL`, `TMPDIR`) need to have properly-configured values in order to get standard behavior for any utility Emacs might invoke. Even seemingly-benign variables like `TZ` may have security implications. See Section 42.3 [System Environment], page 1265.

Emacs has customization and other variables with similar considerations. For example, if the variable `shell-file-name` specifies a shell with nonstandard behavior, an Emacs-based application may misbehave.

#### Installation

When Emacs is installed, if the installation directory hierarchy can be modified by untrusted users, the application cannot be trusted. This applies also to the directory hierarchies of the programs that Emacs uses, and of the files that Emacs reads and writes.

#### Network access

Emacs often accesses the network, and you may want to configure it to avoid network accesses that it would normally do. For example, unless you set `tramp-mode` to `nil`, file names using a certain syntax are interpreted as being network files, and are retrieved across the network. See *The Tramp Manual*.

#### Race conditions

Emacs applications have the same sort of race-condition issues that other applications do. For example, even when `(file-readable-p "foo.txt")` returns `t`,

it could be that `foo.txt` is unreadable because some other program changed the file's permissions between the call to `file-readable-p` and now. See Section 26.6.1 [Testing Accessibility], page 619.

#### Resource limits

When Emacs exhausts memory or other operating system resources, its behavior can be less reliable, in that computations that ordinarily run to completion may abort back to the top level. This may cause Emacs to neglect operations that it normally would have done.

## 43 Preparing Lisp code for distribution

Emacs provides a standard way to distribute Emacs Lisp code to users. A *package* is a collection of one or more files, formatted and bundled in such a way that users can easily download, install, uninstall, and upgrade it.

The following sections describe how to create a package, and how to put it in a *package archive* for others to download. See Section “*Packages*” in *The GNU Emacs Manual*, for a description of user-level features of the packaging system.

These sections are mostly directed towards package archive maintainers—much of this information is not relevant for package authors (i.e., people who write code that will be distributed via these archives).

### 43.1 Packaging Basics

A package is either a *simple package* or a *multi-file package*. A simple package is stored in a package archive as a single Emacs Lisp file, while a multi-file package is stored as a tar file (containing multiple Lisp files, and possibly non-Lisp files such as a manual).

In ordinary usage, the difference between simple packages and multi-file packages is relatively unimportant; the Package Menu interface makes no distinction between them. However, the procedure for creating them differs, as explained in the following sections.

Each package (whether simple or multi-file) has certain *attributes*:

|         |                                                                                                                                                                                                                                                                                                |
|---------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Name    | A short word (e.g., ‘ <code>auctex</code> ’). This is usually also the symbol prefix used in the program (see Section D.1 [Coding Conventions], page 1331).                                                                                                                                    |
| Version | A version number, in a form that the function <code>version-to-list</code> understands (e.g., ‘ <code>11.86</code> ’). Each release of a package should be accompanied by an increase in the version number so that it will be recognized as an upgrade by users querying the package archive. |

#### Brief description

This is shown when the package is listed in the Package Menu. It should occupy a single line, ideally in 36 characters or less.

#### Long description

This is shown in the buffer created by `C-h P (describe-package)`, following the package’s brief description and installation status. It normally spans multiple lines, and should fully describe the package’s capabilities and how to begin using it once it is installed.

#### Dependencies

A list of other packages (possibly including minimal acceptable version numbers) on which this package depends. The list may be empty, meaning this package has no dependencies. Otherwise, installing this package also automatically installs its dependencies, recursively; if any dependency cannot be found, the package cannot be installed.

Installing a package, either via the command `package-install-file`, or via the Package Menu, creates a subdirectory of `package-user-dir` named `name-version`, where `name` is the package’s name and `version` its version (e.g., `~/.emacs.d/elpa/auctex-11.86/`). We

call this the package’s *content directory*. It is where Emacs puts the package’s contents (the single Lisp file for a simple package, or the files extracted from a multi-file package).

Emacs then searches every Lisp file in the content directory for autoload magic comments (see Section 16.5 [Autoload], page 304). These autoload definitions are saved to a file named `name-autoloads.el` in the content directory. They are typically used to autoload the principal user commands defined in the package, but they can also perform other tasks, such as adding an element to `auto-mode-alist` (see Section 24.2.2 [Auto Major Mode], page 531). Note that a package typically does *not* autoload every function and variable defined within it—only the handful of commands typically called to begin using the package. Emacs then byte-compiles every Lisp file in the package.

After installation, the installed package is *loaded*: Emacs adds the package’s content directory to `load-path`, and evaluates the autoload definitions in `name-autoloads.el`.

Whenever Emacs starts up, it automatically calls the function `package-activate-all` to make installed packages available to the current session. This is done after loading the early init file, but before loading the regular init file (see Section 42.1.1 [Startup Summary], page 1255). Packages are not automatically made available if the user option `package-enable-at-startup` is set to `nil` in the early init file.

### `package-activate-all`

[Function]

This function makes the packages available to the current session. The user option `package-load-list` specifies which packages to make available; by default, all installed packages are made available. See Section “Package Installation” in *The GNU Emacs Manual*.

In most cases, you should not need to call `package-activate-all`, as this is done automatically during startup. Simply make sure to put any code that should run before `package-activate-all` in the early init file, and any code that should run after it in the primary init file (see Section “Init File” in *The GNU Emacs Manual*).

### `package-initialize &optional no-activate`

[Command]

This function initializes Emacs’ internal record of which packages are installed, and then calls `package-activate-all`.

The optional argument `no-activate`, if non-`nil`, causes Emacs to update its record of installed packages without actually making them available.

## 43.2 Simple Packages

A simple package consists of a single Emacs Lisp source file. The file must conform to the Emacs Lisp library header conventions (see Section D.8 [Library Headers], page 1343). The package’s attributes are taken from the various headers, as illustrated by the following example:

```
;;; superfrobnicator.el --- Frobinate and bifurcate flanges -*- lexical-binding:t -*-

;; Copyright (C) 2022 Free Software Foundation, Inc.

;; Author: J. R. Hacker <jrh@example.com>
;; Version: 1.3
```

```

;; Package-Requires: ((flange "1.0"))
;; Keywords: multimedia, hypermedia
;; URL: https://example.com/jrhacker/superfrobnicate

...
;;;;
;; Commentary:

;; This package provides a minor mode to frobnicate and/or
;; bifurcate any flanges you desire. To activate it, just type
...
;;;;
;; #autoload
(define-minor-mode superfrobnicator-mode
...

```

The name of the package is the same as the base name of the file, as written on the first line. Here, it is ‘superfrobnicator’.

The brief description is also taken from the first line. Here, it is ‘Frobnicate and bifurcate flanges’.

The version number comes from the ‘Package-Version’ header, if it exists, or from the ‘Version’ header otherwise. One or the other *must* be present. Here, the version number is 1.3.

If the file has a ‘;;; Commentary:’ section, this section is used as the long description. (When displaying the description, Emacs omits the ‘;;; Commentary:’ line, as well as the leading comment characters in the commentary itself.)

If the file has a ‘Package-Requires’ header, that is used as the package dependencies. In the above example, the package depends on the ‘flange’ package, version 1.0 or higher. See Section D.8 [Library Headers], page 1343, for a description of the ‘Package-Requires’ header. If the header is omitted, the package has no dependencies.

The ‘Keywords’ and ‘URL’ headers are optional, but recommended. The command `describe-package` uses these to add links to its output. The ‘Keywords’ header should contain at least one standard keyword from the `finder-known-keywords` list.

The file ought to also contain one or more autoload magic comments, as explained in Section 43.1 [Packaging Basics], page 1303. In the above example, a magic comment autoloads `superfrobnicator-mode`.

See Section 43.4 [Package Archives], page 1307, for an explanation of how to add a single-file package to a package archive.

### 43.3 Multi-file Packages

A multi-file package is less convenient to create than a single-file package, but it offers more features: it can include multiple Emacs Lisp files, an Info manual, and other file types (such as images).

Prior to installation, a multi-file package is stored in a package archive as a tar file. The tar file must be named `name-version.tar`, where `name` is the package name and `version`

is the version number. Its contents, once extracted, must all appear in a directory named `name-version`, the *content directory* (see Section 43.1 [Packaging Basics], page 1303). Files may also extract into subdirectories of the content directory.

One of the files in the content directory must be named `name-pkg.el`. It must contain a single Lisp form, consisting of a call to the function `define-package`, described below. This defines the package’s attributes: version, brief description, and requirements.

For example, if we distribute version 1.3 of the superfrobnicator as a multi-file package, the tar file would be `superfrobnicator-1.3.tar`. Its contents would extract into the directory `superfrobnicator-1.3`, and one of these would be the file `superfrobnicator-pkg.el`.

`define-package name version &optional docstring requirements` [Function]

This function defines a package. `name` is the package name, a string. `version` is the version, as a string of a form that can be understood by the function `version-to-list`. `docstring` is the brief description.

`requirements` is a list of required packages and their versions. Each element in this list should have the form `(dep-name dep-version)`, where `dep-name` is a symbol whose name is the dependency’s package name, and `dep-version` is the dependency’s version (a string).

If the content directory contains a file named `README`, this file is used as the long description (overriding any ‘`;; ; Commentary:`’ section).

If the content directory contains a file named `dir`, this is assumed to be an Info directory file made with `install-info`. See Section “Invoking `install-info`” in *Texinfo*. The relevant Info files should also be present in the content directory. In this case, Emacs will automatically add the content directory to `Info-directory-list` when the package is activated.

Do not include any `.elc` files in the package. Those are created when the package is installed. Note that there is no way to control the order in which files are byte-compiled.

Do not include any file named `name-autoloads.el`. This file is reserved for the package’s autoload definitions (see Section 43.1 [Packaging Basics], page 1303). It is created automatically when the package is installed, by searching all the Lisp files in the package for autoload magic comments.

If the multi-file package contains auxiliary data files (such as images), the package’s Lisp code can refer to these files via the variable `load-file-name` (see Chapter 16 [Loading], page 298). Here is an example:

```
(defconst superfrobnicator-base (file-name-directory load-file-name))

(defun superfrobnicator-fetch-image (file)
 (expand-file-name file superfrobnicator-base))
```

If your package contains files that you don’t wish to distribute to users (e.g. regression tests), you can add them to an `.elpaignore` file. In this file, each line lists a file or a wildcard matching files; those files should be ignored when producing your package’s tarball on ELPA (see Section 43.4 [Package Archives], page 1307). (ELPA will pass this file to the `tar` command via the `-X` command-line option, when it prepares the package for download.)

## 43.4 Creating and Maintaining Package Archives

Via the Package Menu, users may download packages from *package archives*. Such archives are specified by the variable `package-archives`, whose default value lists the archives hosted on GNU ELPA (<https://elpa.gnu.org>) and non-GNU ELPA (<https://elpa.nongnu.org>). This section describes how to set up and maintain a package archive.

### `package-archives` [User Option]

The value of this variable is an alist of package archives recognized by the Emacs package manager.

Each alist element corresponds to one archive, and should have the form `(id . location)`, where *id* is the name of the archive (a string) and *location* is its *base location* (a string).

If the base location starts with ‘`http:`’ or ‘`https:`’, it is treated as an HTTP(S) URL, and packages are downloaded from this archive via HTTP(S) (as is the case for the default GNU archive).

Otherwise, the base location should be a directory name. In this case, Emacs retrieves packages from this archive via ordinary file access. Such local archives are mainly useful for testing.

A package archive is simply a directory in which the package files, and associated files, are stored. If you want the archive to be reachable via HTTP, this directory must be accessible to a web server; See Section 43.5 [Archive Web Server], page 1308.

A convenient way to set up and update a package archive is via the `package-x` library. This is included with Emacs, but not loaded by default; type `M-x load-library RET package-x` RET to load it, or add `(require 'package-x)` to your init file. See Section “Lisp Libraries” in *The GNU Emacs Manual*.

After you create an archive, remember that it is not accessible in the Package Menu interface unless it is in `package-archives`.

Maintaining a public package archive entails a degree of responsibility. When Emacs users install packages from your archive, those packages can cause Emacs to run arbitrary code with the permissions of the installing user. (This is true for Emacs code in general, not just for packages.) So you should ensure that your archive is well-maintained and keep the hosting system secure.

One way to increase the security of your packages is to *sign* them using a cryptographic key. If you have generated a private/public gpg key pair, you can use gpg to sign the package like this:

```
gpg -ba -o file.sig file
```

For a single-file package, *file* is the package Lisp file; for a multi-file package, it is the package tar file. You can also sign the archive’s contents file in the same way. Make the `.sig` files available in the same location as the packages. You should also make your public key available for people to download; e.g., by uploading it to a key server such as <https://pgp.mit.edu/>. When people install packages from your archive, they can use your public key to verify the signatures.

A full explanation of these matters is outside the scope of this manual. For more information on cryptographic keys and signing, see Section “GnuPG” in *The GNU Privacy*

*Guard Manual.* Emacs comes with an interface to GNU Privacy Guard, see Section “EasyPG” in *Emacs EasyPG Assistant Manual*.

### 43.5 Interfacing to an archive web server

A web server providing access to a package archive must support the following queries:

archive-contents

Return a lisp form describing the archive contents. The form is a list of ‘package-desc’ structures (see `package.el`), except the first element of the list is the archive version.

<package name>-readme.txt

Return the long description of the package.

<file name>.sig

Return the signature for the file.

<file name>

Return the file. This will be the tarball for a multi-file package, or the single file for a simple package.

## Appendix A Emacs 28 Antinews

For those users who live backwards in time, here is information about downgrading to Emacs version 28.2. We hope you will enjoy the greater simplicity that results from the absence of many Emacs 29.1.90 features.

- The implementation of overlays is back to its simple, time-proven storage in a pair of linear linked lists centered around some buffer position. No more fancy interval trees and suchlikes. Lisp programs that use overlays once again need to recenter overlays around the buffer position of interest, and display-related features should again make sure they don't use too many overlays in a buffer, lest redisplay will be too slow.
- Several functions stopped the annoying conversion of quotes and key sequences by no longer calling `substitute-command-keys`. One prominent example is `format-prompt` and all its many callers. This makes the strings they produce much more predictable, returning to you, the Lisp programmer, control on which punctuation characters will appear in the text presented to the users. For similar reasons, the `substitute-quotes` function was deleted.
- The venerable `buffer-modified-p` function again reliably returns either `nil` or `t`, not any other confusing values.
- The support for ‘`medium`’ weight of fonts was dropped. Emacs now considers ‘`medium`’ and ‘`regular`’ weights to be the same. We believe this will simplify your font setup, since there's no longer a need to worry about fonts that support ‘`regular`’ weight, but not the ‘`medium`’ one, or vice versa: either one will do!
- To reduce the amount of code in Emacs related to unimportant features, we've removed the function `compiled-function-p`. Lisp programs are expected to test explicitly for the relevant types of function objects: built-in, byte-compiled, and natively-compiled. For the same reasons we deleted the functions `pos-bol`, `pos-eol`, `file-attribute-file-identifier`, and quite a few others. We don't expect anyone to miss those fancy functions.
- The timeout used by `x-show-tip` can no longer be specified by Lisp programs; it is hard-coded in the function. This will lead to a simpler, easier maintained code, and no one should want to control the timeout after which the tip pops down.
- The macro `setopt` was deleted; use `customize-variable` instead, or invoke the `:set` function from Lisp.
- We removed the `lisp-directory` variable, as the value can be easily deduced from other similar variables, like `installation-directory` and `source-directory`, each one when it's relevant.
- To simplify code and reduce complexity, we deleted the functions `get-display-property` and `add-display-text-property`; use the generic `get-text-property` and `put-text-property` instead.
- Support for pinch input events and for modern drag-and-drop functionality on X was dropped. As you move back in time, these facilities will become less and less important, and will soon enough disappear, so there's no reason to keep them in Emacs.
- To keep Emacs clean and elegant, we've removed the `textsec.el` library, with its facilities for checking whether some text is “suspicious”. We consider our users smart

enough to detect maliciously modified text by just looking at it or by moving the cursor across it, and the whole idea that someone would wish to deliberately deceive Emacs users ridiculous and unworthy of complicating our elegant text-processing and display capabilities.

- The functions `keymap-set`, `keymap-global-set`, `keymap-local-set`, `keymap-substitute`, `keymap-lookup`, and some others were deleted. We have found the traditional `define-key`, `global-set-key`, `local-set-key`, `substitute-key-definition`, and `key-binding` more than enough, and their minor inconsistencies in the syntax of keys they accept a source of endless fun in Emacs Lisp programming. Why make Emacs programming a dull place? For the same reasons we deleted `key-valid-p`, since we consider the permissive nature of `kbd` more in the spirit of Emacs Lisp.
- Yanking of anything but plain text from other applications becomes more and more an unnecessary feature as you move back in time, so we dropped support for pasting media like HTML and images via the clipboard. If you *really* need to yank those into an Emacs buffer, you can go via a disk file.
- We removed unnecessary functions `string-pixel-width` and `string-glyph-split`, as we consider it inappropriate for Lisp programs to do display layout calculations, where these functions come in handy. Display is for the display engine, written in C, and should stay there!
- Various new Xwidget functions, such as `xwidget-perform-lispy-event`, `xwidget-webkit-load-html`, and `xwidget-webkit-back-forward-list`, were deleted as part of our continuing effort to gradually delete the entire Xwidget functionality in some previous release of Emacs.
- Setting the `:stderr` property of a process in a `make-process` call once again forces the process's connection to use pipes, not ptys, for all the standard streams — a considerable simplification of this complex interface.
- To keep the amount of Lisp functions from growing out of control, we deleted `string-equal-ignore-case`. Use `compare-strings` instead.

Several features that complicated the byte compiler have been removed:

- The warnings about quoting mistakes in documentation strings. You are expected to find such mistakes yourself, by eyeballing the resulting `*Help*` buffer display.
- The warnings about malformed `defcustom` types, like double-quoting symbols in `choice` lists.
- The macro `with-buffer-unmodified-if-unchanged` was deleted. Lisp programs that need to leave the buffer unmodified in these cases can always compare the text before and after the modifications.
- The functions `string-edit` and `read-string-from-buffer` were removed, as we consider the fun of programming them anew every time an important part of the education of each Emacs Lisp developer.
- We deleted the function `readablep` and the related variable `print-unreadable-function`, since no one is supposed to want to print unreadable Lisp objects.
- The facility for storing multisession variables was deleted as an unnecessary complication. With it are gone `multisession-value`, `define-multisession-variable`, and `list-multisession-values`.

- The support for the `cursor-face` text property was dropped. We consider the rest of the faces adequate for supporting this functionality.
- The function `tooltip-show` dropped support for optional face arguments `text-face` and `default-face` that allow fancy control of the face of the tip text and top frame colors. We decided that tooltips should all look the same, to prevent user confusion.
- As part of the ongoing quest for simplicity, many other functions and variables have been eliminated. Other functions and variables, that were declared obsolete since Emacs 24, have been added back, in preparation for releasing Emacs 24 in some distant past.

# Appendix B GNU Free Documentation License

Version 1.3, 3 November 2008

Copyright © 2000, 2001, 2002, 2007, 2008 Free Software Foundation, Inc.  
<https://fsf.org/>

Everyone is permitted to copy and distribute verbatim copies of this license document, but changing it is not allowed.

## 0. PREAMBLE

The purpose of this License is to make a manual, textbook, or other functional and useful document *free* in the sense of freedom: to assure everyone the effective freedom to copy and redistribute it, with or without modifying it, either commercially or noncommercially. Secondarily, this License preserves for the author and publisher a way to get credit for their work, while not being considered responsible for modifications made by others.

This License is a kind of “copyleft”, which means that derivative works of the document must themselves be free in the same sense. It complements the GNU General Public License, which is a copyleft license designed for free software.

We have designed this License in order to use it for manuals for free software, because free software needs free documentation: a free program should come with manuals providing the same freedoms that the software does. But this License is not limited to software manuals; it can be used for any textual work, regardless of subject matter or whether it is published as a printed book. We recommend this License principally for works whose purpose is instruction or reference.

## 1. APPLICABILITY AND DEFINITIONS

This License applies to any manual or other work, in any medium, that contains a notice placed by the copyright holder saying it can be distributed under the terms of this License. Such a notice grants a world-wide, royalty-free license, unlimited in duration, to use that work under the conditions stated herein. The “Document”, below, refers to any such manual or work. Any member of the public is a licensee, and is addressed as “you”. You accept the license if you copy, modify or distribute the work in a way requiring permission under copyright law.

A “Modified Version” of the Document means any work containing the Document or a portion of it, either copied verbatim, or with modifications and/or translated into another language.

A “Secondary Section” is a named appendix or a front-matter section of the Document that deals exclusively with the relationship of the publishers or authors of the Document to the Document’s overall subject (or to related matters) and contains nothing that could fall directly within that overall subject. (Thus, if the Document is in part a textbook of mathematics, a Secondary Section may not explain any mathematics.) The relationship could be a matter of historical connection with the subject or with related matters, or of legal, commercial, philosophical, ethical or political position regarding them.

The “Invariant Sections” are certain Secondary Sections whose titles are designated, as being those of Invariant Sections, in the notice that says that the Document is released

under this License. If a section does not fit the above definition of Secondary then it is not allowed to be designated as Invariant. The Document may contain zero Invariant Sections. If the Document does not identify any Invariant Sections then there are none.

The “Cover Texts” are certain short passages of text that are listed, as Front-Cover Texts or Back-Cover Texts, in the notice that says that the Document is released under this License. A Front-Cover Text may be at most 5 words, and a Back-Cover Text may be at most 25 words.

A “Transparent” copy of the Document means a machine-readable copy, represented in a format whose specification is available to the general public, that is suitable for revising the document straightforwardly with generic text editors or (for images composed of pixels) generic paint programs or (for drawings) some widely available drawing editor, and that is suitable for input to text formatters or for automatic translation to a variety of formats suitable for input to text formatters. A copy made in an otherwise Transparent file format whose markup, or absence of markup, has been arranged to thwart or discourage subsequent modification by readers is not Transparent. An image format is not Transparent if used for any substantial amount of text. A copy that is not “Transparent” is called “Opaque”.

Examples of suitable formats for Transparent copies include plain ASCII without markup, Texinfo input format, LaTEX input format, SGML or XML using a publicly available DTD, and standard-conforming simple HTML, PostScript or PDF designed for human modification. Examples of transparent image formats include PNG, XCF and JPG. Opaque formats include proprietary formats that can be read and edited only by proprietary word processors, SGML or XML for which the DTD and/or processing tools are not generally available, and the machine-generated HTML, PostScript or PDF produced by some word processors for output purposes only.

The “Title Page” means, for a printed book, the title page itself, plus such following pages as are needed to hold, legibly, the material this License requires to appear in the title page. For works in formats which do not have any title page as such, “Title Page” means the text near the most prominent appearance of the work’s title, preceding the beginning of the body of the text.

The “publisher” means any person or entity that distributes copies of the Document to the public.

A section “Entitled XYZ” means a named subunit of the Document whose title either is precisely XYZ or contains XYZ in parentheses following text that translates XYZ in another language. (Here XYZ stands for a specific section name mentioned below, such as “Acknowledgements”, “Dedications”, “Endorsements”, or “History”.) To “Preserve the Title” of such a section when you modify the Document means that it remains a section “Entitled XYZ” according to this definition.

The Document may include Warranty Disclaimers next to the notice which states that this License applies to the Document. These Warranty Disclaimers are considered to be included by reference in this License, but only as regards disclaiming warranties: any other implication that these Warranty Disclaimers may have is void and has no effect on the meaning of this License.

## 2. VERBATIM COPYING

You may copy and distribute the Document in any medium, either commercially or noncommercially, provided that this License, the copyright notices, and the license notice saying this License applies to the Document are reproduced in all copies, and that you add no other conditions whatsoever to those of this License. You may not use technical measures to obstruct or control the reading or further copying of the copies you make or distribute. However, you may accept compensation in exchange for copies. If you distribute a large enough number of copies you must also follow the conditions in section 3.

You may also lend copies, under the same conditions stated above, and you may publicly display copies.

### 3. COPYING IN QUANTITY

If you publish printed copies (or copies in media that commonly have printed covers) of the Document, numbering more than 100, and the Document's license notice requires Cover Texts, you must enclose the copies in covers that carry, clearly and legibly, all these Cover Texts: Front-Cover Texts on the front cover, and Back-Cover Texts on the back cover. Both covers must also clearly and legibly identify you as the publisher of these copies. The front cover must present the full title with all words of the title equally prominent and visible. You may add other material on the covers in addition. Copying with changes limited to the covers, as long as they preserve the title of the Document and satisfy these conditions, can be treated as verbatim copying in other respects.

If the required texts for either cover are too voluminous to fit legibly, you should put the first ones listed (as many as fit reasonably) on the actual cover, and continue the rest onto adjacent pages.

If you publish or distribute Opaque copies of the Document numbering more than 100, you must either include a machine-readable Transparent copy along with each Opaque copy, or state in or with each Opaque copy a computer-network location from which the general network-using public has access to download using public-standard network protocols a complete Transparent copy of the Document, free of added material. If you use the latter option, you must take reasonably prudent steps, when you begin distribution of Opaque copies in quantity, to ensure that this Transparent copy will remain thus accessible at the stated location until at least one year after the last time you distribute an Opaque copy (directly or through your agents or retailers) of that edition to the public.

It is requested, but not required, that you contact the authors of the Document well before redistributing any large number of copies, to give them a chance to provide you with an updated version of the Document.

### 4. MODIFICATIONS

You may copy and distribute a Modified Version of the Document under the conditions of sections 2 and 3 above, provided that you release the Modified Version under precisely this License, with the Modified Version filling the role of the Document, thus licensing distribution and modification of the Modified Version to whoever possesses a copy of it. In addition, you must do these things in the Modified Version:

- A. Use in the Title Page (and on the covers, if any) a title distinct from that of the Document, and from those of previous versions (which should, if there were any,

be listed in the History section of the Document). You may use the same title as a previous version if the original publisher of that version gives permission.

- B. List on the Title Page, as authors, one or more persons or entities responsible for authorship of the modifications in the Modified Version, together with at least five of the principal authors of the Document (all of its principal authors, if it has fewer than five), unless they release you from this requirement.
- C. State on the Title page the name of the publisher of the Modified Version, as the publisher.
- D. Preserve all the copyright notices of the Document.
- E. Add an appropriate copyright notice for your modifications adjacent to the other copyright notices.
- F. Include, immediately after the copyright notices, a license notice giving the public permission to use the Modified Version under the terms of this License, in the form shown in the Addendum below.
- G. Preserve in that license notice the full lists of Invariant Sections and required Cover Texts given in the Document's license notice.
- H. Include an unaltered copy of this License.
- I. Preserve the section Entitled "History", Preserve its Title, and add to it an item stating at least the title, year, new authors, and publisher of the Modified Version as given on the Title Page. If there is no section Entitled "History" in the Document, create one stating the title, year, authors, and publisher of the Document as given on its Title Page, then add an item describing the Modified Version as stated in the previous sentence.
- J. Preserve the network location, if any, given in the Document for public access to a Transparent copy of the Document, and likewise the network locations given in the Document for previous versions it was based on. These may be placed in the "History" section. You may omit a network location for a work that was published at least four years before the Document itself, or if the original publisher of the version it refers to gives permission.
- K. For any section Entitled "Acknowledgements" or "Dedications", Preserve the Title of the section, and preserve in the section all the substance and tone of each of the contributor acknowledgements and/or dedications given therein.
- L. Preserve all the Invariant Sections of the Document, unaltered in their text and in their titles. Section numbers or the equivalent are not considered part of the section titles.
- M. Delete any section Entitled "Endorsements". Such a section may not be included in the Modified Version.
- N. Do not retitle any existing section to be Entitled "Endorsements" or to conflict in title with any Invariant Section.
- O. Preserve any Warranty Disclaimers.

If the Modified Version includes new front-matter sections or appendices that qualify as Secondary Sections and contain no material copied from the Document, you may at your option designate some or all of these sections as invariant. To do this, add their

titles to the list of Invariant Sections in the Modified Version's license notice. These titles must be distinct from any other section titles.

You may add a section Entitled "Endorsements", provided it contains nothing but endorsements of your Modified Version by various parties—for example, statements of peer review or that the text has been approved by an organization as the authoritative definition of a standard.

You may add a passage of up to five words as a Front-Cover Text, and a passage of up to 25 words as a Back-Cover Text, to the end of the list of Cover Texts in the Modified Version. Only one passage of Front-Cover Text and one of Back-Cover Text may be added by (or through arrangements made by) any one entity. If the Document already includes a cover text for the same cover, previously added by you or by arrangement made by the same entity you are acting on behalf of, you may not add another; but you may replace the old one, on explicit permission from the previous publisher that added the old one.

The author(s) and publisher(s) of the Document do not by this License give permission to use their names for publicity for or to assert or imply endorsement of any Modified Version.

## 5. COMBINING DOCUMENTS

You may combine the Document with other documents released under this License, under the terms defined in section 4 above for modified versions, provided that you include in the combination all of the Invariant Sections of all of the original documents, unmodified, and list them all as Invariant Sections of your combined work in its license notice, and that you preserve all their Warranty Disclaimers.

The combined work need only contain one copy of this License, and multiple identical Invariant Sections may be replaced with a single copy. If there are multiple Invariant Sections with the same name but different contents, make the title of each such section unique by adding at the end of it, in parentheses, the name of the original author or publisher of that section if known, or else a unique number. Make the same adjustment to the section titles in the list of Invariant Sections in the license notice of the combined work.

In the combination, you must combine any sections Entitled "History" in the various original documents, forming one section Entitled "History"; likewise combine any sections Entitled "Acknowledgements", and any sections Entitled "Dedications". You must delete all sections Entitled "Endorsements."

## 6. COLLECTIONS OF DOCUMENTS

You may make a collection consisting of the Document and other documents released under this License, and replace the individual copies of this License in the various documents with a single copy that is included in the collection, provided that you follow the rules of this License for verbatim copying of each of the documents in all other respects.

You may extract a single document from such a collection, and distribute it individually under this License, provided you insert a copy of this License into the extracted document, and follow this License in all other respects regarding verbatim copying of that document.

## 7. AGGREGATION WITH INDEPENDENT WORKS

A compilation of the Document or its derivatives with other separate and independent documents or works, in or on a volume of a storage or distribution medium, is called an “aggregate” if the copyright resulting from the compilation is not used to limit the legal rights of the compilation’s users beyond what the individual works permit. When the Document is included in an aggregate, this License does not apply to the other works in the aggregate which are not themselves derivative works of the Document.

If the Cover Text requirement of section 3 is applicable to these copies of the Document, then if the Document is less than one half of the entire aggregate, the Document’s Cover Texts may be placed on covers that bracket the Document within the aggregate, or the electronic equivalent of covers if the Document is in electronic form. Otherwise they must appear on printed covers that bracket the whole aggregate.

## 8. TRANSLATION

Translation is considered a kind of modification, so you may distribute translations of the Document under the terms of section 4. Replacing Invariant Sections with translations requires special permission from their copyright holders, but you may include translations of some or all Invariant Sections in addition to the original versions of these Invariant Sections. You may include a translation of this License, and all the license notices in the Document, and any Warranty Disclaimers, provided that you also include the original English version of this License and the original versions of those notices and disclaimers. In case of a disagreement between the translation and the original version of this License or a notice or disclaimer, the original version will prevail.

If a section in the Document is Entitled “Acknowledgements”, “Dedications”, or “History”, the requirement (section 4) to Preserve its Title (section 1) will typically require changing the actual title.

## 9. TERMINATION

You may not copy, modify, sublicense, or distribute the Document except as expressly provided under this License. Any attempt otherwise to copy, modify, sublicense, or distribute it is void, and will automatically terminate your rights under this License.

However, if you cease all violation of this License, then your license from a particular copyright holder is reinstated (a) provisionally, unless and until the copyright holder explicitly and finally terminates your license, and (b) permanently, if the copyright holder fails to notify you of the violation by some reasonable means prior to 60 days after the cessation.

Moreover, your license from a particular copyright holder is reinstated permanently if the copyright holder notifies you of the violation by some reasonable means, this is the first time you have received notice of violation of this License (for any work) from that copyright holder, and you cure the violation prior to 30 days after your receipt of the notice.

Termination of your rights under this section does not terminate the licenses of parties who have received copies or rights from you under this License. If your rights have been terminated and not permanently reinstated, receipt of a copy of some or all of the same material does not give any rights to use it.

## 10. FUTURE REVISIONS OF THIS LICENSE

The Free Software Foundation may publish new, revised versions of the GNU Free Documentation License from time to time. Such new versions will be similar in spirit to the present version, but may differ in detail to address new problems or concerns. See <https://www.gnu.org/licenses/>.

Each version of the License is given a distinguishing version number. If the Document specifies that a particular numbered version of this License “or any later version” applies to it, you have the option of following the terms and conditions either of that specified version or of any later version that has been published (not as a draft) by the Free Software Foundation. If the Document does not specify a version number of this License, you may choose any version ever published (not as a draft) by the Free Software Foundation. If the Document specifies that a proxy can decide which future versions of this License can be used, that proxy’s public statement of acceptance of a version permanently authorizes you to choose that version for the Document.

## 11. RELICENSING

“Massive Multiauthor Collaboration Site” (or “MMC Site”) means any World Wide Web server that publishes copyrightable works and also provides prominent facilities for anybody to edit those works. A public wiki that anybody can edit is an example of such a server. A “Massive Multiauthor Collaboration” (or “MMC”) contained in the site means any set of copyrightable works thus published on the MMC site.

“CC-BY-SA” means the Creative Commons Attribution-Share Alike 3.0 license published by Creative Commons Corporation, a not-for-profit corporation with a principal place of business in San Francisco, California, as well as future copyleft versions of that license published by that same organization.

“Incorporate” means to publish or republish a Document, in whole or in part, as part of another Document.

An MMC is “eligible for relicensing” if it is licensed under this License, and if all works that were first published under this License somewhere other than this MMC, and subsequently incorporated in whole or in part into the MMC, (1) had no cover texts or invariant sections, and (2) were thus incorporated prior to November 1, 2008.

The operator of an MMC Site may republish an MMC contained in the site under CC-BY-SA on the same site at any time before August 1, 2009, provided the MMC is eligible for relicensing.

## ADDENDUM: How to use this License for your documents

To use this License in a document you have written, include a copy of the License in the document and put the following copyright and license notices just after the title page:

```
Copyright (C) year your name.
Permission is granted to copy, distribute and/or modify this document
under the terms of the GNU Free Documentation License, Version 1.3
or any later version published by the Free Software Foundation;
with no Invariant Sections, no Front-Cover Texts, and no Back-Cover
Texts. A copy of the license is included in the section entitled ``GNU
Free Documentation License''.
```

If you have Invariant Sections, Front-Cover Texts and Back-Cover Texts, replace the “with... Texts.” line with this:

```
with the Invariant Sections being list their titles, with
the Front-Cover Texts being list, and with the Back-Cover Texts
being list.
```

If you have Invariant Sections without Cover Texts, or some other combination of the three, merge those two alternatives to suit the situation.

If your document contains nontrivial examples of program code, we recommend releasing these examples in parallel under your choice of free software license, such as the GNU General Public License, to permit their use in free software.

# Appendix C GNU General Public License

Version 3, 29 June 2007

Copyright © 2007 Free Software Foundation, Inc. <https://fsf.org/>

Everyone is permitted to copy and distribute verbatim copies of this license document, but changing it is not allowed.

## Preamble

The GNU General Public License is a free, copyleft license for software and other kinds of works.

The licenses for most software and other practical works are designed to take away your freedom to share and change the works. By contrast, the GNU General Public License is intended to guarantee your freedom to share and change all versions of a program—to make sure it remains free software for all its users. We, the Free Software Foundation, use the GNU General Public License for most of our software; it applies also to any other work released this way by its authors. You can apply it to your programs, too.

When we speak of free software, we are referring to freedom, not price. Our General Public Licenses are designed to make sure that you have the freedom to distribute copies of free software (and charge for them if you wish), that you receive source code or can get it if you want it, that you can change the software or use pieces of it in new free programs, and that you know you can do these things.

To protect your rights, we need to prevent others from denying you these rights or asking you to surrender the rights. Therefore, you have certain responsibilities if you distribute copies of the software, or if you modify it: responsibilities to respect the freedom of others.

For example, if you distribute copies of such a program, whether gratis or for a fee, you must pass on to the recipients the same freedoms that you received. You must make sure that they, too, receive or can get the source code. And you must show them these terms so they know their rights.

Developers that use the GNU GPL protect your rights with two steps: (1) assert copyright on the software, and (2) offer you this License giving you legal permission to copy, distribute and/or modify it.

For the developers' and authors' protection, the GPL clearly explains that there is no warranty for this free software. For both users' and authors' sake, the GPL requires that modified versions be marked as changed, so that their problems will not be attributed erroneously to authors of previous versions.

Some devices are designed to deny users access to install or run modified versions of the software inside them, although the manufacturer can do so. This is fundamentally incompatible with the aim of protecting users' freedom to change the software. The systematic pattern of such abuse occurs in the area of products for individuals to use, which is precisely where it is most unacceptable. Therefore, we have designed this version of the GPL to prohibit the practice for those products. If such problems arise substantially in other domains, we stand ready to extend this provision to those domains in future versions of the GPL, as needed to protect the freedom of users.

Finally, every program is threatened constantly by software patents. States should not allow patents to restrict development and use of software on general-purpose computers, but in those that do, we wish to avoid the special danger that patents applied to a free program could make it effectively proprietary. To prevent this, the GPL assures that patents cannot be used to render the program non-free.

The precise terms and conditions for copying, distribution and modification follow.

## TERMS AND CONDITIONS

### 0. Definitions.

“This License” refers to version 3 of the GNU General Public License.

“Copyright” also means copyright-like laws that apply to other kinds of works, such as semiconductor masks.

“The Program” refers to any copyrightable work licensed under this License. Each licensee is addressed as “you”. “Licensees” and “recipients” may be individuals or organizations.

To “modify” a work means to copy from or adapt all or part of the work in a fashion requiring copyright permission, other than the making of an exact copy. The resulting work is called a “modified version” of the earlier work or a work “based on” the earlier work.

A “covered work” means either the unmodified Program or a work based on the Program.

To “propagate” a work means to do anything with it that, without permission, would make you directly or secondarily liable for infringement under applicable copyright law, except executing it on a computer or modifying a private copy. Propagation includes copying, distribution (with or without modification), making available to the public, and in some countries other activities as well.

To “convey” a work means any kind of propagation that enables other parties to make or receive copies. Mere interaction with a user through a computer network, with no transfer of a copy, is not conveying.

An interactive user interface displays “Appropriate Legal Notices” to the extent that it includes a convenient and prominently visible feature that (1) displays an appropriate copyright notice, and (2) tells the user that there is no warranty for the work (except to the extent that warranties are provided), that licensees may convey the work under this License, and how to view a copy of this License. If the interface presents a list of user commands or options, such as a menu, a prominent item in the list meets this criterion.

### 1. Source Code.

The “source code” for a work means the preferred form of the work for making modifications to it. “Object code” means any non-source form of a work.

A “Standard Interface” means an interface that either is an official standard defined by a recognized standards body, or, in the case of interfaces specified for a particular programming language, one that is widely used among developers working in that language.

The “System Libraries” of an executable work include anything, other than the work as a whole, that (a) is included in the normal form of packaging a Major Component, but

which is not part of that Major Component, and (b) serves only to enable use of the work with that Major Component, or to implement a Standard Interface for which an implementation is available to the public in source code form. A “Major Component”, in this context, means a major essential component (kernel, window system, and so on) of the specific operating system (if any) on which the executable work runs, or a compiler used to produce the work, or an object code interpreter used to run it.

The “Corresponding Source” for a work in object code form means all the source code needed to generate, install, and (for an executable work) run the object code and to modify the work, including scripts to control those activities. However, it does not include the work’s System Libraries, or general-purpose tools or generally available free programs which are used unmodified in performing those activities but which are not part of the work. For example, Corresponding Source includes interface definition files associated with source files for the work, and the source code for shared libraries and dynamically linked subprograms that the work is specifically designed to require, such as by intimate data communication or control flow between those subprograms and other parts of the work.

The Corresponding Source need not include anything that users can regenerate automatically from other parts of the Corresponding Source.

The Corresponding Source for a work in source code form is that same work.

## 2. Basic Permissions.

All rights granted under this License are granted for the term of copyright on the Program, and are irrevocable provided the stated conditions are met. This License explicitly affirms your unlimited permission to run the unmodified Program. The output from running a covered work is covered by this License only if the output, given its content, constitutes a covered work. This License acknowledges your rights of fair use or other equivalent, as provided by copyright law.

You may make, run and propagate covered works that you do not convey, without conditions so long as your license otherwise remains in force. You may convey covered works to others for the sole purpose of having them make modifications exclusively for you, or provide you with facilities for running those works, provided that you comply with the terms of this License in conveying all material for which you do not control copyright. Those thus making or running the covered works for you must do so exclusively on your behalf, under your direction and control, on terms that prohibit them from making any copies of your copyrighted material outside their relationship with you.

Conveying under any other circumstances is permitted solely under the conditions stated below. Sublicensing is not allowed; section 10 makes it unnecessary.

## 3. Protecting Users’ Legal Rights From Anti-Circumvention Law.

No covered work shall be deemed part of an effective technological measure under any applicable law fulfilling obligations under article 11 of the WIPO copyright treaty adopted on 20 December 1996, or similar laws prohibiting or restricting circumvention of such measures.

When you convey a covered work, you waive any legal power to forbid circumvention of technological measures to the extent such circumvention is effected by exercising rights under this License with respect to the covered work, and you disclaim any intention

to limit operation or modification of the work as a means of enforcing, against the work's users, your or third parties' legal rights to forbid circumvention of technological measures.

#### 4. Conveying Verbatim Copies.

You may convey verbatim copies of the Program's source code as you receive it, in any medium, provided that you conspicuously and appropriately publish on each copy an appropriate copyright notice; keep intact all notices stating that this License and any non-permissive terms added in accord with section 7 apply to the code; keep intact all notices of the absence of any warranty; and give all recipients a copy of this License along with the Program.

You may charge any price or no price for each copy that you convey, and you may offer support or warranty protection for a fee.

#### 5. Conveying Modified Source Versions.

You may convey a work based on the Program, or the modifications to produce it from the Program, in the form of source code under the terms of section 4, provided that you also meet all of these conditions:

- a. The work must carry prominent notices stating that you modified it, and giving a relevant date.
- b. The work must carry prominent notices stating that it is released under this License and any conditions added under section 7. This requirement modifies the requirement in section 4 to "keep intact all notices".
- c. You must license the entire work, as a whole, under this License to anyone who comes into possession of a copy. This License will therefore apply, along with any applicable section 7 additional terms, to the whole of the work, and all its parts, regardless of how they are packaged. This License gives no permission to license the work in any other way, but it does not invalidate such permission if you have separately received it.
- d. If the work has interactive user interfaces, each must display Appropriate Legal Notices; however, if the Program has interactive interfaces that do not display Appropriate Legal Notices, your work need not make them do so.

A compilation of a covered work with other separate and independent works, which are not by their nature extensions of the covered work, and which are not combined with it such as to form a larger program, in or on a volume of a storage or distribution medium, is called an "aggregate" if the compilation and its resulting copyright are not used to limit the access or legal rights of the compilation's users beyond what the individual works permit. Inclusion of a covered work in an aggregate does not cause this License to apply to the other parts of the aggregate.

#### 6. Conveying Non-Source Forms.

You may convey a covered work in object code form under the terms of sections 4 and 5, provided that you also convey the machine-readable Corresponding Source under the terms of this License, in one of these ways:

- a. Convey the object code in, or embodied in, a physical product (including a physical distribution medium), accompanied by the Corresponding Source fixed on a durable physical medium customarily used for software interchange.

- b. Convey the object code in, or embodied in, a physical product (including a physical distribution medium), accompanied by a written offer, valid for at least three years and valid for as long as you offer spare parts or customer support for that product model, to give anyone who possesses the object code either (1) a copy of the Corresponding Source for all the software in the product that is covered by this License, on a durable physical medium customarily used for software interchange, for a price no more than your reasonable cost of physically performing this conveying of source, or (2) access to copy the Corresponding Source from a network server at no charge.
- c. Convey individual copies of the object code with a copy of the written offer to provide the Corresponding Source. This alternative is allowed only occasionally and noncommercially, and only if you received the object code with such an offer, in accord with subsection 6b.
- d. Convey the object code by offering access from a designated place (gratis or for a charge), and offer equivalent access to the Corresponding Source in the same way through the same place at no further charge. You need not require recipients to copy the Corresponding Source along with the object code. If the place to copy the object code is a network server, the Corresponding Source may be on a different server (operated by you or a third party) that supports equivalent copying facilities, provided you maintain clear directions next to the object code saying where to find the Corresponding Source. Regardless of what server hosts the Corresponding Source, you remain obligated to ensure that it is available for as long as needed to satisfy these requirements.
- e. Convey the object code using peer-to-peer transmission, provided you inform other peers where the object code and Corresponding Source of the work are being offered to the general public at no charge under subsection 6d.

A separable portion of the object code, whose source code is excluded from the Corresponding Source as a System Library, need not be included in conveying the object code work.

A “User Product” is either (1) a “consumer product”, which means any tangible personal property which is normally used for personal, family, or household purposes, or (2) anything designed or sold for incorporation into a dwelling. In determining whether a product is a consumer product, doubtful cases shall be resolved in favor of coverage. For a particular product received by a particular user, “normally used” refers to a typical or common use of that class of product, regardless of the status of the particular user or of the way in which the particular user actually uses, or expects or is expected to use, the product. A product is a consumer product regardless of whether the product has substantial commercial, industrial or non-consumer uses, unless such uses represent the only significant mode of use of the product.

“Installation Information” for a User Product means any methods, procedures, authorization keys, or other information required to install and execute modified versions of a covered work in that User Product from a modified version of its Corresponding Source. The information must suffice to ensure that the continued functioning of the modified object code is in no case prevented or interfered with solely because modification has been made.

If you convey an object code work under this section in, or with, or specifically for use in, a User Product, and the conveying occurs as part of a transaction in which the right of possession and use of the User Product is transferred to the recipient in perpetuity or for a fixed term (regardless of how the transaction is characterized), the Corresponding Source conveyed under this section must be accompanied by the Installation Information. But this requirement does not apply if neither you nor any third party retains the ability to install modified object code on the User Product (for example, the work has been installed in ROM).

The requirement to provide Installation Information does not include a requirement to continue to provide support service, warranty, or updates for a work that has been modified or installed by the recipient, or for the User Product in which it has been modified or installed. Access to a network may be denied when the modification itself materially and adversely affects the operation of the network or violates the rules and protocols for communication across the network.

Corresponding Source conveyed, and Installation Information provided, in accord with this section must be in a format that is publicly documented (and with an implementation available to the public in source code form), and must require no special password or key for unpacking, reading or copying.

## 7. Additional Terms.

“Additional permissions” are terms that supplement the terms of this License by making exceptions from one or more of its conditions. Additional permissions that are applicable to the entire Program shall be treated as though they were included in this License, to the extent that they are valid under applicable law. If additional permissions apply only to part of the Program, that part may be used separately under those permissions, but the entire Program remains governed by this License without regard to the additional permissions.

When you convey a copy of a covered work, you may at your option remove any additional permissions from that copy, or from any part of it. (Additional permissions may be written to require their own removal in certain cases when you modify the work.) You may place additional permissions on material, added by you to a covered work, for which you have or can give appropriate copyright permission.

Notwithstanding any other provision of this License, for material you add to a covered work, you may (if authorized by the copyright holders of that material) supplement the terms of this License with terms:

- a. Disclaiming warranty or limiting liability differently from the terms of sections 15 and 16 of this License; or
- b. Requiring preservation of specified reasonable legal notices or author attributions in that material or in the Appropriate Legal Notices displayed by works containing it; or
- c. Prohibiting misrepresentation of the origin of that material, or requiring that modified versions of such material be marked in reasonable ways as different from the original version; or
- d. Limiting the use for publicity purposes of names of licensors or authors of the material; or

- e. Declining to grant rights under trademark law for use of some trade names, trademarks, or service marks; or
- f. Requiring indemnification of licensors and authors of that material by anyone who conveys the material (or modified versions of it) with contractual assumptions of liability to the recipient, for any liability that these contractual assumptions directly impose on those licensors and authors.

All other non-permissive additional terms are considered “further restrictions” within the meaning of section 10. If the Program as you received it, or any part of it, contains a notice stating that it is governed by this License along with a term that is a further restriction, you may remove that term. If a license document contains a further restriction but permits relicensing or conveying under this License, you may add to a covered work material governed by the terms of that license document, provided that the further restriction does not survive such relicensing or conveying.

If you add terms to a covered work in accord with this section, you must place, in the relevant source files, a statement of the additional terms that apply to those files, or a notice indicating where to find the applicable terms.

Additional terms, permissive or non-permissive, may be stated in the form of a separately written license, or stated as exceptions; the above requirements apply either way.

#### 8. Termination.

You may not propagate or modify a covered work except as expressly provided under this License. Any attempt otherwise to propagate or modify it is void, and will automatically terminate your rights under this License (including any patent licenses granted under the third paragraph of section 11).

However, if you cease all violation of this License, then your license from a particular copyright holder is reinstated (a) provisionally, unless and until the copyright holder explicitly and finally terminates your license, and (b) permanently, if the copyright holder fails to notify you of the violation by some reasonable means prior to 60 days after the cessation.

Moreover, your license from a particular copyright holder is reinstated permanently if the copyright holder notifies you of the violation by some reasonable means, this is the first time you have received notice of violation of this License (for any work) from that copyright holder, and you cure the violation prior to 30 days after your receipt of the notice.

Termination of your rights under this section does not terminate the licenses of parties who have received copies or rights from you under this License. If your rights have been terminated and not permanently reinstated, you do not qualify to receive new licenses for the same material under section 10.

#### 9. Acceptance Not Required for Having Copies.

You are not required to accept this License in order to receive or run a copy of the Program. Ancillary propagation of a covered work occurring solely as a consequence of using peer-to-peer transmission to receive a copy likewise does not require acceptance. However, nothing other than this License grants you permission to propagate or modify any covered work. These actions infringe copyright if you do not accept this License. Therefore, by modifying or propagating a covered work, you indicate your acceptance of this License to do so.

## 10. Automatic Licensing of Downstream Recipients.

Each time you convey a covered work, the recipient automatically receives a license from the original licensors, to run, modify and propagate that work, subject to this License. You are not responsible for enforcing compliance by third parties with this License.

An “entity transaction” is a transaction transferring control of an organization, or substantially all assets of one, or subdividing an organization, or merging organizations. If propagation of a covered work results from an entity transaction, each party to that transaction who receives a copy of the work also receives whatever licenses to the work the party’s predecessor in interest had or could give under the previous paragraph, plus a right to possession of the Corresponding Source of the work from the predecessor in interest, if the predecessor has it or can get it with reasonable efforts.

You may not impose any further restrictions on the exercise of the rights granted or affirmed under this License. For example, you may not impose a license fee, royalty, or other charge for exercise of rights granted under this License, and you may not initiate litigation (including a cross-claim or counterclaim in a lawsuit) alleging that any patent claim is infringed by making, using, selling, offering for sale, or importing the Program or any portion of it.

## 11. Patents.

A “contributor” is a copyright holder who authorizes use under this License of the Program or a work on which the Program is based. The work thus licensed is called the contributor’s “contributor version”.

A contributor’s “essential patent claims” are all patent claims owned or controlled by the contributor, whether already acquired or hereafter acquired, that would be infringed by some manner, permitted by this License, of making, using, or selling its contributor version, but do not include claims that would be infringed only as a consequence of further modification of the contributor version. For purposes of this definition, “control” includes the right to grant patent sublicenses in a manner consistent with the requirements of this License.

Each contributor grants you a non-exclusive, worldwide, royalty-free patent license under the contributor’s essential patent claims, to make, use, sell, offer for sale, import and otherwise run, modify and propagate the contents of its contributor version.

In the following three paragraphs, a “patent license” is any express agreement or commitment, however denominated, not to enforce a patent (such as an express permission to practice a patent or covenant not to sue for patent infringement). To “grant” such a patent license to a party means to make such an agreement or commitment not to enforce a patent against the party.

If you convey a covered work, knowingly relying on a patent license, and the Corresponding Source of the work is not available for anyone to copy, free of charge and under the terms of this License, through a publicly available network server or other readily accessible means, then you must either (1) cause the Corresponding Source to be so available, or (2) arrange to deprive yourself of the benefit of the patent license for this particular work, or (3) arrange, in a manner consistent with the requirements of this License, to extend the patent license to downstream recipients. “Knowingly relying” means you have actual knowledge that, but for the patent license, your conveying the

covered work in a country, or your recipient's use of the covered work in a country, would infringe one or more identifiable patents in that country that you have reason to believe are valid.

If, pursuant to or in connection with a single transaction or arrangement, you convey, or propagate by procuring conveyance of, a covered work, and grant a patent license to some of the parties receiving the covered work authorizing them to use, propagate, modify or convey a specific copy of the covered work, then the patent license you grant is automatically extended to all recipients of the covered work and works based on it.

A patent license is "discriminatory" if it does not include within the scope of its coverage, prohibits the exercise of, or is conditioned on the non-exercise of one or more of the rights that are specifically granted under this License. You may not convey a covered work if you are a party to an arrangement with a third party that is in the business of distributing software, under which you make payment to the third party based on the extent of your activity of conveying the work, and under which the third party grants, to any of the parties who would receive the covered work from you, a discriminatory patent license (a) in connection with copies of the covered work conveyed by you (or copies made from those copies), or (b) primarily for and in connection with specific products or compilations that contain the covered work, unless you entered into that arrangement, or that patent license was granted, prior to 28 March 2007.

Nothing in this License shall be construed as excluding or limiting any implied license or other defenses to infringement that may otherwise be available to you under applicable patent law.

## 12. No Surrender of Others' Freedom.

If conditions are imposed on you (whether by court order, agreement or otherwise) that contradict the conditions of this License, they do not excuse you from the conditions of this License. If you cannot convey a covered work so as to satisfy simultaneously your obligations under this License and any other pertinent obligations, then as a consequence you may not convey it at all. For example, if you agree to terms that obligate you to collect a royalty for further conveying from those to whom you convey the Program, the only way you could satisfy both those terms and this License would be to refrain entirely from conveying the Program.

## 13. Use with the GNU Affero General Public License.

Notwithstanding any other provision of this License, you have permission to link or combine any covered work with a work licensed under version 3 of the GNU Affero General Public License into a single combined work, and to convey the resulting work. The terms of this License will continue to apply to the part which is the covered work, but the special requirements of the GNU Affero General Public License, section 13, concerning interaction through a network will apply to the combination as such.

## 14. Revised Versions of this License.

The Free Software Foundation may publish revised and/or new versions of the GNU General Public License from time to time. Such new versions will be similar in spirit to the present version, but may differ in detail to address new problems or concerns.

Each version is given a distinguishing version number. If the Program specifies that a certain numbered version of the GNU General Public License "or any later version" applies to it, you have the option of following the terms and conditions either of that

numbered version or of any later version published by the Free Software Foundation. If the Program does not specify a version number of the GNU General Public License, you may choose any version ever published by the Free Software Foundation.

If the Program specifies that a proxy can decide which future versions of the GNU General Public License can be used, that proxy's public statement of acceptance of a version permanently authorizes you to choose that version for the Program.

Later license versions may give you additional or different permissions. However, no additional obligations are imposed on any author or copyright holder as a result of your choosing to follow a later version.

15. Disclaimer of Warranty.

THERE IS NO WARRANTY FOR THE PROGRAM, TO THE EXTENT PERMITTED BY APPLICABLE LAW. EXCEPT WHEN OTHERWISE STATED IN WRITING THE COPYRIGHT HOLDERS AND/OR OTHER PARTIES PROVIDE THE PROGRAM "AS IS" WITHOUT WARRANTY OF ANY KIND, EITHER EXPRESSED OR IMPLIED, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE. THE ENTIRE RISK AS TO THE QUALITY AND PERFORMANCE OF THE PROGRAM IS WITH YOU. SHOULD THE PROGRAM PROVE DEFECTIVE, YOU ASSUME THE COST OF ALL NECESSARY SERVICING, REPAIR OR CORRECTION.

16. Limitation of Liability.

IN NO EVENT UNLESS REQUIRED BY APPLICABLE LAW OR AGREED TO IN WRITING WILL ANY COPYRIGHT HOLDER, OR ANY OTHER PARTY WHO MODIFIES AND/OR CONVEYS THE PROGRAM AS PERMITTED ABOVE, BE LIABLE TO YOU FOR DAMAGES, INCLUDING ANY GENERAL, SPECIAL, INCIDENTAL OR CONSEQUENTIAL DAMAGES ARISING OUT OF THE USE OR INABILITY TO USE THE PROGRAM (INCLUDING BUT NOT LIMITED TO LOSS OF DATA OR DATA BEING RENDERED INACCURATE OR LOSSES SUSTAINED BY YOU OR THIRD PARTIES OR A FAILURE OF THE PROGRAM TO OPERATE WITH ANY OTHER PROGRAMS), EVEN IF SUCH HOLDER OR OTHER PARTY HAS BEEN ADVISED OF THE POSSIBILITY OF SUCH DAMAGES.

17. Interpretation of Sections 15 and 16.

If the disclaimer of warranty and limitation of liability provided above cannot be given local legal effect according to their terms, reviewing courts shall apply local law that most closely approximates an absolute waiver of all civil liability in connection with the Program, unless a warranty or assumption of liability accompanies a copy of the Program in return for a fee.

## END OF TERMS AND CONDITIONS

### How to Apply These Terms to Your New Programs

If you develop a new program, and you want it to be of the greatest possible use to the public, the best way to achieve this is to make it free software which everyone can redistribute and change under these terms.

To do so, attach the following notices to the program. It is safest to attach them to the start of each source file to most effectively state the exclusion of warranty; and each file should have at least the “copyright” line and a pointer to where the full notice is found.

*one line to give the program's name and a brief idea of what it does.*

Copyright (C) year name of author

This program is free software: you can redistribute it and/or modify it under the terms of the GNU General Public License as published by the Free Software Foundation, either version 3 of the License, or (at your option) any later version.

This program is distributed in the hope that it will be useful, but WITHOUT ANY WARRANTY; without even the implied warranty of MERCHANTABILITY or FITNESS FOR A PARTICULAR PURPOSE. See the GNU General Public License for more details.

You should have received a copy of the GNU General Public License along with this program. If not, see <https://www.gnu.org/licenses/>.

Also add information on how to contact you by electronic and paper mail.

If the program does terminal interaction, make it output a short notice like this when it starts in an interactive mode:

*program Copyright (C) year name of author*

*This program comes with ABSOLUTELY NO WARRANTY; for details type ‘show w’.*

*This is free software, and you are welcome to redistribute it  
under certain conditions; type ‘show c’ for details.*

The hypothetical commands ‘show w’ and ‘show c’ should show the appropriate parts of the General Public License. Of course, your program’s commands might be different; for a GUI interface, you would use an “about box”.

You should also get your employer (if you work as a programmer) or school, if any, to sign a “copyright disclaimer” for the program, if necessary. For more information on this, and how to apply and follow the GNU GPL, see <https://www.gnu.org/licenses/>.

The GNU General Public License does not permit incorporating your program into proprietary programs. If your program is a subroutine library, you may consider it more useful to permit linking proprietary applications with the library. If this is what you want to do, use the GNU Lesser General Public License instead of this License. But first, please read <https://www.gnu.org/licenses/why-not-lgpl.html>.

## Appendix D Tips and Conventions

This chapter describes no additional features of Emacs Lisp. Instead it gives advice on making effective use of the features described in the previous chapters, and describes conventions Emacs Lisp programmers should follow.

You can automatically check some of the conventions described below by running the command *M-x checkdoc RET* when visiting a Lisp file. It cannot check all of the conventions, and not all the warnings it gives necessarily correspond to problems, but it is worth examining them all. Alternatively, use the command *M-x checkdoc-current-buffer RET* to check the conventions in the current buffer, or *checkdoc-file* when you want to check a file in batch mode, e.g., with a command run by *M-x compile RET*.

### D.1 Emacs Lisp Coding Conventions

Here are conventions that you should follow when writing Emacs Lisp code intended for widespread use:

- Simply loading a package should not change Emacs's editing behavior. Include a command or commands to enable and disable the feature, or to invoke it.

This convention is mandatory for any file that includes custom definitions. If fixing such a file to follow this convention requires an incompatible change, go ahead and make the incompatible change; don't postpone it.

- You should choose a short word to distinguish your program from other Lisp programs. The names of all global symbols in your program, that is the names of variables, constants, and functions, should begin with that chosen prefix. Separate the prefix from the rest of the name with a hyphen, ‘-’. This practice helps avoid name conflicts, since all global variables in Emacs Lisp share the same name space, and all functions share another name space<sup>1</sup>. Use two hyphens to separate prefix and name if the symbol is not meant to be used by other packages.

Occasionally, for a command name intended for users to use, it is more convenient if some words come before the package's name prefix. For example, it is our convention to have commands that list objects named as ‘*list-something*’, e.g., a package called ‘*frob*’ could have a command ‘*list-frobs*’, when its other global symbols begin with ‘*frob-*’. Also, constructs that define functions, variables, etc., work better if they start with ‘*define-*’, so put the name prefix later on in the name.

This recommendation applies even to names for traditional Lisp primitives that are not primitives in Emacs Lisp—such as *copy-list*. Believe it or not, there is more than one plausible way to define *copy-list*. Play it safe; append your name prefix to produce a name like *foo-copy-list* or *mylib-copy-list* instead.

If you write a function that you think ought to be added to Emacs under a certain name, such as *twiddle-files*, don't call it by that name in your program. Call it *mylib-twiddle-files* in your program, and send mail to ‘[bug-gnu-emacs@gnu.org](mailto:bug-gnu-emacs@gnu.org)’ suggesting we add it to Emacs. If and when we do, we can change the name easily enough.

---

<sup>1</sup> The benefits of a Common Lisp-style package system are considered not to outweigh the costs.

If one prefix is insufficient, your package can use two or three alternative common prefixes, so long as they make sense.

- We recommend enabling `lexical-binding` in new code, and converting existing Emacs Lisp code to enable `lexical-binding` if it doesn't already. See Section 12.10.4 [Using Lexical Binding], page 204.
- Put a call to `provide` at the end of each separate Lisp file. See Section 16.7 [Named Features], page 309.
- If a file requires certain other Lisp programs to be loaded beforehand, then the comments at the beginning of the file should say so. Also, use `require` to make sure they are loaded. See Section 16.7 [Named Features], page 309.
- If a file *foo* uses a macro defined in another file *bar*, but does not use any functions or variables defined in *bar*, then *foo* should contain the following expression:

```
(eval-when-compile (require 'bar))
```

This tells Emacs to load *bar* just before byte-compiling *foo*, so that the macro definition is available during compilation. Using `eval-when-compile` avoids loading *bar* when the compiled version of *foo* is used. It should be called before the first use of the macro in the file. See Section 14.3 [Compiling Macros], page 270.

- Avoid loading additional libraries at run time unless they are really needed. If your file simply cannot work without some other library, then just `require` that library at the top-level and be done with it. But if your file contains several independent features, and only one or two require the extra library, then consider putting `require` statements inside the relevant functions rather than at the top-level. Or use `autoload` statements to load the extra library when needed. This way people who don't use those aspects of your file do not need to load the extra library.
- If you need Common Lisp extensions, use the `cl-lib` library rather than the old `cl` library. The latter library is deprecated and will be removed in a future version of Emacs.
- When defining a major mode, please follow the major mode conventions. See Section 24.2.1 [Major Mode Conventions], page 528.
- When defining a minor mode, please follow the minor mode conventions. See Section 24.3.1 [Minor Mode Conventions], page 544.
- If the purpose of a function is to tell you whether a certain condition is true or false, give the function a name that ends in ‘`p`’ (which stands for “predicate”). If the name is one word, add just ‘`p`’; if the name is multiple words, add ‘`-p`’. Examples are `framep` and `frame-live-p`. We recommend to avoid using this `-p` suffix in boolean variable names, unless the variable is bound to a predicate function; instead, use a `-flag` suffix or names like `is-foo`.
- If the purpose of a variable is to store a single function, give it a name that ends in ‘`-function`’. If the purpose of a variable is to store a list of functions (i.e., the variable is a hook), please follow the naming conventions for hooks. See Section 24.1 [Hooks], page 524.
- Using `unload-feature` will undo the changes usually done by loading a feature (like adding functions to hooks). However, if loading *feature* does something unusual and more complex, you can define a function named `feature-unload-function`, and make

it undo any such special changes. `unload-feature` will then automatically run this function if it exists. See Section 16.9 [Unloading], page 313.

- It is a bad idea to define aliases for the Emacs primitives. Normally you should use the standard names instead. The case where an alias may be useful is where it facilitates backwards compatibility or portability.
- If a package needs to define an alias or a new function for compatibility with some other version of Emacs, name it with the package prefix, not with the raw name with which it occurs in the other version. Here is an example from Gnus, which provides many examples of such compatibility issues.

```
(defalias 'gnus-point-at-bol
 (if (fboundp 'point-at-bol)
 'point-at-bol
 'line-beginning-position))
```

- Redefining or advising an Emacs primitive is a bad idea. It may do the right thing for a particular program, but there is no telling what other programs might break as a result.
- It is likewise a bad idea for one Lisp package to advise a function in another Lisp package (see Section 13.12 [Advising Functions], page 252).
- Avoid using `eval-after-load` and `with-eval-after-load` in libraries and packages (see Section 16.10 [Hooks for Loading], page 313). This feature is meant for personal customizations; using it in a Lisp program is unclean, because it modifies the behavior of another Lisp file in a way that's not visible in that file. This is an obstacle for debugging, much like advising a function in the other package.
- If a file does replace any of the standard functions or library programs of Emacs, prominent comments at the beginning of the file should say which functions are replaced, and how the behavior of the replacements differs from that of the originals.
- Constructs that define a function or variable should be macros, not functions, and their names should start with ‘`define-`’. The macro should receive the name to be defined as the first argument. That will help various tools find the definition automatically. Avoid constructing the names in the macro itself, since that would confuse these tools.
- In some other systems there is a convention of choosing variable names that begin and end with ‘\*’. We don't use that convention in Emacs Lisp, so please don't use it in your programs. (Emacs uses such names only for special-purpose buffers.) People will find Emacs more coherent if all libraries use the same conventions.
- The default file coding system for Emacs Lisp source files is UTF-8 (see Section 34.1 [Text Representations], page 963). In the rare event that your program contains characters which are *not* in UTF-8, you should specify an appropriate coding system in the source file's ‘`-*-`’ line or local variables list. See Section “Local Variables in Files” in *The GNU Emacs Manual*.
- Indent the file using the default indentation parameters.
- Don't make a habit of putting close-parentheses on lines by themselves; Lisp programmers find this disconcerting.
- Please put a copyright notice and copying permission notice on the file if you distribute copies. See Section D.8 [Library Headers], page 1343.

- For variables holding (or functions returning) a file or directory name, avoid using `path` in its name, preferring `file`, `file-name`, or `directory` instead, since Emacs follows the GNU convention to use the term *path* only for search paths, which are lists of directory names.

## D.2 Key Binding Conventions

- Many special major modes, like `Dired`, `Info`, `Compilation`, and `Occur`, are designed to handle read-only text that contains *hyper-links*. Such a major mode should redefine `mouse-2` and `RET` to follow the links. It should also set up a `follow-link` condition, so that the link obeys `mouse-1-click-follows-link`. See Section 33.19.8 [Clickable Text], page 934. See Section 41.20 [Buttons], page 1232, for an easy method of implementing such clickable links.
- Don't define `C-c letter` as a key in Lisp programs. Sequences consisting of `C-c` and a letter (either upper or lower case; ASCII or non-ASCII) are reserved for users; they are the **only** sequences reserved for users, so do not block them.

Changing all the Emacs major modes to respect this convention was a lot of work; abandoning this convention would make that work go to waste, and inconvenience users. Please comply with it.

- Function keys F5 through F9 without modifier keys are also reserved for users to define.
- Sequences consisting of `C-c` followed by a control character or a digit are reserved for major modes.
- Sequences consisting of `C-c` followed by `{`, `}`, `<`, `>`, `:` or `;` are also reserved for major modes.
- Sequences consisting of `C-c` followed by any other ASCII punctuation or symbol character are allocated for minor modes. Using them in a major mode is not absolutely prohibited, but if you do that, the major mode binding may be shadowed from time to time by minor modes.
- Don't bind `C-h` following any prefix character (including `C-c`). If you don't bind `C-h`, it is automatically available as a help character for listing the subcommands of the prefix character.
- Don't bind a key sequence ending in `ESC` except following another `ESC`. (That is, it is OK to bind a sequence ending in `ESC ESC`.)

The reason for this rule is that a non-prefix binding for `ESC` in any context prevents recognition of escape sequences as function keys in that context.

- Similarly, don't bind a key sequence ending in `C-g`, since that is commonly used to cancel a key sequence.
- Anything that acts like a temporary mode or state that the user can enter and leave should define `ESC ESC` or `ESC ESC ESC` as a way to escape.

For a state that accepts ordinary Emacs commands, or more generally any kind of state in which `ESC` followed by a function key or arrow key is potentially meaningful, then you must not define `ESC ESC`, since that would preclude recognizing an escape sequence after `ESC`. In these states, you should define `ESC ESC ESC` as the way to escape. Otherwise, define `ESC ESC` instead.

### D.3 Emacs Programming Tips

Following these conventions will make your program fit better into Emacs when it runs.

- Don’t use `next-line` or `previous-line` in programs; nearly always, `forward-line` is more convenient as well as more predictable and robust. See Section 31.2.4 [Text Lines], page 856.
- Don’t call functions that set the mark, unless setting the mark is one of the intended features of your program. The mark is a user-level feature, so it is incorrect to change the mark except to supply a value for the user’s benefit. See Section 32.7 [The Mark], page 873.

In particular, don’t use any of these functions:

- `beginning-of-buffer`, `end-of-buffer`
- `replace-string`, `replace-regexp`
- `insert-file`, `insert-buffer`

If you just want to move point, or replace a certain string, or insert a file or buffer’s contents, without any of the other features intended for interactive users, you can replace these functions with one or two lines of simple Lisp code.

- Use lists rather than vectors, except when there is a particular reason to use a vector. Lisp has more facilities for manipulating lists than for vectors, and working with lists is usually more convenient.

Vectors are advantageous for tables that are substantial in size and are accessed in random order (not searched front to back), provided there is no need to insert or delete elements (only lists allow that).

- The recommended way to show a message in the echo area is with the `message` function, not `princ`. See Section 41.4 [The Echo Area], page 1131.
  - When you encounter an error condition, call the function `error` (or `signal`). The function `error` does not return. See Section 11.7.3.1 [Signaling Errors], page 180.
- Don’t use `message`, `throw`, `sleep-for`, or `beep` to report errors.
- An error message should start with a capital letter but should not end with a period or other punctuation.

It is occasionally useful to tell the user where an error originated, even if `debug-on-error` is `nil`. In such cases, a lower-case Lisp symbol can be prepended to the error message. For example, the error message “Invalid input” could be extended to say “`some-function`: Invalid input”.

- A question asked in the minibuffer with `yes-or-no-p` or `y-or-n-p` should start with a capital letter and end with ‘?’.
- When you mention a default value in a minibuffer prompt, put it and the word ‘`default`’ inside parentheses. It should look like this:

Enter the answer (default 42):

- In `interactive`, if you use a Lisp expression to produce a list of arguments, don’t try to provide the correct default values for region or position arguments. Instead, provide `nil` for those arguments if they were not specified, and have the function body compute the default value when the argument is `nil`. For instance, write this:

```
(defun foo (pos)
```

```
(interactive
 (list (if specified specified-pos)))
(unless pos (setq pos default-pos))
...)
```

rather than this:

```
(defun foo (pos)
 (interactive
 (list (if specified specified-pos
 default-pos)))
 ...)
```

This is so that repetition of the command will recompute these defaults based on the current circumstances.

You do not need to take such precautions when you use interactive specs ‘d’, ‘m’ and ‘r’, because they make special arrangements to recompute the argument values on repetition of the command.

- Many commands that take a long time to execute display a message that says something like ‘Operating...’ when they start, and change it to ‘Operating...done’ when they finish. Please keep the style of these messages uniform: *no* space around the ellipsis, and *no* period after ‘done’. See Section 41.4.2 [Progress], page 1134, for an easy way to generate such messages.
- Try to avoid using recursive edits. Instead, do what the Rmail `e` command does: use a new local keymap that contains a command defined to switch back to the old local keymap. Or simply switch to another buffer and let the user switch back at will. See Section 22.13 [Recursive Editing], page 475.

## D.4 Tips for Making Compiled Code Fast

Here are ways of improving the execution speed of byte-compiled Lisp programs.

- Profile your program, to find out where the time is being spent. See Section 19.5 [Profiling], page 369.
- Use iteration rather than recursion whenever possible. Function calls are slow in Emacs Lisp even when a compiled function is calling another compiled function.
- Using the primitive list-searching functions `memq`, `member`, `assq`, or `assoc` is even faster than explicit iteration. It can be worth rearranging a data structure so that one of these primitive search functions can be used.
- Certain built-in functions are handled specially in byte-compiled code, avoiding the need for an ordinary function call. It is a good idea to use these functions rather than alternatives. To see whether a function is handled specially by the compiler, examine its `byte-compile` property. If the property is non-`nil`, then the function is handled specially.

For example, the following input will show you that `aref` is compiled specially (see Section 6.3 [Array Functions], page 116):

```
(get 'aref 'byte-compile)
⇒ byte-compile-two-args
```

Note that in this case (and many others), you must first load the `bytecomp` library, which defines the `byte-compile` property.

- If calling a small function accounts for a substantial part of your program’s running time, make the function inline. This eliminates the function call overhead. Since making a function inline reduces the flexibility of changing the program, don’t do it unless it gives a noticeable speedup in something slow enough that users care about the speed. See Section 13.14 [Inline Functions], page 261.

## D.5 Tips for Avoiding Compiler Warnings

- Try to avoid compiler warnings about undefined free variables, by adding dummy `defvar` definitions for these variables, like this:

```
(defvar foo)
```

Such a definition has no effect except to tell the compiler not to warn about uses of the variable `foo` in this file.

- Similarly, to avoid a compiler warning about an undefined function that you know *will* be defined, use a `declare-function` statement (see Section 13.16 [Declaring Functions], page 265).
- If you use many functions, macros, and variables from a certain file, you can add a `require` (see Section 16.7 [Named Features], page 309) for that package to avoid compilation warnings for them, like this:

```
(require 'foo)
```

If you need only macros from some file, you can require it only at compile time (see Section 17.5 [Eval During Compile], page 320). For instance,

```
(eval-when-compile
 (require 'foo))
```

- If you bind a variable in one function, and use it or set it in another function, the compiler warns about the latter function unless the variable has a definition. But adding a definition would be unclean if the variable has a short name, since Lisp packages should not define short variable names. The right thing to do is to rename this variable to start with the name prefix used for the other functions and variables in your package.
- The last resort for avoiding a warning, when you want to do something that is usually a mistake but you know is not a mistake in your usage, is to put it inside `with-no-warnings`. See Section 17.6 [Compiler Errors], page 321.

## D.6 Tips for Documentation Strings

Here are some tips and conventions for the writing of documentation strings. You can check many of these conventions by running the command `M-x checkdoc-minor-mode`.

- Every command, function, or variable intended for users to know about should have a documentation string.
- An internal variable or subroutine of a Lisp program might as well have a documentation string. Documentation strings take up very little space in a running Emacs.
- Format the documentation string so that it fits in an Emacs window on an 80-column screen. It is a good idea for most lines to be no wider than 60 characters. The first line should not be wider than 67 characters or it will look bad in the output of `apropos`.

You can fill the text if that looks good. Emacs Lisp mode fills documentation strings to the width specified by `emacs-lisp-docstring-fill-column`. However, you can sometimes make a documentation string much more readable by adjusting its line breaks with care. Use blank lines between sections if the documentation string is long.

- The first line of the documentation string should consist of one or two complete sentences that stand on their own as a summary. `M-x apropos` displays just the first line, and if that line's contents don't stand on their own, the result looks bad. In particular, start the first line with a capital letter and end it with a period.

For a function, the first line should briefly answer the question, “What does this function do?” For a variable, the first line should briefly answer the question, “What does this value mean?” Prefer to answer these questions in a way that will make sense to users and callers of the function or the variable. In particular, do *not* tell what the function does by enumerating the actions of its code; instead, describe the role of these actions and the function's contract.

Don't limit the documentation string to one line; use as many lines as you need to explain the details of how to use the function or variable. Please use complete sentences for the rest of the text too.

- When the user tries to use a disabled command, Emacs displays just the first paragraph of its documentation string—everything through the first blank line. If you wish, you can choose which information to include before the first blank line so as to make this display useful.
- The first line should mention all the important arguments of the function (in particular, the mandatory arguments), and should mention them in the order that they are written in a function call. If the function has many arguments, then it is not feasible to mention them all in the first line; in that case, the first line should mention the first few arguments, including the most important arguments.
- When a function's documentation string mentions the value of an argument of the function, use the argument name in capital letters as if it were a name for that value. Thus, the documentation string of the function `eval` refers to its first argument as ‘`FORM`’, because the actual argument name is `form`:

Evaluate `FORM` and return its value.

Also write metasyntactic variables in capital letters, such as when you show the decomposition of a list or vector into subunits, some of which may vary. ‘`KEY`’ and ‘`VALUE`’ in the following example illustrate this practice:

The argument `TABLE` should be an alist whose elements have the form (`KEY` . `VALUE`). Here, `KEY` is ...

- Never change the case of a Lisp symbol when you mention it in a doc string. If the symbol's name is `foo`, write “`foo`”, not “`Foo`” (which is a different symbol).

This might appear to contradict the policy of writing function argument values, but there is no real contradiction; the argument *value* is not the same thing as the *symbol* that the function uses to hold the value.

If this puts a lower-case letter at the beginning of a sentence and that annoys you, rewrite the sentence so that the symbol is not at the start of it.

- Do not start or end a documentation string with whitespace.

- **Do not** indent subsequent lines of a documentation string so that the text is lined up in the source code with the text of the first line. This looks nice in the source code, but looks bizarre when users view the documentation. Remember that the indentation before the starting double-quote is not part of the string!
- When documentation should display an ASCII apostrophe or grave accent, use ‘\\=’ or ‘\\`’ in the documentation string literal so that the character is displayed as-is.
- In documentation strings, do not quote expressions that are not Lisp symbols, as these expressions can stand for themselves. For example, write ‘Return the list (NAME TYPE RANGE) ...’ instead of ‘Return the list `(NAME TYPE RANGE)` ...’ or ‘Return the list \\=(NAME TYPE RANGE) ...’.
- When a documentation string refers to a Lisp symbol, write it as it would be printed (which usually means in lower case), with a grave accent ‘`’ before and apostrophe ‘’’ after it. There are two exceptions: write `t` and `nil` without surrounding punctuation. For example:

CODE can be `lambda', nil, or t.

Note that when Emacs displays these doc strings, Emacs will usually display ‘`’ (grave accent) as ‘‘’ (left single quotation mark) and ‘’’ (apostrophe) as ‘’’ (right single quotation mark), if the display supports displaying these characters. See Section 25.3 [Keys in Documentation], page 598. (Some previous versions of this section recommended using the non-ASCII single quotation marks directly in doc strings, but this is now discouraged, since that leads to broken help string displays on terminals that don’t support displaying those characters.)

Help mode automatically creates a hyperlink when a documentation string uses a single-quoted symbol name, if the symbol has either a function or a variable definition. You do not need to do anything special to make use of this feature. However, when a symbol has both a function definition and a variable definition, and you want to refer to just one of them, you can specify which one by writing one of the words ‘variable’, ‘option’, ‘function’, or ‘command’, immediately before the symbol name. (Case makes no difference in recognizing these indicator words.) For example, if you write

This function sets the variable `buffer-file-name'.

then the hyperlink will refer only to the variable documentation of `buffer-file-name`, and not to its function documentation.

If a symbol has a function definition and/or a variable definition, but those are irrelevant to the use of the symbol that you are documenting, you can write the words ‘symbol’ or ‘program’ before the symbol name to prevent making any hyperlink. For example,

If the argument KIND-OF-RESULT is the symbol `list',  
this function returns a list of all the objects  
that satisfy the criterion.

does not make a hyperlink to the documentation, irrelevant here, of the function `list`. Normally, no hyperlink is made for a variable without variable documentation. You can force a hyperlink for such variables by preceding them with one of the words ‘variable’ or ‘option’.

Hyperlinks for faces are only made if the face name is preceded or followed by the word ‘face’. In that case, only the face documentation will be shown, even if the symbol is also defined as a variable or as a function.

To make a hyperlink to Info documentation, write the single-quoted name of the Info node (or anchor), preceded by ‘info node’, ‘Info node’, ‘info anchor’ or ‘Info anchor’. The Info file name defaults to ‘emacs’. For example,

See Info node ‘Font Lock’ and Info node `(elisp)Font Lock Basics’.

To make a hyperlink to a man page, write the single-quoted name of the man page, preceded by ‘Man page’, ‘man page’, or ‘man page for’. For example,

See the man page ‘chmod(1)’ for details.

The Info documentation is always preferable to man pages, so be sure to link to an Info manual where available. For example, `chmod` is documented in the GNU Coreutils manual, so it is better to link to that instead of the man page.

To link to a customization group, write the single-quoted name of the group, preceded by ‘customization group’ (the first character in each word is case-insensitive). For example,

See the customization group ‘whitespace’ for details.

Finally, to create a hyperlink to URLs, write the single-quoted URL, preceded by ‘URL’. For example,

The GNU project website has more information (see URL  
‘<https://www.gnu.org/>’).

- Don’t write key sequences directly in documentation strings. Instead, use the ‘\\[...]’ construct to stand for them. For example, instead of writing ‘C-f’, write the construct ‘\\[forward-char]’. When Emacs displays the documentation string, it substitutes whatever key is currently bound to `forward-char`. (This is normally ‘C-f’, but it may be some other character if the user has moved key bindings.) See Section 25.3 [Keys in Documentation], page 598.
- In documentation strings for a major mode, you will want to refer to the key bindings of that mode’s local map, rather than global ones. Therefore, use the construct ‘\\<...>’ once in the documentation string to specify which key map to use. Do this before the first use of ‘\\[...]’, and not in the middle of a sentence (since if the map is not loaded, the reference to the map will be replaced with a sentence saying the map is not currently defined). The text inside the ‘\\<...>’ should be the name of the variable containing the local keymap for the major mode.

Each use of ‘\\[...]’ slows the display of the documentation string by a tiny amount. If you use a lot of them, these tiny slowdowns will add up, and might become tangible, especially on slow systems. So our recommendation is not to over-use them; e.g., try to avoid using more than one reference to the same command in the same doc string.

- For consistency, phrase the verb in the first sentence of a function’s documentation string as an imperative—for instance, use “Return the cons of A and B.” in preference to “Returns the cons of A and B.” Usually it looks good to do likewise for the rest of the first paragraph. Subsequent paragraphs usually look better if each sentence is indicative and has a proper subject.
- The documentation string for a function that is a yes-or-no predicate should start with words such as “Return t if”, to indicate explicitly what constitutes truth. The word “return” avoids starting the sentence with lower-case “t”, which could be somewhat distracting.

- Write documentation strings in the active voice, not the passive, and in the present tense, not the future. For instance, use “Return a list containing A and B.” instead of “A list containing A and B will be returned.”
- Avoid using the word “cause” (or its equivalents) unnecessarily. Instead of, “Cause Emacs to display text in boldface”, write just “Display text in boldface”.
- Avoid using “iff” (a mathematics term meaning “if and only if”), since many people are unfamiliar with it and mistake it for a typo. In most cases, the meaning is clear with just “if”. Otherwise, try to find an alternate phrasing that conveys the meaning.
- Try to avoid using abbreviations such as “e.g.” (for “for example”), “i.e.” (for “that is”), “no.” (for “number”), “cf.” (for “compare”/“see also”) and “w.r.t.” (for “with respect to”) as much as possible. It is almost always clearer and easier to read the expanded version.<sup>2</sup>
- When a command is meaningful only in a certain mode or situation, do mention that in the documentation string. For example, the documentation of `dired-find-file` is:

In `Dired`, visit the file or directory named on this line.

- When you define a variable that represents an option users might want to set, use `defcustom`. See Section 12.5 [Defining Variables], page 194.
- The documentation string for a variable that is a yes-or-no flag should start with words such as “Non-nil means”, to make it clear that all non-`nil` values are equivalent and indicate explicitly what `nil` and non-`nil` mean.
- If a line in a documentation string begins with an open-parenthesis, consider writing a backslash before the open-parenthesis, like this:

The argument `FOO` can be either a number  
`\(a buffer position)` or a string (a file name).

This avoids a bug in Emacs versions older than 27.1, where the ‘(’ was treated as the start of a defun (see Section “Defuns” in *The GNU Emacs Manual*). If you do not anticipate anyone editing your code with older Emacs versions, there is no need for this work-around.

## D.7 Tips on Writing Comments

We recommend these conventions for comments:

- ‘;’       Comments that start with a single semicolon, ‘;’, should all be aligned to the same column on the right of the source code. Such comments usually explain how the code on that line does its job. For example:

```
(setq base-version-list ; There was a base
 (assoc (substring fn 0 start-vn) ; version to which
 file-version-assoc-list)) ; this looks like
 ; a subversion.
```

- ‘;;’       Comments that start with two semicolons, ‘;;’, should be aligned to the same level of indentation as the code. Such comments usually describe the purpose of the following lines or the state of the program at that point. For example:

---

<sup>2</sup> We do use these occasionally, but try not to overdo it.

```
(prog1 (setq auto-fill-function
 ...
 ...
 ;; Update mode line.
 (force-mode-line-update)))
```

We also normally use two semicolons for comments outside functions.

```
;; This Lisp code is run in Emacs when it is to operate as
;; a server for other processes.
```

If a function has no documentation string, it should instead have a two-semicolon comment right before the function, explaining what the function does and how to call it properly. Explain precisely what each argument means and how the function interprets its possible values. It is much better to convert such comments to documentation strings, though.

';;;

Comments that start with three (or more) semicolons, ';;;', should start at the left margin. We use them for comments that should be considered a heading by Outline minor mode. By default, comments starting with at least three semicolons (followed by a single space and a non-whitespace character) are considered section headings, comments starting with two or fewer are not.

(Historically, triple-semicolon comments have also been used for commenting out lines within a function, but this use is discouraged in favor of using just two semicolons. This also applies when commenting out entire functions; when doing that use two semicolons as well.)

Three semicolons are used for top-level sections, four for sub-sections, five for sub-sub-sections and so on.

Typically libraries have at least four top-level sections. For example when the bodies of all of these sections are hidden:

```
;;; backquote.el --- implement the `Lisp construct...
;;; Commentary:...
;;; Code:...
;;; backquote.el ends here
```

(In a sense the last line is not a section heading as it must never be followed by any text; after all it marks the end of the file.)

For longer libraries it is advisable to split the code into multiple sections. This can be done by splitting the 'Code:' section into multiple sub-sections. Even though that was the only recommended approach for a long time, many people have chosen to use multiple top-level code sections instead. You may choose either style.

Using multiple top-level code sections has the advantage that it avoids introducing an additional nesting level but it also means that the section named 'Code' does not contain all the code, which is awkward. To avoid that, you should put no code at all inside that section; that way it can be considered a separator instead of a section heading.

Finally, we recommend that you don't end headings with a colon or any other punctuation for that matter. For historic reasons the 'Code:' and 'Commentary:'

headings end with a colon, but we recommend that you don't do the same for other headings anyway.

Generally speaking, the *M-;* (`(comment-dwim)`) command automatically starts a comment of the appropriate type; or indents an existing comment to the right place, depending on the number of semicolons. See Section “Manipulating Comments” in *The GNU Emacs Manual*.

## D.8 Conventional Headers for Emacs Libraries

Emacs has conventions for using special comments in Lisp libraries to divide them into sections and give information such as who wrote them. Using a standard format for these items makes it easier for tools (and people) to extract the relevant information. This section explains these conventions, starting with an example:

```
;;; foo.el --- Support for the Foo programming language -*- lexical-binding: t; -*-

;; Copyright (C) 2010-2021 Your Name

;; Author: Your Name <yourname@example.com>
;; Maintainer: Someone Else <someone@example.com>
;; Created: 14 Jul 2010
;; Keywords: languages
;; URL: https://example.com/foo

;; This file is not part of GNU Emacs.

;; This file is free software...
...
;; along with this file. If not, see <https://www.gnu.org/licenses/>.
```

The very first line should have this format:

```
;;; filename --- description -*- lexical-binding: t; -*-
```

The description should be contained in one line. If the file needs to set more variables in the ‘*-\*-*’ specification, add it after `lexical-binding`. If this would make the first line too long, use a Local Variables section at the end of the file.

The copyright notice usually lists your name (if you wrote the file). If you have an employer who claims copyright on your work, you might need to list them instead. Do not say that the copyright holder is the Free Software Foundation (or that the file is part of GNU Emacs) unless your file has been accepted into the Emacs distribution. For more information on the form of copyright and license notices, see the guide on the GNU website (<https://www.gnu.org/licenses/gpl-howto.html>).

After the copyright notice come several *header comment* lines, each beginning with ‘*;; header-name:*’. Here is a table of the conventional possibilities for *header-name*:

‘Author’ This header states the name and email address of at least the principal author of the library. If there are multiple authors, list them on continuation lines led by `;;` and a tab or at least two spaces. We recommend including a contact email address, of the form ‘`<...>`’. For example:

```
;; Author: Your Name <yourname@example.com>
;; Someone Else <someone@example.com>
;; Another Person <another@example.com>
```

**'Maintainer'**

This header has the same format as the Author header. It lists the person(s) who currently maintain(s) the file (respond to bug reports, etc.).

If there is no Maintainer header, the person(s) in the Author header is/are presumed to be the maintainer(s). Some files in Emacs use ‘`emacs-devel@gnu.org`’ for the maintainer, which means the author is no longer responsible for the file, and that it is maintained as part of Emacs.

**'Created'** This optional line gives the original creation date of the file, and is for historical interest only.

**'Version'** If you wish to record version numbers for the individual Lisp program, put them in this line. Lisp files distributed with Emacs generally do not have a ‘Version’ header, since the version number of Emacs itself serves the same purpose. If you are distributing a collection of multiple files, we recommend not writing the version in every file, but only the main one.

**'Keywords'**

This line lists keywords for the `finder-by-keyword` help command. Please use that command to see a list of the meaningful keywords. The command `M-x checkdoc-package-keywords RET` will find and display any keywords that are not in `finder-known-keywords`. If you set the variable `checkdoc-package-keywords-flag` non-`nil`, checkdoc commands will include the keyword verification in its checks.

This field is how people will find your package when they’re looking for things by topic. To separate the keywords, you can use spaces, commas, or both.

The name of this field is unfortunate, since people often assume it is the place to write arbitrary keywords that describe their package, rather than just the relevant Finder keywords.

**'URL'****'Homepage'**

These lines state the website of the library.

**'Package-Version'**

If ‘Version’ is not suitable for use by the package manager, then a package can define ‘Package-Version’; it will be used instead. This is handy if ‘Version’ is an RCS id or something else that cannot be parsed by `version-to-list`. See Section 43.1 [Packaging Basics], page 1303.

**'Package-Requires'**

If this exists, it names packages on which the current package depends for proper operation. See Section 43.1 [Packaging Basics], page 1303. This is used by the package manager both at download time (to ensure that a complete set of packages is downloaded) and at activation time (to ensure that a package is only activated if all its dependencies have been).

Its format is a list of lists on a single line. The `car` of each sub-list is the name of a package, as a symbol. The `cadr` of each sub-list is the minimum acceptable version number, as a string that can be parsed by `version-to-list`. An entry

that lacks a version (i.e., an entry which is just a symbol, or a sub-list of one element) is equivalent to entry with version "0". For instance:

```
;; Package-Requires: ((gnus "1.0") (bubbles "2.7.2") cl-lib (seq))
```

Packages that don't need to support Emacs versions older than Emacs 27 can have the ‘Package-Requires’ header split across multiple lines, like this:

```
;; Package-Requires: ((emacs "27.1")
;; (compat "29.1.4.1"))
```

Note that with this format, you still need to start the list on the same line as ‘Package-Requires’.

The package code automatically defines a package named ‘`emacs`’ with the version number of the currently running Emacs. This can be used to require a minimal version of Emacs for a package.

Just about every Lisp library ought to have the ‘Author’ and ‘Keywords’ header comment lines. Use the others if they are appropriate. You can also put in header lines with other header names—they have no standard meanings, so they can't do any harm.

We use additional stylized comments to subdivide the contents of the library file. These should be separated from anything else by blank lines. Here is a table of them:

‘;;; Commentary:’

This begins introductory comments that explain how the library works. It should come right after the copying permissions, terminated by a ‘Change Log’, ‘History’ or ‘Code’ comment line. This text is used by the Finder package, so it should make sense in that context.

‘;;; Change Log:’

This begins an optional log of changes to the file over time. Don't put too much information in this section—it is better to keep the detailed logs in a version control system (as Emacs does) or in a separate `ChangeLog` file. ‘History’ is an alternative to ‘Change Log’.

‘;;; Code:’

This begins the actual code of the program.

‘;;; *filename* ends here’

This is the *footer line*; it appears at the very end of the file. Its purpose is to enable people to detect truncated versions of the file from the lack of a footer line.

## Appendix E GNU Emacs Internals

This chapter describes how the runnable Emacs executable is dumped with the preloaded Lisp libraries in it, how storage is allocated, and some internal aspects of GNU Emacs that may be of interest to C programmers.

### E.1 Building Emacs

This section explains the steps involved in building the Emacs executable. You don't have to know this material to build and install Emacs, since the makefiles do all these things automatically. This information is pertinent to Emacs developers.

Building Emacs requires GNU Make version 3.81 or later.

Compilation of the C source files in the `src` directory produces an executable file called `temacs`, also called a *bare impure Emacs*. It contains the Emacs Lisp interpreter and I/O routines, but not the editing commands.

The command `temacs -l loadup` would run `temacs` and direct it to load `loadup.el`. The `loadup` library loads additional Lisp libraries, which set up the normal Emacs editing environment. After this step, the Emacs executable is no longer *bare*.

Because it takes some time to load the standard Lisp files, the `temacs` executable usually isn't run directly by users. Instead, one of the last steps of building Emacs runs the command '`temacs -batch -l loadup --temacs=dump-method`'. The special option `--temacs` tells `temacs` how to record all the standard preloaded Lisp functions and variables, so that when you subsequently run Emacs, it will start much faster. The `--temacs` option requires an argument `dump-method`, which can be one of the following:

**'pdump'** Record the preloaded Lisp data in a *dump file*. This method produces an additional data file which Emacs will load at startup. The produced dump file is usually called `emacs.pdmp`, and is installed in the Emacs `exec-directory` (see Section 25.6 [Help Functions], page 602). This method is the most preferred one, as it does not require Emacs to employ any special techniques of memory allocation, which might get in the way of various memory-layout techniques used by modern systems to enhance security and privacy.

**'pbootstrap'** Like '`pdump`', but used while *bootstrapping* Emacs, when no previous Emacs binary and no `*.elc` byte-compiled Lisp files are available. The produced dump file is usually named `bootstrap-emacs.pdmp` in this case.

**'dump'** This method causes `temacs` to dump out an executable program, called `emacs`, which has all the standard Lisp files already preloaded into it. (The '`-batch`' argument prevents `temacs` from trying to initialize any of its data on the terminal, so that the tables of terminal information are empty in the dumped Emacs.) This method is also known as *unexec*, because it produces a program file from a running process, and thus is in some sense the opposite of executing a program to start a process. Although this method was the way that Emacs traditionally saved its state, it is now deprecated.

**'bootstrap'** Like '`dump`', but used when bootstrapping Emacs with the `unexec` method.

The dumped `emacs` executable (also called a *pure* Emacs) is the one which is installed. If the portable dumper was used to build Emacs, the `emacs` executable is actually an exact copy of `temacs`, and the corresponding `emacs.pdmp` file is installed as well. The variable `preloaded-file-list` stores a list of the preloaded Lisp files recorded in the dump file or in the dumped Emacs executable. If you port Emacs to a new operating system, and are not able to implement dumping of any kind, then Emacs must load `loadup.el` each time it starts.

By default the dumped `emacs` executable records details such as the build time and host name. Use the `--disable-build-details` option of `configure` to suppress these details, so that building and installing Emacs twice from the same sources is more likely to result in identical copies of Emacs.

You can specify additional files to preload by writing a library named `site-load.el` that loads them. You may need to rebuild Emacs with an added definition

```
#define SITELOAD_PURESIZE_EXTRA n
```

to make `n` added bytes of pure space to hold the additional files; see `src/puresize.h`. (Try adding increments of 20000 until it is big enough.) However, the advantage of preloading additional files decreases as machines get faster. On modern machines, it is usually not advisable.

After `loadup.el` reads `site-load.el`, it finds the documentation strings for primitive and preloaded functions (and variables) in the file `etc/DOC` where they are stored, by calling `Snarf-documentation` (see [Accessing Documentation], page 598).

You can specify other Lisp expressions to execute just before dumping by putting them in a library named `site-init.el`. This file is executed after the documentation strings are found.

If you want to preload function or variable definitions, there are three ways you can do this and make their documentation strings accessible when you subsequently run Emacs:

- Arrange to scan these files when producing the `etc/DOC` file, and load them with `site-load.el`.
- Load the files with `site-init.el`, then copy the files into the installation directory for Lisp files when you install Emacs.
- Specify a `nil` value for `byte-compile-dynamic-docstrings` as a local variable in each of these files, and load them with either `site-load.el` or `site-init.el`. (This method has the drawback that the documentation strings take up space in Emacs all the time.)

It is not advisable to put anything in `site-load.el` or `site-init.el` that would alter any of the features that users expect in an ordinary unmodified Emacs. If you feel you must override normal features for your site, do it with `default.el`, so that users can override your changes if they wish. See Section 42.1.1 [Startup Summary], page 1255. Note that if either `site-load.el` or `site-init.el` changes `load-path`, the changes will be lost after dumping. See Section 16.3 [Library Search], page 301. To make a permanent change to `load-path`, use the `--enable-local-lisp-path` option of `configure`.

In a package that can be preloaded, it is sometimes necessary (or useful) to delay certain evaluations until Emacs subsequently starts up. The vast majority of such cases relate to the values of customizable variables. For example, `tutorial-directory` is a variable defined in `startup.el`, which is preloaded. The default value is set based on `data-directory`. The

variable needs to access the value of `data-directory` when Emacs starts, not when it is dumped, because the Emacs executable has probably been installed in a different location since it was dumped.

**custom-initialize-delay symbol value** [Function]

This function delays the initialization of `symbol` to the next Emacs start. You normally use this function by specifying it as the `:initialize` property of a customizable variable. (The argument `value` is unused, and is provided only for compatibility with the form `Custom` expects.)

In the unlikely event that you need a more general functionality than `custom-initialize-delay` provides, you can use `before-init-hook` (see Section 42.1.1 [Startup Summary], page 1255).

**dump-emacs-portable to-file &optional track-referrers** [Function]

This function dumps the current state of Emacs into a dump file `to-file`, using the `pdump` method. Normally, the dump file is called `emacs-name.dmp`, where `emacs-name` is the name of the Emacs executable file. The optional argument `track-referrers`, if non-`nil`, causes the portable dumper to keep additional information to help track down the provenance of object types that are not yet supported by the `pdump` method.

Although the portable dumper code can run on many platforms, the dump files that it produces are not portable—they can be loaded only by the Emacs executable that dumped them.

If you want to use this function in an Emacs that was already dumped, you must run Emacs with the ‘`-batch`’ option.

If you’re including ‘`.el`’ files in the dumped Emacs and that ‘`.el`’ file has code that is normally run at load time, that code won’t be run when Emacs starts after dumping. To help work around that problem, you can put functions on the `after-pdump-load-hook` hook. This hook is run when starting Emacs.

**dump-emacs to-file from-file** [Function]

This function dumps the current state of Emacs into an executable file `to-file`, using the `unexec` method. It takes symbols from `from-file` (this is normally the executable file `temacs`).

This function cannot be used in an Emacs that was already dumped. This function is deprecated, and by default Emacs is built without `unexec` support so this function is not available.

**pdumper-stats** [Function]

If the current Emacs session restored its state from a dump file, this function returns information about the dump file and the time it took to restore the Emacs state. The value is an alist `((dumped-with-pdumper . t) (load-time . time) (dump-file-name . file))`, where `file` is the name of the dump file, and `time` is the time in seconds it took to restore the state from the dump file. If the current session was not restored from a dump file, the value is `nil`.

## E.2 Pure Storage

Emacs Lisp uses two kinds of storage for user-created Lisp objects: *normal storage* and *pure storage*. Normal storage is where all the new data created during an Emacs session are kept (see Section E.3 [Garbage Collection], page 1350). Pure storage is used for certain data in the preloaded standard Lisp files—data that should never change during actual use of Emacs.

Pure storage is allocated only while `temacs` is loading the standard preloaded Lisp libraries. In the file `emacs`, it is marked as read-only (on operating systems that permit this), so that the memory space can be shared by all the Emacs jobs running on the machine at once. Pure storage is not expandable; a fixed amount is allocated when Emacs is compiled, and if that is not sufficient for the preloaded libraries, `temacs` allocates dynamic memory for the part that didn't fit. If Emacs will be dumped using the `pdump` method (see Section E.1 [Building Emacs], page 1346), the pure-space overflow is of no special importance (it just means some of the preloaded stuff cannot be shared with other Emacs jobs). However, if Emacs will be dumped using the now obsolete `unexec` method, the resulting image will work, but garbage collection (see Section E.3 [Garbage Collection], page 1350) is disabled in this situation, causing a memory leak. Such an overflow normally won't happen unless you try to preload additional libraries or add features to the standard ones. Emacs will display a warning about the overflow when it starts, if it was dumped using `unexec`. If this happens, you should increase the compilation parameter `SYSTEM_PURESIZE_EXTRA` in the file `src/puresize.h` and rebuild Emacs.

### `purecopy object`

[Function]

This function makes a copy in pure storage of *object*, and returns it. It copies a string by simply making a new string with the same characters, but without text properties, in pure storage. It recursively copies the contents of vectors and cons cells. It does not make copies of other objects such as symbols, but just returns them unchanged. It signals an error if asked to copy markers.

This function is a no-op except while Emacs is being built and dumped; it is usually called only in preloaded Lisp files.

### `pure-bytes-used`

[Variable]

The value of this variable is the number of bytes of pure storage allocated so far. Typically, in a dumped Emacs, this number is very close to the total amount of pure storage available—if it were not, we would preallocate less.

### `purify-flag`

[Variable]

This variable determines whether `defun` should make a copy of the function definition in pure storage. If it is non-`nil`, then the function definition is copied into pure storage.

This flag is `t` while loading all of the basic functions for building Emacs initially (allowing those functions to be shareable and non-collectible). Dumping Emacs as an executable always writes `nil` in this variable, regardless of the value it actually has before and after dumping.

You should not change this flag in a running Emacs.

### E.3 Garbage Collection

When a program creates a list or the user defines a new function (such as by loading a library), that data is placed in normal storage. If normal storage runs low, then Emacs asks the operating system to allocate more memory. Different types of Lisp objects, such as symbols, cons cells, small vectors, markers, etc., are segregated in distinct blocks in memory. (Large vectors, long strings, buffers and certain other editing types, which are fairly large, are allocated in individual blocks, one per object; small strings are packed into blocks of 8k bytes, and small vectors are packed into blocks of 4k bytes).

Beyond the basic vector, a lot of objects like markers, overlays and buffers are managed as if they were vectors. The corresponding C data structures include the `union vectorlike_header` field whose `size` member contains the subtype enumerated by `enum pvec_type` and an information about how many `Lisp_Object` fields this structure contains and what the size of the rest data is. This information is needed to calculate the memory footprint of an object, and used by the vector allocation code while iterating over the vector blocks.

It is quite common to use some storage for a while, then release it by (for example) killing a buffer or deleting the last pointer to an object. Emacs provides a *garbage collector* to reclaim this abandoned storage. The garbage collector operates, in essence, by finding and marking all Lisp objects that are still accessible to Lisp programs. To begin with, it assumes all the symbols, their values and associated function definitions, and any data presently on the stack, are accessible. Any objects that can be reached indirectly through other accessible objects are also accessible, but this calculation is done “conservatively”, so it may slightly overestimate how many objects that are accessible.

When marking is finished, all objects still unmarked are garbage. No matter what the Lisp program or the user does, it is impossible to refer to them, since there is no longer a way to reach them. Their space might as well be reused, since no one will miss them. The second (sweep) phase of the garbage collector arranges to reuse them. (But since the marking was done “conservatively”, not all unused objects are guaranteed to be garbage-collected by any one sweep.)

The sweep phase puts unused cons cells onto a *free list* for future allocation; likewise for symbols and markers. It compacts the accessible strings so they occupy fewer 8k blocks; then it frees the other 8k blocks. Unreachable vectors from vector blocks are coalesced to create largest possible free areas; if a free area spans a complete 4k block, that block is freed. Otherwise, the free area is recorded in a free list array, where each entry corresponds to a free list of areas of the same size. Large vectors, buffers, and other large objects are allocated and freed individually.

**Common Lisp note:** Unlike other Lisps, GNU Emacs Lisp does not call the garbage collector when the free list is empty. Instead, it simply requests the operating system to allocate more storage, and processing continues until `gc-cons-threshold` bytes have been used.

This means that you can make sure that the garbage collector will not run during a certain portion of a Lisp program by calling the garbage collector explicitly just before it (provided that portion of the program does not use so much space as to force a second garbage collection).

**garbage-collect**

[Command]

This command runs a garbage collection, and returns information on the amount of space in use. (Garbage collection can also occur spontaneously if you use more than `gc-cons-threshold` bytes of Lisp data since the previous garbage collection.)

`garbage-collect` returns a list with information on amount of space in use, where each entry has the form ‘`(name size used)`’ or ‘`(name size used free)`’. In the entry, `name` is a symbol describing the kind of objects this entry represents, `size` is the number of bytes used by each one, `used` is the number of those objects that were found live in the heap, and optional `free` is the number of those objects that are not live but that Emacs keeps around for future allocations. So an overall result is:

```
((conses cons-size used-conses free-conses)
 (symbols symbol-size used-symbols free-symbols)
 (strings string-size used-strings free-strings)
 (string-bytes byte-size used-bytes)
 (vectors vector-size used-vectors)
 (vector-slots slot-size used-slots free-slots)
 (floats float-size used-floats free-floats)
 (intervals interval-size used-intervals free-intervals)
 (buffers buffer-size used-buffers)
 (heap unit-size total-size free-size))
```

Here is an example:

```
(garbage-collect)
 ⇒ ((conses 16 49126 8058) (symbols 48 14607 0)
 (strings 32 2942 2607)
 (string-bytes 1 78607) (vectors 16 7247)
 (vector-slots 8 341609 29474) (floats 8 71 102)
 (intervals 56 27 26) (buffers 944 8)
 (heap 1024 11715 2678))
```

Below is a table explaining each element. Note that last `heap` entry is optional and present only if an underlying `malloc` implementation provides `mallinfo` function.

`cons-size` Internal size of a cons cell, i.e., `sizeof (struct Lisp_Cons)`.

`used-conses`

The number of cons cells in use.

`free-conses`

The number of cons cells for which space has been obtained from the operating system, but that are not currently being used.

`symbol-size`

Internal size of a symbol, i.e., `sizeof (struct Lisp_Symbol)`.

`used-symbols`

The number of symbols in use.

`free-symbols`

The number of symbols for which space has been obtained from the operating system, but that are not currently being used.

|                       |                                                                                                                                                                           |
|-----------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <i>string-size</i>    | Internal size of a string header, i.e., <code>sizeof (struct Lisp_String)</code> .                                                                                        |
| <i>used-strings</i>   | The number of string headers in use.                                                                                                                                      |
| <i>free-strings</i>   | The number of string headers for which space has been obtained from the operating system, but that are not currently being used.                                          |
| <i>byte-size</i>      | This is used for convenience and equals to <code>sizeof (char)</code> .                                                                                                   |
| <i>used-bytes</i>     | The total size of all string data in bytes.                                                                                                                               |
| <i>vector-size</i>    | Size in bytes of a vector of length 1, including its header.                                                                                                              |
| <i>used-vectors</i>   | The number of vector headers allocated from the vector blocks.                                                                                                            |
| <i>slot-size</i>      | Internal size of a vector slot, always equal to <code>sizeof (Lisp_Object)</code> .                                                                                       |
| <i>used-slots</i>     | The number of slots in all used vectors. Slot counts might include some or all overhead from vector headers, depending on the platform.                                   |
| <i>free-slots</i>     | The number of free slots in all vector blocks.                                                                                                                            |
| <i>float-size</i>     | Internal size of a float object, i.e., <code>sizeof (struct Lisp_Float)</code> . (Do not confuse it with the native platform <code>float</code> or <code>double</code> .) |
| <i>used-floats</i>    | The number of floats in use.                                                                                                                                              |
| <i>free-floats</i>    | The number of floats for which space has been obtained from the operating system, but that are not currently being used.                                                  |
| <i>interval-size</i>  | Internal size of an interval object, i.e., <code>sizeof (struct interval)</code> .                                                                                        |
| <i>used-intervals</i> | The number of intervals in use.                                                                                                                                           |
| <i>free-intervals</i> | The number of intervals for which space has been obtained from the operating system, but that are not currently being used.                                               |
| <i>buffer-size</i>    | Internal size of a buffer, i.e., <code>sizeof (struct buffer)</code> . (Do not confuse with the value returned by <code>buffer-size</code> function.)                     |
| <i>used-buffers</i>   | The number of buffer objects in use. This includes killed buffers invisible to users, i.e., all buffers in <code>all_buffers</code> list.                                 |
| <i>unit-size</i>      | The unit of heap space measurement, always equal to 1024 bytes.                                                                                                           |
| <i>total-size</i>     | Total heap size, in <i>unit-size</i> units.                                                                                                                               |
| <i>free-size</i>      | Heap space which is not currently used, in <i>unit-size</i> units.                                                                                                        |

If there was overflow in pure space (see Section E.2 [Pure Storage], page 1349), and Emacs was dumped using the (now obsolete) `unexec` method (see Section E.1 [Building Emacs], page 1346), then `garbage-collect` returns `nil`, because a real garbage collection cannot be done in that case.

**garbage-collection-messages**

[User Option]

If this variable is non-`nil`, Emacs displays a message at the beginning and end of garbage collection. The default value is `nil`.

**post-gc-hook**

[Variable]

This is a normal hook that is run at the end of garbage collection. Garbage collection is inhibited while the hook functions run, so be careful writing them.

**gc-cons-threshold**

[User Option]

The value of this variable is the number of bytes of storage that must be allocated for Lisp objects after one garbage collection in order to trigger another garbage collection. You can use the result returned by `garbage-collect` to get an information about size of the particular object type; space allocated to the contents of buffers does not count.

The initial threshold value is `GC_DEFAULT_THRESHOLD`, defined in `alloc.c`. Since it's defined in `word_size` units, the value is 400,000 for the default 32-bit configuration and 800,000 for the 64-bit one. If you specify a larger value, garbage collection will happen less often. This reduces the amount of time spent garbage collecting (so Lisp programs will run faster between cycles of garbage collection that happen more rarely), but increases total memory use. You may want to do this when running a program that creates lots of Lisp data, especially if you need it to run faster. However, we recommend against increasing the threshold for prolonged periods of time, and advise that you never set it higher than needed for the program to run in reasonable time. Using thresholds higher than necessary could potentially cause higher system-wide memory pressure, and also make each garbage-collection cycle take much more time, and should therefore be avoided.

You can make collections more frequent by specifying a smaller value, down to 1/10th of `GC_DEFAULT_THRESHOLD`. A value less than this minimum will remain in effect only until the subsequent garbage collection, at which time `garbage-collect` will set the threshold back to the minimum.

**gc-cons-percentage**

[User Option]

The value of this variable specifies the amount of consing before a garbage collection occurs, as a fraction of the current heap size. This criterion and `gc-cons-threshold` apply in parallel, and garbage collection occurs only when both criteria are satisfied. As the heap size increases, the time to perform a garbage collection increases. Thus, it can be desirable to do them less frequently in proportion.

As with `gc-cons-threshold`, do not enlarge this more than necessary, and never for prolonged periods of time.

Control over the garbage collector via `gc-cons-threshold` and `gc-cons-percentage` is only approximate. Although Emacs checks for threshold exhaustion regularly, for efficiency reasons it does not do so immediately after every change to the heap or to `gc-cons-threshold` or `gc-cons-percentage`, so exhausting the threshold does not immediately trigger garbage collection. Also, for efficiency in threshold calculations Emacs approximates the heap size, which counts the bytes used by currently-accessible objects in the heap.

The value returned by `garbage-collect` describes the amount of memory used by Lisp data, broken down by data type. By contrast, the function `memory-limit` provides information on the total amount of memory Emacs is currently using.

**memory-limit**

[Function]

This function returns an estimate of the total amount of bytes of virtual memory that Emacs is currently using, divided by 1024. You can use this to get a general idea of how your actions affect the memory usage.

**memory-full**

[Variable]

This variable is `t` if Emacs is nearly out of memory for Lisp objects, and `nil` otherwise.

**memory-use-counts**

[Function]

This returns a list of numbers that count the number of objects created in this Emacs session. Each of these counters increments for a certain kind of object. See the documentation string for details.

**memory-info**

[Function]

This function returns an amount of total system memory and how much of it is free. On an unsupported system, the value may be `nil`.

If `default-directory` points to a remote host, memory information of that host is returned.

**gcs-done**

[Variable]

This variable contains the total number of garbage collections done so far in this Emacs session.

**gc-elapsed**

[Variable]

This variable contains the total number of seconds of elapsed time during garbage collection so far in this Emacs session, as a floating-point number.

**memory-report**

[Function]

It can sometimes be useful to see where Emacs is using memory (in various variables, buffers, and caches). This command will open a new buffer (called “`*Memory Report*`”) that will give an overview, in addition to listing the “largest” buffers and variables.

All the data here is approximate, because there’s really no consistent way to compute the size of a variable. For instance, two variables may share parts of a data structure, and this will be counted twice, but this command may still give a useful high-level overview of which parts of Emacs are using memory.

## E.4 Stack-allocated Objects

The garbage collector described above is used to manage data visible from Lisp programs, as well as most of the data internally used by the Lisp interpreter. Sometimes it may be useful to allocate temporary internal objects using the C stack of the interpreter. This can help performance, as stack allocation is typically faster than using heap memory to allocate and the garbage collector to free. The downside is that using such objects after they are freed results in undefined behavior, so uses should be well thought out and carefully debugged by using the `GC_CHECK_MARKED_OBJECTS` feature (see `src/alloc.c`). In particular, stack-allocated objects should never be made visible to user Lisp code.

Currently, cons cells and strings can be allocated this way. This is implemented by C macros like `AUTO_CONS` and `AUTO_STRING` that define a named `Lisp_Object` with block

lifetime. These objects are not freed by the garbage collector; instead, they have automatic storage duration, i.e., they are allocated like local variables and are automatically freed at the end of execution of the C block that defined the object.

For performance reasons, stack-allocated strings are limited to ASCII characters, and many of these strings are immutable, i.e., calling `ASET` on them produces undefined behavior.

## E.5 Memory Usage

These functions and variables give information about the total amount of memory allocation that Emacs has done, broken down by data type. Note the difference between these and the values returned by `garbage-collect`; those count objects that currently exist, but these count the number or size of all allocations, including those for objects that have since been freed.

### `cons-cells-consed`

[Variable]

The total number of cons cells that have been allocated so far in this Emacs session.

### `floats-consed`

[Variable]

The total number of floats that have been allocated so far in this Emacs session.

### `vector-cells-consed`

[Variable]

The total number of vector cells that have been allocated so far in this Emacs session. This includes vector-like objects such as markers and overlays, plus certain objects not visible to users.

### `symbols-consed`

[Variable]

The total number of symbols that have been allocated so far in this Emacs session.

### `string-chars-consed`

[Variable]

The total number of string characters that have been allocated so far in this session.

### `intervals-consed`

[Variable]

The total number of intervals that have been allocated so far in this Emacs session.

### `strings-consed`

[Variable]

The total number of strings that have been allocated so far in this Emacs session.

## E.6 C Dialect

The C part of Emacs is portable to C99 or later: C11-specific features such as ‘`<stdalign.h>`’ and ‘`_Noreturn`’ are not used without a check, typically at configuration time, and the Emacs build procedure provides a substitute implementation if necessary. Some C11 features, such as anonymous structures and unions, are too difficult to emulate, so they are avoided entirely.

At some point in the future the base C dialect will no doubt change to C11.

## E.7 Writing Emacs Primitives

Lisp primitives are Lisp functions implemented in C. The details of interfacing the C function so that Lisp can call it are handled by a few C macros. The only way to really understand how to write new C code is to read the source, but we can explain some things here.

An example of a special form is the definition of `or`, from `eval.c`. (An ordinary function would have the same general appearance.)

```
DEFUN ("or", For, Sor, 0, UNEVALLED, 0,
 doc: /* Eval args until one of them yields non-nil,
then return that value.
The remaining args are not evalled at all.
If all args return nil, return nil.
usage: (or CONDITIONS...) */
(Lisp_Object args)
{
 Lisp_Object val = Qnil;

 while (CONSP (args))
 {
 val = eval_sub (XCAR (args));
 if (!NILP (val))
 break;
 args = XCDR (args);
 maybe_quit ();
 }

 return val;
}
```

Let's start with a precise explanation of the arguments to the `DEFUN` macro. Here is a template for them:

|                    |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
|--------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                    | <code>DEFUN (lname, fname, sname, min, max, interactive, doc)</code>                                                                                                                                                                                                                                                                                                                                                                                                                             |
| <code>lname</code> | This is the name of the Lisp symbol to define as the function name; in the example above, it is <code>or</code> .                                                                                                                                                                                                                                                                                                                                                                                |
| <code>fname</code> | This is the C function name for this function. This is the name that is used in C code for calling the function. The name is, by convention, 'F' prepended to the Lisp name, with all dashes ('-') in the Lisp name changed to underscores. Thus, to call this function from C code, call <code>For</code> .                                                                                                                                                                                     |
| <code>sname</code> | This is a C variable name to use for a structure that holds the data for the subr object that represents the function in Lisp. This structure conveys the Lisp symbol name to the initialization routine that will create the symbol and store the subr object as its definition. By convention, this name is always <code>fname</code> with 'F' replaced with 'S'.                                                                                                                              |
| <code>min</code>   | This is the minimum number of arguments that the function requires. The function <code>or</code> allows a minimum of zero arguments.                                                                                                                                                                                                                                                                                                                                                             |
| <code>max</code>   | This is the maximum number of arguments that the function accepts, if there is a fixed maximum. Alternatively, it can be <code>UNEVALLED</code> , indicating a special form that receives unevaluated arguments, or <code>MANY</code> , indicating an unlimited number of evaluated arguments (the equivalent of <code>&amp;rest</code> ). Both <code>UNEVALLED</code> and <code>MANY</code> are macros. If <code>max</code> is a number, it must be more than <code>min</code> but less than 8. |

**interactive**

This is an interactive specification, a string such as might be used as the argument of `interactive` in a Lisp function (see Section 22.2.1 [Using Interactive], page 424). In the case of `or`, it is 0 (a null pointer), indicating that `or` cannot be called interactively. A value of "" indicates a function that should receive no arguments when called interactively. If the value begins with a "(", the string is evaluated as a Lisp form. For example:

```
DEFUN ("foo", Ffoo, Sfoo, 0, 3,
 "(list (read-char-by-name \"Insert character: \")\
 (prefix-numeric-value current-prefix-arg) \
 t)",
 doc: /* ... */)
```

**doc**

This is the documentation string. It uses C comment syntax rather than C string syntax because comment syntax requires nothing special to include multiple lines. The ‘`doc:`’ identifies the comment that follows as the documentation string. The ‘`/*`’ and ‘`*/`’ delimiters that begin and end the comment are not part of the documentation string.

If the last line of the documentation string begins with the keyword ‘`usage:`’, the rest of the line is treated as the argument list for documentation purposes. This way, you can use different argument names in the documentation string from the ones used in the C code. ‘`usage:`’ is required if the function has an unlimited number of arguments.

Some primitives have multiple definitions, one per platform (e.g., `x-create-frame`). In such cases, rather than writing the same documentation string in each definition, only one definition has the actual documentation. The others have placeholders beginning with ‘`SKIP`’, which are ignored by the function that parses the `DOC` file.

All the usual rules for documentation strings in Lisp code (see Section D.6 [Documentation Tips], page 1337) apply to C code documentation strings too.

The documentation string can be followed by a list of C function attributes for the C function that implements the primitive, like this:

```
DEFUN ("bar", Fbar, Sbar, 0, UNEVALLED, 0
 doc: /* ... */
 attributes: attr1 attr2 ...)
```

You can specify more than a single attribute, one after the other. Currently, only the following attributes are recognized:

**noreturn** Declares the C function as one that never returns. This corresponds to the C11 keyword `_Noreturn` and to `__attribute__((__noreturn__))` attribute of GCC (see Section “Function Attributes” in *Using the GNU Compiler Collection*).

**const** Declares that the function does not examine any values except its arguments, and has no effects except the return value. This corresponds to `__attribute__((__const__))` attribute of GCC.

**noinline** This corresponds to `__attribute__((__noinline__))` attribute of GCC, which prevents the function from being considered for inlining. This might be needed, e.g., to countermand effects of link-time optimizations on stack-based variables.

After the call to the `DEFUN` macro, you must write the argument list for the C function, including the types for the arguments. If the primitive accepts a fixed maximum number of Lisp arguments, there must be one C argument for each Lisp argument, and each argument must be of type `Lisp_Object`. (Various macros and functions for creating values of type `Lisp_Object` are declared in the file `lisp.h`.) If the primitive is a special form, it must accept a Lisp list containing its unevaluated Lisp arguments as a single argument of type `Lisp_Object`. If the primitive has no upper limit on the number of evaluated Lisp arguments, it must have exactly two C arguments: the first is the number of Lisp arguments, and the second is the address of a block containing their values. These have types `ptrdiff_t` and `Lisp_Object *`, respectively. Since `Lisp_Object` can hold any Lisp object of any data type, you can determine the actual data type only at run time; so if you want a primitive to accept only a certain type of argument, you must check the type explicitly using a suitable predicate (see Section 2.7 [Type Predicates], page 30).

Within the function `For` itself, the local variable `args` refers to objects controlled by Emacs's stack-marking garbage collector. Although the garbage collector does not reclaim objects reachable from C `Lisp_Object` stack variables, it may move some of the components of an object, such as the contents of a string or the text of a buffer. Therefore, functions that access these components must take care to refetch their addresses after performing Lisp evaluation. This means that instead of keeping C pointers to string contents or buffer text, the code should keep the buffer or string position, and recompute the C pointer from the position after performing Lisp evaluation. Lisp evaluation can occur via calls to `eval_sub` or `Feval`, either directly or indirectly.

Note the call to `maybe_quit` inside the loop: this function checks whether the user pressed `C-g`, and if so, aborts the processing. You should do that in any loop that can potentially require a large number of iterations; in this case, the list of arguments could be very long. This increases Emacs responsiveness and improves user experience.

You must not use C initializers for static or global variables unless the variables are never written once Emacs is dumped. These variables with initializers are allocated in an area of memory that becomes read-only (on certain operating systems) as a result of dumping Emacs. See Section E.2 [Pure Storage], page 1349.

Defining the C function is not enough to make a Lisp primitive available; you must also create the Lisp symbol for the primitive and store a suitable subr object in its function cell. The code looks like this:

```
defsubr (&sname);
```

Here `sname` is the name you used as the third argument to `DEFUN`.

If you add a new primitive to a file that already has Lisp primitives defined in it, find the function (near the end of the file) named `syms_of_something`, and add the call to `defsubr` there. If the file doesn't have this function, or if you create a new file, add to it a `syms_of_filename` (e.g., `syms_of_myfile`). Then find the spot in `emacs.c` where all of these functions are called, and add a call to `syms_of_filename` there.

The function `syms_of_filename` is also the place to define any C variables that are to be visible as Lisp variables. `DEFVAR_LISP` makes a C variable of type `Lisp_Object` visible in Lisp. `DEFVAR_INT` makes a C variable of type `int` visible in Lisp with a value that is always an integer. `DEFVAR_BOOL` makes a C variable of type `int` visible in Lisp with a value that is either `t` or `nil`. Note that variables defined with `DEFVAR_BOOL` are automatically added to the list `byte-boolean-vars` used by the byte compiler.

These macros all expect three arguments:

- `lname`      The name of the variable to be used by Lisp programs.
- `vname`      The name of the variable in the C sources.
- `doc`        The documentation for the variable, as a C comment. See Section 25.1 [Documentation Basics], page 595, for more details.

By convention, when defining variables of a “native” type (`int` and `bool`), the name of the C variable is the name of the Lisp variable with `-` replaced by `_`. When the variable has type `Lisp_Object`, the convention is to also prefix the C variable name with `V`. i.e.

```
DEFVAR_INT ("my-int-variable", my_int_variable,
 doc: /* An integer variable. */);

DEFVAR_LISP ("my-lisp-variable", Vmy_lisp_variable,
 doc: /* A Lisp variable. */);
```

There are situations in Lisp where you need to refer to the symbol itself rather than the value of that symbol. One such case is when temporarily overriding the value of a variable, which in Lisp is done with `let`. In C sources, this is done by defining a corresponding, constant symbol, and using `specbind`. By convention, `Qmy_lisp_variable` corresponds to `Vmy_lisp_variable`; to define it, use the `DEFSYM` macro. i.e.

```
DEFSYM (Qmy_lisp_variable, "my-lisp-variable");
```

To perform the actual binding:

```
specbind (Qmy_lisp_variable, Qt);
```

In Lisp symbols sometimes need to be quoted, to achieve the same effect in C you again use the corresponding constant symbol `Qmy_lisp_variable`. For example, when creating a buffer-local variable (see Section 12.11 [Buffer-Local Variables], page 207) in Lisp you would write:

```
(make-variable-buffer-local 'my-lisp-variable)
```

In C the corresponding code uses `Fmake_variable_buffer_local` in combination with `DEFSYM`, i.e.

```
DEFSYM (Qmy_lisp_variable, "my-lisp-variable");
Fmake_variable_buffer_local (Qmy_lisp_variable);
```

If you want to make a Lisp variable that is defined in C behave like one declared with `defcustom`, add an appropriate entry to `cus-start.el`. See Section 15.3 [Variable Definitions], page 280, for a description of the format to use.

If you directly define a file-scope C variable of type `Lisp_Object`, you must protect it from garbage-collection by calling `staticpro` in `syms_of_filename`, like this:

```
staticpro (&variable);
```

Here is another example function, with more complicated arguments. This comes from the code in `window.c`, and it demonstrates the use of macros and functions to manipulate Lisp objects.

```
DEFUN ("coordinates-in-window-p", Fcoordinates_in_window_p,
 Scoordinates_in_window_p, 2, 2, 0,
 doc: /* Return non-nil if COORDINATES are in WINDOW.
...
or `right-margin' is returned. */
(register Lisp_Object coordinates, Lisp_Object window)
{
 struct window *w;
 struct frame *f;
 int x, y;
 Lisp_Object lx, ly;

 w = decode_live_window (window);
 f = XFRAME (w->frame);
 CHECK_CONS (coordinates);
 lx = Fcar (coordinates);
 ly = Fcdr (coordinates);
 CHECK_NUMBER (lx);
 CHECK_NUMBER (ly);
 x = FRAME_PIXEL_X_FROM_CANON_X (f, lx) + FRAME_INTERNAL_BORDER_WIDTH (f);
 y = FRAME_PIXEL_Y_FROM_CANON_Y (f, ly) + FRAME_INTERNAL_BORDER_WIDTH (f);

 switch (coordinates_in_window (w, x, y))
 {
 case ON_NOTHING: /* NOT in window at all. */
 return Qnil;
 ...
 case ON_MODE_LINE: /* In mode line of window. */
 return Qmode_line;
 ...
 case ON_SCROLL_BAR: /* On scroll-bar of window. */
 /* Historically we are supposed to return nil in this case. */
 return Qnil;
 default:
 emacs_abort ();
 }
}
```

Note that C code cannot call functions by name unless they are defined in C. The way to call a function written in Lisp is to use `Ffuncall`, which embodies the Lisp function `funcall`. Since the Lisp function `funcall` accepts an unlimited number of arguments, in C it takes two: the number of Lisp-level arguments, and a one-dimensional array containing their values. The first Lisp-level argument is the Lisp function to call, and the rest are the arguments to pass to it.

The C functions `call0`, `call1`, `call2`, and so on, provide handy ways to call a Lisp function conveniently with a fixed number of arguments. They work by calling `Ffuncall`.

`eval.c` is a very good file to look through for examples; `lisp.h` contains the definitions for some important macros and functions.

If you define a function which is side-effect free or pure, give it a non-nil `side-effect-free` or `pure` property, respectively (see Section 9.4.2 [Standard Properties], page 139).

## E.8 Writing Dynamically-Loaded Modules

This section describes the Emacs module API and how to use it as part of writing extension modules for Emacs. The module API is defined in the C programming language, therefore the description and the examples in this section assume the module is written in C. For other programming languages, you will need to use the appropriate bindings, interfaces and facilities for calling C code. Emacs C code requires a C99 or later compiler (see Section E.6 [C Dialect], page 1355), and so the code examples in this section also follow that standard.

Writing a module and integrating it into Emacs comprises the following tasks:

- Writing initialization code for the module.
- Writing one or more module functions.
- Communicating values and objects between Emacs and your module functions.
- Handling of error conditions and nonlocal exits.

The following subsections describe these tasks and the API itself in more detail.

Once your module is written, compile it to produce a shared library, according to the conventions of the underlying platform. Then place the shared library in a directory mentioned in `load-path` (see Section 16.3 [Library Search], page 301), where Emacs will find it.

If you wish to verify the conformance of a module to the Emacs dynamic module API, invoke Emacs with the `--module-assertions` option. See Section “Initial Options” in *The GNU Emacs Manual*.

### E.8.1 Module Initialization Code

Begin your module by including the header file `emacs-module.h` and defining the GPL compatibility symbol:

```
#include <emacs-module.h>

int plugin_is_GPL_compatible;
```

The `emacs-module.h` file is installed into your system’s include tree as part of the Emacs installation. Alternatively, you can find it in the Emacs source tree.

Next, write an initialization function for the module.

```
int emacs_module_init (struct emacs_runtime *runtime) [Function]
 Emacs calls this function when it loads a module. If a module does not export a
 function named emacs_module_init, trying to load the module will signal an error.
 The initialization function should return zero if the initialization succeeds, non-zero
 otherwise. In the latter case, Emacs will signal an error, and the loading of the module
 will fail. If the user presses C-g during the initialization, Emacs ignores the return
 value of the initialization function and quits (see Section 22.11 [Quitting], page 471). (If
```

needed, you can catch user quitting inside the initialization function, see [should\_quit], page 1374.)

The argument *runtime* is a pointer to a C **struct** that includes 2 public fields: **size**, which provides the size of the structure in bytes; and **get\_environment**, which provides a pointer to a function that allows the module initialization function access to the Emacs environment object and its interfaces.

The initialization function should perform whatever initialization is required for the module. In addition, it can perform the following tasks:

#### Compatibility verification

A module can verify that the Emacs executable which loads the module is compatible with the module, by comparing the **size** member of the *runtime* structure with the value compiled into the module:

```
int
emacs_module_init (struct emacs_runtime *runtime)
{
 if (runtime->size < sizeof (*runtime))
 return 1;
}
```

If the size of the runtime object passed to the module is smaller than what it expects, it means the module was compiled for an Emacs version newer (later) than the one which attempts to load it, i.e. the module might be incompatible with the Emacs binary.

In addition, a module can verify the compatibility of the module API with what the module expects. The following sample code assumes it is part of the **emacs\_module\_init** function shown above:

```
emacs_env *env = runtime->get_environment (runtime);
if (env->size < sizeof (*env))
 return 2;
```

This calls the **get\_environment** function using the pointer provided in the **runtime** structure to retrieve a pointer to the API's **environment**, a C **struct** which also has a **size** field holding the size of the structure in bytes.

Finally, you can write a module that will work with older versions of Emacs, by comparing the size of the environment passed by Emacs with known sizes, like this:

```
emacs_env *env = runtime->get_environment (runtime);
if (env->size >= sizeof (struct emacs_env_26))
 emacs_version = 26; /* Emacs 26 or later. */
else if (env->size >= sizeof (struct emacs_env_25))
 emacs_version = 25;
else
 return 2; /* Unknown or unsupported version. */
```

This works because later Emacs versions always *add* members to the environment, never *remove* any members, so the size can only grow with

new Emacs releases. Given the version of Emacs, the module can use only the parts of the module API that existed in that version, since those parts are identical in later versions.

`emacs-module.h` defines a preprocessor macro `EMACS_MAJOR_VERSION`. It expands to an integer literal which is the latest major version of Emacs supported by the header. See Section 1.4 [Version Info], page 6. Note that the value of `EMACS_MAJOR_VERSION` is a compile-time constant and does not represent the version of Emacs that is currently running and has loaded your module. If you want your module to be compatible with various versions of `emacs-module.h` as well as various versions of Emacs, you can use conditional compilation based on `EMACS_MAJOR_VERSION`.

We recommend that modules always perform the compatibility verification, unless they do their job entirely in the initialization function, and don't access any Lisp objects or use any Emacs functions accessible through the environment structure.

#### Binding module functions to Lisp symbols

This gives the module functions names so that Lisp code could call it by that name. We describe how to do this in Section E.8.2 [Module Functions], page 1363, below.

### E.8.2 Writing Module Functions

The main reason for writing an Emacs module is to make additional functions available to Lisp programs that load the module. This subsection describes how to write such *module functions*.

A module function has the following general form and signature:

```
emacs_value emacs_function (emacs_env *env, ptrdiff_t [Function]
 nargs, emacs_value *args, void *data)
```

The `env` argument provides a pointer to the API environment, needed to access Emacs objects and functions. The `nargs` argument is the required number of arguments, which can be zero (see `make_function` below for more flexible specification of the argument number), and `args` is a pointer to the array of the function arguments. The argument `data` points to additional data required by the function, which was arranged when `make_function` (see below) was called to create an Emacs function from `emacs_function`.

Module functions use the type `emacs_value` to communicate Lisp objects between Emacs and the module (see Section E.8.3 [Module Values], page 1366). The API, described below and in the following subsections, provides facilities for conversion between basic C data types and the corresponding `emacs_value` objects.

In the module function's body, do *not* attempt to access elements of the `args` array beyond the index `nargs-1`: memory for the `args` array is allocated exactly to accommodate `nargs` values, and accessing beyond that will most probably crash your module. In particular, if the value of `nargs` passed to the function at run time is zero, it must not access `args` at all, as no memory will have been allocated for it in that case.

A module function always returns a value. If the function returns normally, the Lisp code which called it will see the Lisp object corresponding to the `emacs_value` value

the function returned. However, if the user typed *C-g*, or if the module function or its callees signaled an error or exited nonlocally (see Section E.8.5 [Module Nonlocal], page 1375), Emacs will ignore the returned value and quit or throw as it does when Lisp code encounters the same situations.

The header `emacs-module.h` provides the type `emacs_function` as an alias type for a function pointer to a module function.

After writing your C code for a module function, you should make a Lisp function object from it using the `make_function` function, whose pointer is provided in the environment (recall that the pointer to the environment is returned by `get_environment`). This is normally done in the module initialization function (see [module initialization function], page 1361), after verifying the API compatibility.

```
emacs_value make_function (emacs_env *env, ptrdiff_t min arity, ptrdiff_t max arity, emacs_function func, const char *docstring, void *data) [Function]
```

This returns an Emacs function created from the C function `func`, whose signature is as described for `emacs_function` above. The arguments `min_arity` and `max_arity` specify the minimum and maximum number of arguments that `func` can accept. The `max_arity` argument can have the special value `emacs_variadic_function`, which makes the function accept an unlimited number of arguments, like the `&rest` keyword in Lisp (see Section 13.2.3 [Argument List], page 234).

The argument `data` is a way to arrange for arbitrary additional data to be passed to `func` when it is called. Whatever pointer is passed to `make_function` will be passed unaltered to `func`.

The argument `docstring` specifies the documentation string for the function. It should be either an ASCII string, or a UTF-8 encoded non-ASCII string, or a NULL pointer; in the latter case the function will have no documentation. The documentation string can end with a line that specifies the advertised calling convention, see Section 13.2.4 [Function Documentation], page 235.

Since every module function must accept the pointer to the environment as its first argument, the call to `make_function` could be made from any module function, but you will normally want to do that from the module initialization function, so that all the module functions are known to Emacs once the module is loaded.

Finally, you should bind the Lisp function to a symbol, so that Lisp code could call your function by name. For that, use the module API function `intern` (see [intern], page 1374) whose pointer is also provided in the environment that module functions can access.

Combining the above steps, code that arranges for a C function `module_func` to be callable as `module-func` from Lisp will look like this, as part of the module initialization function:

```
emacs_env *env = runtime->get_environment (runtime);
emacs_value func = env->make_function (env, min_arity, max_arity,
 module_func, docstring, data);
emacs_value symbol = env->intern (env, "module-func");
emacs_value args[] = {symbol, func};
```

```
env->funcall (env, env->intern (env, "defalias"), 2, args);
```

This makes the symbol `module-func` known to Emacs by calling `env->intern`, then invokes `defalias` from Emacs to bind the function to that symbol. Note that it is possible to use `fset` instead of `defalias`; the differences are described in Section 13.4 [Defining Functions], page 237.

Module functions including the `emacs_module_init` function (see [module initialization function], page 1361) may only interact with Emacs by calling environment functions from some live `emacs_env` pointer while being called directly or indirectly from Emacs. In other words, if a module function wants to call Lisp functions or Emacs primitives, convert `emacs_value` objects to and from C datatypes (see Section E.8.3 [Module Values], page 1366), or interact with Emacs in any other way, some call from Emacs to `emacs_module_init` or to a module function must be in the call stack. Module functions may not interact with Emacs while garbage collection is running; see Section E.3 [Garbage Collection], page 1350. They may only interact with Emacs from Lisp interpreter threads (including the main thread) created by Emacs; see Chapter 39 [Threads], page 1073. The `--module-assertions` command-line option can detect some violations of the above requirements. See Section “Initial Options” in *The GNU Emacs Manual*.

Using the module API, it is possible to define more complex function and data types: inline functions, macros, etc. However, the resulting C code will be cumbersome and hard to read. Therefore, we recommend that you limit the module code which creates functions and data structures to the absolute minimum, and leave the rest for a Lisp package that will accompany your module, because doing these additional tasks in Lisp is much easier, and will produce a much more readable code. For example, given a module function `module-func` defined as above, one way of making a macro `module-macro` based on it is with the following simple Lisp wrapper:

```
(defmacro module-macro (&rest args)
 "Documentation string for the macro."
 (module-func args))
```

The Lisp package which goes with your module could then load the module using the `load` primitive (see Section 16.11 [Dynamic Modules], page 314) when the package is loaded into Emacs.

By default, module functions created by `make_function` are not interactive. To make them interactive, you can use the following function.

|                                                                 |            |
|-----------------------------------------------------------------|------------|
| <code>void make_interactive (emacs_env *env, emacs_value</code> | [Function] |
| <code>function, emacs_value spec)</code>                        |            |

This function, which is available since Emacs 28, makes the function `function` interactive using the interactive specification `spec`. Emacs interprets `spec` like the argument to the `interactive` form. Section 22.2.1 [Using Interactive], page 424, and see Section 22.2.2 [Interactive Codes], page 427. `function` must be an Emacs module function returned by `make_function`.

Note that there is no native module support for retrieving the interactive specification of a module function. Use the function `interactive-form` for that. Section 22.2.1 [Using Interactive], page 424. It is not possible to make a module function non-interactive once you have made it interactive using `make_interactive`.

If you want to run some code when a module function object (i.e., an object returned by `make_function`) is garbage-collected, you can install a *function finalizer*. Function finalizers are available since Emacs 28. For example, if you have passed some heap-allocated structure to the `data` argument of `make_function`, you can use the finalizer to deallocate the structure. See Section “Basic Allocation” in `libc`, and see Section “Freeing after Malloc” in `libc`. The finalizer function has the following signature:

```
void finalizer (void *data)
```

Here, `data` receives the value passed to `data` when calling `make_function`. Note that the finalizer can't interact with Emacs in any way.

Directly after calling `make_function`, the newly-created function doesn't have a finalizer. Use `set_function_finalizer` to add one, if desired.

`void emacs_finalizer (void *ptr)`

[Function]

The header `emacs-module.h` provides the type `emacs_finalizer` as a type alias for an Emacs finalizer function.

`emacs_finalizer get_function_finalizer (emacs_env *env, emacs_value arg)`

[Function]

This function, which is available since Emacs 28, returns the function finalizer associated with the module function represented by `arg`. `arg` must refer to a module function, that is, an object returned by `make_function`. If no finalizer is associated with the function, `NULL` is returned.

`void set_function_finalizer (emacs_env *env, emacs_value arg, emacs_finalizer fin)`

[Function]

This function, which is available since Emacs 28, sets the function finalizer associated with the module function represented by `arg` to `fin`. `arg` must refer to a module function, that is, an object returned by `make_function`. `fin` can either be `NULL` to clear `arg`'s function finalizer, or a pointer to a function to be called when the object represented by `arg` is garbage-collected. At most one function finalizer can be set per function; if `arg` already has a finalizer, it is replaced by `fin`.

### E.8.3 Conversion Between Lisp and Module Values

With very few exceptions, most modules need to exchange data with Lisp programs that call them: accept arguments to module functions and return values from module functions. For this purpose, the module API provides the `emacs_value` type, which represents Emacs Lisp objects communicated via the API; it is the functional equivalent of the `Lisp_Object` type used in Emacs C primitives (see Section E.7 [Writing Emacs Primitives], page 1356). This section describes the parts of the module API that allow to create `emacs_value` objects corresponding to basic Lisp data types, and how to access from C data in `emacs_value` objects that correspond to Lisp objects.

All of the functions described below are actually *function pointers* provided via the pointer to the environment which every module function accepts. Therefore, module code should call these functions through the environment pointer, like this:

```
emacs_env *env; /* the environment pointer */
env->some_function (arguments...);
```

The `emacs_env` pointer will usually come from the first argument to the module function, or from the call to `get_environment` if you need the environment in the module initialization function.

Most of the functions described below became available in Emacs 25, the first Emacs release that supported dynamic modules. For the few functions that became available in later Emacs releases, we mention the first Emacs version that supported them.

The following API functions extract values of various C data types from `emacs_value` objects. They all raise the `wrong-type-argument` error condition (see Section 2.7 [Type Predicates], page 30) if the argument `emacs_value` object is not of the type expected by the function. See Section E.8.5 [Module Nonlocal], page 1375, for details of how signaling errors works in Emacs modules, and how to catch error conditions inside the module before they are reported to Emacs. The API function `type_of` (see Section E.8.4 [Module Misc], page 1373) can be used to obtain the type of a `emacs_value` object.

`intmax_t extract_integer (emacs_env *env, emacs_value arg)` [Function]

This function returns the value of a Lisp integer specified by `arg`. The C data type of the return value, `intmax_t`, is the widest integer data type supported by the C compiler, typically `long long`. If the value of `arg` doesn't fit into an `intmax_t`, the function signals an error using the error symbol `overflow-error`.

`bool extract_big_integer (emacs_env *env, emacs_value arg, int *sign, ptrdiff_t *count, emacs_limb_t *magnitude)` [Function]

This function, which is available since Emacs 27, extracts the integer value of `arg`. The value of `arg` must be an integer (fixnum or bignum). If `sign` is not `NULL`, it stores the sign of `arg` (-1, 0, or +1) into `*sign`. The magnitude is stored into `magnitude` as follows. If `count` and `magnitude` are both non-`NULL`, then `magnitude` must point to an array of at least `*count unsigned long` elements. If `magnitude` is large enough to hold the magnitude of `arg`, then this function writes the magnitude into the `magnitude` array in little-endian form, stores the number of array elements written into `*count`, and returns `true`. If `magnitude` is not large enough, it stores the required array size into `*count`, signals an error, and returns `false`. If `count` is not `NULL` and `magnitude` is `NULL`, then the function stores the required array size into `*count` and returns `true`.

Emacs guarantees that the maximum required value of `*count` never exceeds `min (PTRDIFF_MAX, SIZE_MAX) / sizeof (emacs_limb_t)`, so you can use `malloc (*count * sizeof *magnitude)` to allocate the `magnitude` array without worrying about integer overflow in the size calculation.

`emacs_limb_t` [Type alias]

This is an unsigned integer type, used as the element type for the magnitude arrays for the big integer conversion functions. The type is guaranteed to have unique object representations, i.e., no padding bits.

`EMACS_LIMB_MAX` [Macro]

This macro expands to a constant expression specifying the maximum possible value for an `emacs_limb_t` object. The expression is suitable for use in `#if`.

`double extract_float (emacs_env *env, emacs_value arg)` [Function]

This function returns the value of a Lisp float specified by `arg`, as a C `double` value.

```
struct timespec extract_time (emacs_env *env, emacs_value [Function]
 arg)
```

This function, which is available since Emacs 27, interprets *arg* as an Emacs Lisp time value and returns the corresponding **struct timespec**. See Section 42.5 [Time of Day], page 1270. **struct timespec** represents a timestamp with nanosecond precision. It has the following members:

**time\_t tv\_sec**

Whole number of seconds.

**long tv\_nsec**

Fractional seconds as a number of nanoseconds. For timestamps returned by **extract\_time**, this is always nonnegative and less than one billion. (Although POSIX requires the type of **tv\_nsec** to be **long**, the type is **long long** on some nonstandard platforms.)

See Section “Elapsed Time” in **libc**.

If *time* has higher precision than nanoseconds, then this function truncates it to nanosecond precision towards negative infinity. This function signals an error if *time* (truncated to nanoseconds) cannot be represented by **struct timespec**. For example, if **time\_t** is a 32-bit integer type, then a *time* value of ten billion seconds would signal an error, but a *time* value of 600 picoseconds would get truncated to zero.

If you need to deal with time values that are not representable by **struct timespec**, or if you want higher precision, call the Lisp function **encode-time** and work with its return value. See Section 42.7 [Time Conversion], page 1273.

```
bool copy_string_contents (emacs_env *env, emacs_value [Function]
 arg, char *buf, ptrdiff_t *len)
```

This function stores the UTF-8 encoded text of a Lisp string specified by *arg* in the array of **char** pointed by *buf*, which should have enough space to hold at least *\*len* bytes, including the terminating null byte. The argument *len* must not be a NULL pointer, and, when the function is called, it should point to a value that specifies the size of *buf* in bytes.

If the buffer size specified by *\*len* is large enough to hold the string’s text, the function stores in *\*len* the actual number of bytes copied to *buf*, including the terminating null byte, and returns **true**. If the buffer is too small, the function raises the **args-out-of-range** error condition, stores the required number of bytes in *\*len*, and returns **false**. See Section E.8.5 [Module Nonlocal], page 1375, for how to handle pending error conditions.

The argument *buf* can be a NULL pointer, in which case the function stores in *\*len* the number of bytes required for storing the contents of *arg*, and returns **true**. This is how you can determine the size of *buf* needed to store a particular string: first call **copy\_string\_contents** with NULL as *buf*, then allocate enough memory to hold the number of bytes stored by the function in *\*len*, and call the function again with non-NUL *buf* to actually perform the text copying.

```
emacs_value vec_get (emacs_env *env, emacs_value vector, [Function]
 ptrdiff_t index)
```

This function returns the element of *vector* at *index*. The *index* of the first vector element is zero. The function raises the `args-out-of-range` error condition if the value of *index* is invalid. To extract C data from the value the function returns, use the other extraction functions described here, as appropriate for the Lisp data type stored in that element of the vector.

```
ptrdiff_t vec_size (emacs_env *env, emacs_value vector) [Function]
```

This function returns the number of elements in *vector*.

```
void vec_set (emacs_env *env, emacs_value vector, [Function]
 ptrdiff_t index, emacs_value value)
```

This function stores *value* in the element of *vector* whose index is *index*. It raises the `args-out-of-range` error condition if the value of *index* is invalid.

The following API functions create `emacs_value` objects from basic C data types. They all return the created `emacs_value` object.

```
emacs_value make_integer (emacs_env *env, intmax_t n) [Function]
```

This function takes an integer argument *n* and returns the corresponding `emacs_value` object. It returns either a fixnum or a bignum depending on whether the value of *n* is inside the limits set by `most-negative-fixnum` and `most-positive-fixnum` (see Section 3.1 [Integer Basics], page 38).

```
emacs_value make_big_integer (emacs_env *env, int sign, [Function]
 ptrdiff_t count, const emacs_limb_t *magnitude)
```

This function, which is available since Emacs 27, takes an arbitrary-sized integer argument and returns a corresponding `emacs_value` object. The *sign* argument gives the sign of the return value. If *sign* is nonzero, then *magnitude* must point to an array of at least *count* elements specifying the little-endian magnitude of the return value.

The following example uses the GNU Multiprecision Library (GMP) to calculate the next probable prime after a given integer. See `gmp`, for a general overview of GMP, and see Section “Integer Import and Export” in `gmp` for how to convert the `magnitude` array to and from GMP `mpz_t` values.

 = env->make_function (env, 1, 1, next_prime, NULL, NULL);
 emacs_value args[] = {symbol, func};
 env->funcall (env, env->intern (env, "defalias"), 2, args);
 return 0;
}

emacs_value make_float (emacs_env *env, double d) [Function]
This function takes a double argument d and returns the corresponding Emacs
floating-point value.

```

```
emacs_value make_time (emacs_env *env, struct timespec time) [Function]
```

This function, which is available since Emacs 27, takes a `struct timespec` argument `time` and returns the corresponding Emacs timestamp as a pair (`ticks . hz`). See Section 42.5 [Time of Day], page 1270. The return value represents exactly the same timestamp as `time`: all input values are representable, and there is never a loss of precision. `time.tv_sec` and `time.tv_nsec` can be arbitrary values. In particular, there's no requirement that `time` be normalized. This means that `time.tv_nsec` can be negative or larger than 999,999,999.

```
emacs_value make_string (emacs_env *env, const char *str, ptrdiff_t len) [Function]
```

This function creates an Emacs string from C text string pointed by `str` whose length in bytes, not including the terminating null byte, is `len`. The original string in `str` can be either an ASCII string or a UTF-8 encoded non-ASCII string; it can include embedded null bytes, and doesn't have to end in a terminating null byte at `str[len]`. The function raises the `overflow-error` error condition if `len` is negative or exceeds the maximum length of an Emacs string. If `len` is zero, then `str` can be `NULL`, otherwise it must point to valid memory. For nonzero `len`, `make_string` returns unique mutable string objects.

```
emacs_value make_unibyte_string (emacs_env *env, const char *str, ptrdiff_t len) [Function]
```

This function is like `make_string`, but has no restrictions on the values of the bytes in the C string, and can be used to pass binary data to Emacs in the form of a unibyte string.

The API does not provide functions to manipulate Lisp data structures, for example, create lists with `cons` and `list` (see Section 5.4 [Building Lists], page 82), extract list members with `car` and `cdr` (see Section 5.3 [List Elements], page 79), create vectors with `vector` (see Section 6.5 [Vector Functions], page 118), etc. For these, use `intern` and `funcall`, described in the next subsection, to call the corresponding Lisp functions.

Normally, `emacs_value` objects have a rather short lifetime: it ends when the `emacs_env` pointer used for their creation goes out of scope. Occasionally, you may need to create *global references*: `emacs_value` objects that live as long as you wish. Use the following two functions to manage such objects.

```
emacs_value make_global_ref (emacs_env *env, emacs_value value) [Function]
```

This function returns a global reference for `value`.

```
void free_global_ref (emacs_env *env, emacs_value global_value) [Function]
```

This function frees the `global_value` previously created by `make_global_ref`. The `global_value` is no longer valid after the call. Your module code should pair each call to `make_global_ref` with the corresponding `free_global_ref`.

An alternative to keeping around C data structures that need to be passed to module functions later is to create *user pointer* objects. A user pointer, or `user_ptr`, object is a Lisp

object that encapsulates a C pointer and can have an associated finalizer function, which is called when the object is garbage-collected (see Section E.3 [Garbage Collection], page 1350). The module API provides functions to create and access `user_ptr` objects. These functions raise the `wrong-type-argument` error condition if they are called on `emacs_value` that doesn't represent a `user_ptr` object.

```
emacs_value make_user_ptr (emacs_env *env, emacs_finalizer [Function]
 fin, void *ptr)
```

This function creates and returns a `user_ptr` object which wraps the C pointer `ptr`. The finalizer function `fin` can be a NULL pointer (meaning no finalizer), or it can be a function of the following signature:

```
typedef void (*emacs_finalizer) (void *ptr);
```

If `fin` is not a NULL pointer, it will be called with the `ptr` as the argument when the `user_ptr` object is garbage-collected. Don't run any expensive code in a finalizer, because GC must finish quickly to keep Emacs responsive.

```
void *get_user_ptr (emacs_env *env, emacs_value arg) [Function]
```

This function extracts the C pointer from the Lisp object represented by `arg`.

```
void set_user_ptr (emacs_env *env, emacs_value arg, void [Function]
 *ptr)
```

This function sets the C pointer embedded in the `user_ptr` object represented by `arg` to `ptr`.

```
emacs_finalizer get_user_finalizer (emacs_env *env, [Function]
 emacs_value arg)
```

This function returns the finalizer of the `user_ptr` object represented by `arg`, or NULL if it doesn't have a finalizer.

```
void set_user_finalizer (emacs_env *env, emacs_value arg, [Function]
 emacs_finalizer fin)
```

This function changes the finalizer of the `user_ptr` object represented by `arg` to be `fin`. If `fin` is a NULL pointer, the `user_ptr` object will have no finalizer.

Note that the `emacs_finalizer` type works for both user pointer and module function finalizers. See [Module Function Finalizers], page 1365.

#### E.8.4 Miscellaneous Convenience Functions for Modules

This subsection describes a few convenience functions provided by the module API. Like the functions described in previous subsections, all of them are actually function pointers, and need to be called via the `emacs_env` pointer. Description of functions that were introduced after Emacs 25 calls out the first version where they became available.

```
bool eq (emacs_env *env, emacs_value a, emacs_value b) [Function]
```

This function returns `true` if the Lisp objects represented by `a` and `b` are identical, `false` otherwise. This is the same as the Lisp function `eq` (see Section 2.8 [Equality Predicates], page 34), but avoids the need to intern the objects represented by the arguments.

There are no API functions for other equality predicates, so you will need to use `intern` and `funcall`, described below, to perform more complex equality tests.

`bool is_not_nil (emacs_env *env, emacs_value arg)` [Function]

This function tests whether the Lisp object represented by `arg` is non-nil; it returns `true` or `false` accordingly.

Note that you could implement an equivalent test by using `intern` to get an `emacs_value` representing `nil`, then use `eq`, described above, to test for equality. But using this function is more convenient.

`emacs_value type_of (emacs_env *env, emacs_value arg)` [Function]

This function returns the type of `arg` as a value that represents a symbol: `string` for a string, `integer` for an integer, `process` for a process, etc. See Section 2.7 [Type Predicates], page 30. You can use `intern` and `eq` to compare against known type symbols, if your code needs to depend on the object type.

`emacs_value intern (emacs_env *env, const char *name)` [Function]

This function returns an interned Emacs symbol whose name is `name`, which should be an ASCII null-terminated string. It creates a new symbol if one does not already exist.

Together with `funcall`, described below, this function provides a means for invoking any Lisp-callable Emacs function, provided that its name is a pure ASCII string. For example, here's how to intern a symbol whose name `name_str` is non-ASCII, by calling the more powerful Emacs `intern` function (see Section 9.3 [Creating Symbols], page 135):

```
emacs_value fintern = env->intern (env, "intern");
emacs_value sym_name =
 env->make_string (env, name_str, strlen (name_str));
emacs_value symbol = env->funcall (env, fintern, 1, &sym_name);
```

`emacs_value funcall (emacs_env *env, emacs_value func,` [Function]

`ptrdiff_t nargs, emacs_value *args)`

This function calls the specified `func` passing it `nargs` arguments from the array pointed to by `args`. The argument `func` can be a function symbol (e.g., returned by `intern` described above), a module function returned by `make_function` (see Section E.8.2 [Module Functions], page 1363), a subroutine written in C, etc. If `nargs` is zero, `args` can be a NULL pointer.

The function returns the value that `func` returned.

If your module includes potentially long-running code, it is a good idea to check from time to time in that code whether the user wants to quit, e.g., by typing `C-g` (see Section 22.11 [Quitting], page 471). The following function, which is available since Emacs 26.1, is provided for that purpose.

`bool should_quit (emacs_env *env)` [Function]

This function returns `true` if the user wants to quit. In that case, we recommend that your module function aborts any on-going processing and returns as soon as possible. In most cases, use `process_input` instead.

To process input events in addition to checking whether the user wants to quit, use the following function, which is available since Emacs 27.1.

```
enum emacs_process_input_result process_input (emacs_env *env) [Function]
```

This function processes pending input events. It returns `emacs_process_input_quit` if the user wants to quit or an error occurred while processing signals. In that case, we recommend that your module function aborts any on-going processing and returns as soon as possible. If the module code may continue running, `process_input` returns `emacs_process_input_continue`. The return value is `emacs_process_input_continue` if and only if there is no pending nonlocal exit in `env`. If the module continues after calling `process_input`, global state such as variable values and buffer content may have been modified in arbitrary ways.

```
int open_channel (emacs_env *env, emacs_value pipe_process) [Function]
```

This function, which is available since Emacs 28, opens a channel to an existing pipe process. `pipe_process` must refer to an existing pipe process created by `make-pipe-process`. [Pipe Processes], page 1088. If successful, the return value will be a new file descriptor that you can use to write to the pipe. Unlike all other module functions, you can use the returned file descriptor from arbitrary threads, even if no module environment is active. You can use the `write` function to write to the file descriptor. Once done, close the file descriptor using `close`. Section “Low-Level I/O” in `libc`.

### E.8.5 Nonlocal Exits in Modules

Emacs Lisp supports nonlocal exits, whereby program control is transferred from one point in a program to another remote point. See Section 11.7 [Nonlocal Exits], page 177. Thus, Lisp functions called by your module might exit nonlocally by calling `signal` or `throw`, and your module functions must handle such nonlocal exits properly. Such handling is needed because C programs will not automatically release resources and perform other cleanups in these cases; your module code must itself do it. The module API provides facilities for that, described in this subsection. They are generally available since Emacs 25; those of them that became available in later releases explicitly call out the first Emacs version where they became part of the API.

When some Lisp code called by a module function signals an error or throws, the nonlocal exit is trapped, and the pending exit and its associated data are stored in the environment. Whenever a nonlocal exit is pending in the environment, any module API function called with a pointer to that environment will return immediately without any processing (the functions `non_local_exit_check`, `non_local_exit_get`, and `non_local_exit_clear` are exceptions from this rule). If your module function then does nothing and returns to Emacs, a pending nonlocal exit will cause Emacs to act on it: signal an error or throw to the corresponding `catch`.

So the simplest “handling” of nonlocal exits in module functions is to do nothing special and let the rest of your code to run as if nothing happened. However, this can cause two classes of problems:

- Your module function might use uninitialized or undefined values, since API functions return immediately without producing the expected results.
- Your module might leak resources, because it might not have the opportunity to release them.

Therefore, we recommend that your module functions check for nonlocal exit conditions and recover from them, using the functions described below.

```
enum emacs_funcall_exit_non_local_exit_check (emacs_env *env) [Function]
```

This function returns the kind of nonlocal exit condition stored in `env`. The possible values are:

```
emacs_funcall_exit_return
```

The last API function exited normally.

```
emacs_funcall_exit_signal
```

The last API function signaled an error.

```
emacs_funcall_exit_throw
```

The last API function exited via `throw`.

```
enum emacs_funcall_exit_non_local_exit_get (emacs_env *env) [Function]
```

```
*symbol, emacs_value *data)
```

This function returns the kind of nonlocal exit condition stored in `env`, like `non_local_exit_check` does, but it also returns the full information about the nonlocal exit, if any. If the return value is `emacs_funcall_exit_signal`, the function stores the error symbol in `*symbol` and the error data in `*data` (see Section 11.7.3.1 [Signaling Errors], page 180). If the return value is `emacs_funcall_exit_throw`, the function stores the `catch` tag symbol in `*symbol` and the `throw` value in `*data`. The function doesn't store anything in memory pointed by these arguments when the return value is `emacs_funcall_exit_return`.

You should check nonlocal exit conditions where it matters: before you allocated some resource or after you allocated a resource that might need freeing, or where a failure means further processing is impossible or infeasible.

Once your module function detected that a nonlocal exit is pending, it can either return to Emacs (after performing the necessary local cleanup), or it can attempt to recover from the nonlocal exit. The following API functions will help with these tasks.

```
void non_local_exit_clear (emacs_env *env) [Function]
```

This function clears the pending nonlocal exit conditions and data from `env`. After calling it, the module API functions will work normally. Use this function if your module function can recover from nonlocal exits of the Lisp functions it calls and continue, and also before calling any of the following two functions (or any other API functions, if you want them to perform their intended processing when a nonlocal exit is pending).

```
void non_local_exit_throw (emacs_env *env, emacs_value tag, emacs_value value) [Function]
```

This function throws to the Lisp `catch` symbol represented by `tag`, passing it `value` as the value to return. Your module function should in general return soon after calling this function. One use of this function is when you want to re-throw a non-local exit from one of the called API or Lisp functions.

```
void non_local_exit_signal (emacs_env *env, emacs_value symbol, emacs_value data) [Function]
```

This function signals the error represented by the error symbol *symbol* with the specified error data *data*. The module function should return soon after calling this function. This function could be useful, e.g., for signaling errors from module functions to Emacs.

## E.9 Object Internals

Emacs Lisp provides a rich set of the data types. Some of them, like cons cells, integers and strings, are common to nearly all Lisp dialects. Some others, like markers and buffers, are quite special and needed to provide the basic support to write editor commands in Lisp. To implement such a variety of object types and provide an efficient way to pass objects between the subsystems of an interpreter, there is a set of C data structures and a special type to represent the pointers to all of them, which is known as *tagged pointer*.

In C, the tagged pointer is an object of type **Lisp\_Object**. Any initialized variable of such a type always holds the value of one of the following basic data types: integer, symbol, string, cons cell, float, or vectorlike object. Each of these data types has the corresponding tag value. All tags are enumerated by **enum Lisp\_Type** and placed into a 3-bit bitfield of the **Lisp\_Object**. The rest of the bits is the value itself. Integers are immediate, i.e., directly represented by those *value bits*, and all other objects are represented by the C pointers to a corresponding object allocated from the heap. Width of the **Lisp\_Object** is platform- and configuration-dependent: usually it's equal to the width of an underlying platform pointer (i.e., 32-bit on a 32-bit machine and 64-bit on a 64-bit one), but also there is a special configuration where **Lisp\_Object** is 64-bit but all pointers are 32-bit. The latter trick was designed to overcome the limited range of values for Lisp integers on a 32-bit system by using 64-bit **long long** type for **Lisp\_Object**.

The following C data structures are defined in **lisp.h** to represent the basic data types beyond integers:

```
struct Lisp_Cons
```

Cons cell, an object used to construct lists.

```
struct Lisp_String
```

String, the basic object to represent a sequence of characters.

```
struct Lisp_Vector
```

Array, a fixed-size set of Lisp objects which may be accessed by an index.

```
struct Lisp_Symbol
```

Symbol, the unique-named entity commonly used as an identifier.

```
struct Lisp_Float
```

Floating-point value.

These types are the first-class citizens of an internal type system. Since the tag space is limited, all other types are the subtypes of **Lisp\_Vectorlike**. Vector subtypes are enumerated by **enum pvec\_type**, and nearly all complex objects like windows, buffers, frames, and processes fall into this category.

Below there is a description of a few subtypes of `Lisp_Vectorlike`. Buffer object represents the text to display and edit. Window is the part of display structure which shows the buffer or is used as a container to recursively place other windows on the same frame. (Do not confuse Emacs Lisp window object with the window as an entity managed by the user interface system like X; in Emacs terminology, the latter is called frame.) Finally, process object is used to manage the subprocesses.

### E.9.1 Buffer Internals

Two structures (see `buffer.h`) are used to represent buffers in C. The `buffer_text` structure contains fields describing the text of a buffer; the `buffer` structure holds other fields. In the case of indirect buffers, two or more `buffer` structures reference the same `buffer_text` structure.

Here are some of the fields in `struct buffer_text`:

`beg` The address of the buffer contents. The buffer contents is a linear C array of `char`, with the gap somewhere in its midst.

`gpt`

`gpt_byte` The character and byte positions of the buffer gap. See Section 28.13 [Buffer Gap], page 688.

`z`

`z_byte` The character and byte positions of the end of the buffer text.

`gap_size` The size of buffer's gap. See Section 28.13 [Buffer Gap], page 688.

`modiff`

`save_modiff`

`chars_modiff`

`overlay_modiff`

These fields count the number of buffer-modification events performed in this buffer. `modiff` is incremented after each buffer-modification event, and is never otherwise changed; `save_modiff` contains the value of `modiff` the last time the buffer was visited or saved; `chars_modiff` counts only modifications to the characters in the buffer, ignoring all other kinds of changes (such as text properties); and `overlay_modiff` counts only modifications to the buffer's overlays.

`beg_unchanged`

`end_unchanged`

The number of characters at the start and end of the text that are known to be unchanged since the last complete redisplay.

`unchanged_modified`

`overlay_unchanged_modified`

The values of `modiff` and `overlay_modiff`, respectively, after the last complete redisplay. If their current values match `modiff` or `overlay_modiff`, that means `beg_unchanged` and `end_unchanged` contain no useful information.

`markers` The markers that refer to this buffer. This is actually a single marker, and successive elements in its marker *chain* (a linked list) are the other markers referring to this buffer text.

**intervals**

The interval tree which records the text properties of this buffer.

Some of the fields of **struct buffer** are:

**header** A header of type **union vectorlike\_header** is common to all vectorlike objects.

**own\_text** A **struct buffer\_text** structure that ordinarily holds the buffer contents. In indirect buffers, this field is not used.

**text** A pointer to the **buffer\_text** structure for this buffer. In an ordinary buffer, this is the **own\_text** field above. In an indirect buffer, this is the **own\_text** field of the base buffer.

**next** A pointer to the next buffer, in the chain of all buffers, including killed buffers. This chain is used only for allocation and garbage collection, in order to collect killed buffers properly.

**pt**

**pt\_byte** The character and byte positions of point in a buffer.

**begv**

**begv\_byte**

The character and byte positions of the beginning of the accessible range of text in the buffer.

**zv**

**zv\_byte** The character and byte positions of the end of the accessible range of text in the buffer.

**base\_buffer**

In an indirect buffer, this points to the base buffer. In an ordinary buffer, it is null.

**local\_flags**

This field contains flags indicating that certain variables are local in this buffer. Such variables are declared in the C code using **DEFVAR\_PER\_BUFFER**, and their buffer-local bindings are stored in fields in the buffer structure itself. (Some of these fields are described in this table.)

**modtime**

The modification time of the visited file. It is set when the file is written or read. Before writing the buffer into a file, this field is compared to the modification time of the file to see if the file has changed on disk. See Section 28.5 [Buffer Modification], page 677.

**auto\_save\_modified**

The time when the buffer was last auto-saved.

**last\_window\_start**

The **window-start** position in the buffer as of the last time the buffer was displayed in a window.

**clip\_changed**

This flag indicates that narrowing has changed in the buffer. See Section 31.4 [Narrowing], page 865.

**prevent\_redisplay\_optimizations\_p**

This flag indicates that redisplay optimizations should not be used to display this buffer.

**inhibit\_buffer\_hooks**

This flag indicates that the buffer should not run the hooks `kill-buffer-hook`, `kill-buffer-query-functions` (see Section 28.10 [Killing Buffers], page 685), and `buffer-list-update-hook` (see Section 28.8 [Buffer List], page 681). It is set at buffer creation (see Section 28.9 [Creating Buffers], page 684), and avoids slowing down internal or temporary buffers, such as those created by `with-temp-buffer` (see [Current Buffer], page 673).

**name**

A Lisp string that names the buffer. It is guaranteed to be unique. See Section 28.3 [Buffer Names], page 674. This and the following fields have their names in the C struct definition end in a `_` to indicate that they should not be accessed directly, but via the `BVAR` macro, like this:

```
Lisp_Object buf_name = BVAR (buffer, name);
```

**save\_length**

The length of the file this buffer is visiting, when last read or saved. It can have 2 special values: `-1` means auto-saving was turned off in this buffer, and `-2` means don't turn off auto-saving if buffer text shrinks a lot. This and other fields concerned with saving are not kept in the `buffer_text` structure because indirect buffers are never saved.

**directory**

The directory for expanding relative file names. This is the value of the buffer-local variable `default-directory` (see Section 26.9.4 [File Name Expansion], page 639).

**filename**

The name of the file visited in this buffer, or `nil`. This is the value of the buffer-local variable `buffer-file-name` (see Section 28.4 [Buffer File Name], page 675).

**undo\_list****backed\_up****auto\_save\_file\_name****auto\_save\_file\_format****read\_only****file\_format****file\_truename****invisibility\_spec****display\_count****display\_time**

These fields store the values of Lisp variables that are automatically buffer-local (see Section 12.11 [Buffer-Local Variables], page 207), whose corresponding variable names have the additional prefix `buffer-` and have underscores replaced with dashes. For instance, `undo_list` stores the value of `buffer-undo-list`.

**mark**

The mark for the buffer. The mark is a marker, hence it is also included on the list `markers`. See Section 32.7 [The Mark], page 873.

**local\_var alist**

The association list describing the buffer-local variable bindings of this buffer, not including the built-in buffer-local bindings that have special slots in the buffer object. (Those slots are omitted from this table.) See Section 12.11 [Buffer-Local Variables], page 207.

**major\_mode**

Symbol naming the major mode of this buffer, e.g., `lisp-mode`.

**mode\_name**

Pretty name of the major mode, e.g., "Lisp".

**keymap**  
**abbrev\_table**  
**syntax\_table**  
**category\_table**  
**display\_table**

These fields store the buffer's local keymap (see Chapter 23 [Keymaps], page 480), abbrev table (see Section 38.1 [Abbrev Tables], page 1066), syntax table (see Chapter 36 [Syntax Tables], page 1022), category table (see Section 36.8 [Categories], page 1036), and display table (see Section 41.23.2 [Display Tables], page 1243).

**downcase\_table**  
**upcase\_table**  
**case\_canon\_table**

These fields store the conversion tables for converting text to lower case, upper case, and for canonicalizing text for case-fold search. See Section 4.10 [Case Tables], page 74.

**minor\_modes**

An alist of the minor modes of this buffer.

**pt\_marker**  
**begv\_marker**  
**zv\_marker**

These fields are only used in an indirect buffer, or in a buffer that is the base of an indirect buffer. Each holds a marker that records `pt`, `begv`, and `zv` respectively, for this buffer when the buffer is not current.

```

mode_line_format
header_line_format
case_fold_search
tab_width
fill_column
left_margin
auto_fill_function
truncate_lines
word_wrap
ctl_arrow
bidi_display_reordering
bidi_paragraph_direction
selective_display
selective_display_ellipses
overwrite_mode
abbrev_mode
mark_active
enable_multibyte_characters
buffer_file_coding_system
cache_long_line_scans
point_before_scroll
left_fringe_width
right_fringe_width
fringes_outside_margins
scroll_bar_width
indicate_empty_lines
indicate_buffer_boundaries
fringe_indicator_alist
fringe_cursor_alist
scroll_up_aggressively
scroll_down_aggressively
cursor_type
cursor_in_non_selected_windows

```

These fields store the values of Lisp variables that are automatically buffer-local (see Section 12.11 [Buffer-Local Variables], page 207), whose corresponding variable names have underscores replaced with dashes. For instance, `mode_line_format` stores the value of `mode-line-format`.

`overlays` The interval tree containing this buffer's overlays.

`last_selected_window`

This is the last window that was selected with this buffer in it, or `nil` if that window no longer displays this buffer.

### E.9.2 Window Internals

The fields of a window (for a complete list, see the definition of `struct window` in `window.h`) include:

`frame` The frame that this window is on, as a Lisp object.

|                        |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
|------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>mini</b>            | Non-zero if this window is a minibuffer window, a window showing the minibuffer or the echo area.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| <b>pseudo_window_p</b> | Non-zero if this window is a <i>pseudo window</i> . A pseudo window is either a window used to display the menu bar or the tool bar (when Emacs uses toolkits that don't display their own menu bar and tool bar) or the tab bar or a window showing a tooltip on a tooltip frame. Pseudo windows are in general not accessible from Lisp code.                                                                                                                                                                                                                                  |
| <b>parent</b>          | <p>Internally, Emacs arranges windows in a tree; each group of siblings has a parent window whose area includes all the siblings. This field points to the window's parent in that tree, as a Lisp object. For the root window of the tree and a minibuffer window this is always <code>nil</code>.</p> <p>Parent windows do not display buffers, and play little role in display except to shape their child windows. Emacs Lisp programs cannot directly manipulate parent windows; they operate on the windows at the leaves of the tree, which actually display buffers.</p> |
| <b>contents</b>        | For a leaf window and windows showing a tooltip, this is the buffer, as a Lisp object, that the window is displaying. For an internal ("parent") window, this is its first child window. For a pseudo window showing a menu or tool bar this is <code>nil</code> . It is also <code>nil</code> for a window that has been deleted.                                                                                                                                                                                                                                               |
| <b>next</b>            |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
| <b>prev</b>            | The next and previous sibling of this window as Lisp objects. <code>next</code> is <code>nil</code> if the window is the right-most or bottom-most in its group; <code>prev</code> is <code>nil</code> if it is the left-most or top-most in its group. Whether the sibling is left/right or up/down is determined by the <code>horizontal</code> field of the sibling's parent: if it's non-zero, the siblings are arranged horizontally.                                                                                                                                       |
|                        | As a special case, <code>next</code> of a frame's root window points to the frame's minibuffer window, provided this is not a minibuffer-only or minibuffer-less frame. On such frames <code>prev</code> of the minibuffer window points to that frame's root window. In any other case, the root window's <code>next</code> and the minibuffer window's (if present) <code>prev</code> fields are <code>nil</code> .                                                                                                                                                            |
| <b>left_col</b>        | The left-hand edge of the window, measured in columns, relative to the leftmost column (column 0) of the window's native frame.                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
| <b>top_line</b>        | The top edge of the window, measured in lines, relative to the topmost line (line 0) of the window's native frame.                                                                                                                                                                                                                                                                                                                                                                                                                                                               |
| <b>pixel_left</b>      |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
| <b>pixel_top</b>       | The left-hand and top edges of this window, measured in pixels, relative to the top-left corner (0, 0) of the window's native frame.                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| <b>total_cols</b>      |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
| <b>total_lines</b>     | The total width and height of the window, measured in columns and lines respectively. The values include scroll bars and fringes, dividers and/or the separator line on the right of the window (if any).                                                                                                                                                                                                                                                                                                                                                                        |

`pixel_width;`  
`pixel_height;`

The total width and height of the window measured in pixels.

`start` A marker pointing to the position in the buffer that is the first character (in the logical order, see Section 41.27 [Bidirectional Display], page 1250) displayed in the window.

`pointm` This is the value of point in the current buffer when this window is selected; when it is not selected, it retains its previous value.

`old_pointm`

The value of `pointm` at the last redisplay time.

`force_start`

If this flag is non-`nil`, it says that the window has been scrolled explicitly by the Lisp program, and the value of the window's `start` was set for redisplay to honor. This affects what the next redisplay does if point is off the screen: instead of scrolling the window to show the text around point, it moves point to a location that is on the screen.

`optional_new_start`

This is similar to `force_start`, but the next redisplay will only obey it if point stays visible.

`start_at_line_beg`

Non-`nil` means current value of `start` was the beginning of a line when it was chosen.

`use_time` This is the last time that the window was selected. The function `get-lru-window` uses this field.

`sequence_number`

A unique number assigned to this window when it was created.

`last_modified`

The `modiff` field of the window's buffer, as of the last time a redisplay completed in this window.

`last_overlay_modified`

The `overlay_modiff` field of the window's buffer, as of the last time a redisplay completed in this window.

`last_point`

The buffer's value of point, as of the last time a redisplay completed in this window.

`last_had_star`

A non-zero value means the window's buffer was modified when the window was last updated.

`vertical_scroll_bar_type`

`horizontal_scroll_bar_type`

The types of this window's vertical and horizontal scroll bars.

**scroll\_bar\_width**  
**scroll\_bar\_height**  
     The width of this window's vertical scroll bar and the height of this window's horizontal scroll bar, in pixels.

**left\_margin\_cols**  
**right\_margin\_cols**  
     The widths of the left and right margins in this window. A value of zero means no margin.

**left\_fringe\_width**  
**right\_fringe\_width**  
     The pixel widths of the left and right fringes in this window. A value of  $-1$  means use the values of the frame.

**fringes\_outside\_margins**  
     A non-zero value means the fringes outside the display margins; otherwise they are between the margin and the text.

**window\_end\_pos**  
     This is computed as  $z$  minus the buffer position of the last glyph in the current matrix of the window. The value is only valid if **window\_end\_valid** is non-zero.

**window\_end\_bytupos**  
     The byte position corresponding to **window\_end\_pos**.

**window\_end\_vpos**  
     The window-relative vertical position of the line containing **window\_end\_pos**.

**window\_end\_valid**  
     This field is set to a non-zero value if **window\_end\_pos** and **window\_end\_vpos** are truly valid. This is zero if nontrivial redisplay is pre-empted, since in that case the display that **window\_end\_pos** was computed for did not get onto the screen.

**cursor**    A structure describing where the cursor is in this window.

**last\_cursor\_vpos**  
     The window-relative vertical position of the line showing the cursor as of the last redisplay that finished.

**phys\_cursor**  
     A structure describing where the cursor of this window physically is.

**phys\_cursor\_type**  
**phys\_cursor\_height**  
**phys\_cursor\_width**  
     The type, height, and width of the cursor that was last displayed on this window.

**phys\_cursor\_on\_p**  
     This field is non-zero if the cursor is physically on.

**cursor\_off\_p**  
     Non-zero means the cursor in this window is logically off. This is used for blinking the cursor.

**last\_cursor\_off\_p**

This field contains the value of `cursor_off_p` as of the time of the last redisplay.

**must\_be\_updated\_p**

This is set to 1 during redisplay when this window must be updated.

**hscroll** This is the number of columns that the display in the window is scrolled horizontally to the left. Normally, this is 0. When only the current line is hscrolled, this describes how much the current line is scrolled.

**min\_hscroll**

Minimum value of `hscroll`, set by the user via `set-window-hscroll` (see Section 29.23 [Horizontal Scrolling], page 767). When only the current line is hscrolled, this describes the horizontal scrolling of lines other than the current one.

**vscroll** Vertical scroll amount, in pixels. Normally, this is 0.

**dedicated**

Non-`nil` if this window is dedicated to its buffer.

**combination\_limit**

This window's combination limit, meaningful only for a parent window. If this is `t`, then it is not allowed to delete this window and recombine its child windows with other siblings of this window.

**window\_parameters**

The alist of this window's parameters.

**display\_table**

The window's display table, or `nil` if none is specified for it.

**update\_mode\_line**

Non-zero means this window's mode line needs to be updated.

**mode\_line\_height****header\_line\_height**

The height in pixels of the mode line and the header line, or `-1` if not known.

**base\_line\_number**

The line number of a certain position in the buffer, or zero. This is used for displaying the line number of point in the mode line.

**base\_line\_pos**

The position in the buffer for which the line number is known, or zero meaning none is known. If it is `-1`, don't display the line number as long as the window shows that buffer.

**column\_number\_displayed**

The column number currently displayed in this window's mode line, or `-1` if column numbers are not being displayed.

**current\_matrix****desired\_matrix**

Glyph matrices describing the current and desired display of this window.

### E.9.3 Process Internals

The fields of a process (for a complete list, see the definition of `struct Lisp_Process` in `process.h`) include:

|                                   |                                                                                                                                                                                                               |
|-----------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>name</code>                 | A Lisp string, the name of the process.                                                                                                                                                                       |
| <code>command</code>              | A list containing the command arguments that were used to start this process. For a network or serial process, it is <code>nil</code> if the process is running or <code>t</code> if the process is stopped.  |
| <code>filter</code>               | A Lisp function used to accept output from the process.                                                                                                                                                       |
| <code>sentinel</code>             | A Lisp function called whenever the state of the process changes.                                                                                                                                             |
| <code>buffer</code>               | The associated buffer of the process.                                                                                                                                                                         |
| <code>pid</code>                  | An integer, the operating system's process ID. Pseudo-processes such as network or serial connections use a value of 0.                                                                                       |
| <code>childp</code>               | A flag, <code>t</code> if this is really a child process. For a network or serial connection, it is a plist based on the arguments to <code>make-network-process</code> or <code>make-serial-process</code> . |
| <code>mark</code>                 | A marker indicating the position of the end of the last output from this process inserted into the buffer. This is often but not always the end of the buffer.                                                |
| <code>kill_without_query</code>   | If this is non-zero, killing Emacs while this process is still running does not ask for confirmation about killing the process.                                                                               |
| <code>raw_status</code>           | The raw process status, as returned by the <code>wait</code> system call.                                                                                                                                     |
| <code>status</code>               | The process status, as <code>process-status</code> should return it. This is a Lisp symbol, a cons cell, or a list.                                                                                           |
| <code>tick</code>                 |                                                                                                                                                                                                               |
| <code>update_tick</code>          | If these two fields are not equal, a change in the status of the process needs to be reported, either by running the sentinel or by inserting a message in the process buffer.                                |
| <code>pty_flag</code>             | Non-zero if communication with the subprocess uses a pty; zero if it uses a pipe.                                                                                                                             |
| <code>infd</code>                 | The file descriptor for input from the process.                                                                                                                                                               |
| <code>outfd</code>                | The file descriptor for output to the process.                                                                                                                                                                |
| <code>tty_name</code>             | The name of the terminal that the subprocess is using, or <code>nil</code> if it is using pipes.                                                                                                              |
| <code>decode_coding_system</code> | Coding-system for decoding the input from this process.                                                                                                                                                       |
| <code>decoding_buf</code>         | A working buffer for decoding.                                                                                                                                                                                |
| <code>decoding_carryover</code>   | Size of carryover in decoding.                                                                                                                                                                                |

**encode\_coding\_system**

Coding-system for encoding the output to this process.

**encoding\_buf**

A working buffer for encoding.

**inherit\_coding\_system\_flag**

Flag to set `coding-system` of the process buffer from the coding system used to decode process output.

**type** Symbol indicating the type of process: `real`, `network`, `serial`.

## E.10 C Integer Types

Here are some guidelines for use of integer types in the Emacs C source code. These guidelines sometimes give competing advice; common sense is advised.

- Avoid arbitrary limits. For example, avoid `int len = strlen (s);` unless the length of `s` is required for other reasons to fit in `int` range.
- Do not assume that signed integer arithmetic wraps around on overflow. This is no longer true of Emacs porting targets: signed integer overflow has undefined behavior in practice, and can dump core or even cause earlier or later code to behave illogically. Unsigned overflow does wrap around reliably, modulo a power of two.
- Prefer signed types to unsigned, as code gets confusing when signed and unsigned types are combined. Many other guidelines assume that types are signed; in the rarer cases where unsigned types are needed, similar advice may apply to the unsigned counterparts (e.g., `size_t` instead of `ptrdiff_t`, or `uintptr_t` instead of `intptr_t`).
- Prefer `int` for Emacs character codes, in the range 0 .. 0x3FFFFF. More generally, prefer `int` for integers known to be in `int` range, e.g., screen column counts.
- Prefer `ptrdiff_t` for sizes, i.e., for integers bounded by the maximum size of any individual C object or by the maximum number of elements in any C array. This is part of Emacs's general preference for signed types. Using `ptrdiff_t` limits objects to `PTRDIFF_MAX` bytes, but larger objects would cause trouble anyway since they would break pointer subtraction, so this does not impose an arbitrary limit.
- Avoid `ssize_t` except when communicating to low-level APIs that have `ssize_t`-related limitations. Although it's equivalent to `ptrdiff_t` on typical platforms, `ssize_t` is occasionally narrower, so using it for size-related calculations could overflow. Also, `ptrdiff_t` is more ubiquitous and better-standardized, has standard `printf` formats, and is the basis for Emacs's internal size-overflow checking. When using `ssize_t`, please note that POSIX requires support only for values in the range -1 .. `SSIZE_MAX`.
- Normally, prefer `intptr_t` for internal representations of pointers, or for integers bounded only by the number of objects that can exist at any given time or by the total number of bytes that can be allocated. However, prefer `uintptr_t` to represent pointer arithmetic that could cross page boundaries. For example, on a machine with a 32-bit address space an array could cross the 0x7fffffff/0x80000000 boundary, which would cause an integer overflow when adding 1 to (`intptr_t`) 0x7fffffff.
- Prefer the Emacs-defined type `EMACS_INT` for representing values converted to or from Emacs Lisp fixnums, as fixnum arithmetic is based on `EMACS_INT`.

- When representing a system value (such as a file size or a count of seconds since the Epoch), prefer the corresponding system type (e.g., `off_t`, `time_t`). Do not assume that a system type is signed, unless this assumption is known to be safe. For example, although `off_t` is always signed, `time_t` need not be.
- Prefer `intmax_t` for representing values that might be any signed integer value. A `printf`-family function can print such a value via a format like "%"PRI`d`MAX.
- Prefer `bool`, `false` and `true` for booleans. Using `bool` can make programs easier to read and a bit faster than using `int`. Although it is also OK to use `int`, 0 and 1, this older style is gradually being phased out. When using `bool`, respect the limitations of the replacement implementation of `bool`. In particular, boolean bitfields should be of type `bool_bf`, not `bool`, so that they work correctly even when compiling Objective C with standard GCC.
- In bitfields, prefer `unsigned int` or `signed int` to `int`, as `int` is less portable: it might be signed, and might not be. Single-bit bit fields should be `unsigned int` or `bool_bf` so that their values are 0 or 1.

## Appendix F Standard Errors

Here is a list of the more important error symbols in standard Emacs, grouped by concept. The list includes each symbol's message and a cross reference to a description of how the error can occur.

Each error symbol has a set of parent error conditions that is a list of symbols. Normally this list includes the error symbol itself and the symbol `error`. Occasionally it includes additional symbols, which are intermediate classifications, narrower than `error` but broader than a single error symbol. For example, all the errors in accessing files have the condition `file-error`. If we do not say here that a certain error symbol has additional error conditions, that means it has none.

As a special exception, the error symbols `quit` and `minibuffer-quit` don't have the condition `error`, because quitting is not considered an error.

Most of these error symbols are defined in C (mainly `data.c`), but some are defined in Lisp. For example, the file `userlock.el` defines the `file-locked` and `file-supersession` errors. Several of the specialized Lisp libraries distributed with Emacs define their own error symbols. We do not attempt to list of all those here.

See Section 11.7.3 [Errors], page 179, for an explanation of how errors are generated and handled.

**error**      The message is ‘`error`’. See Section 11.7.3 [Errors], page 179.

**quit**      The message is ‘`Quit`’. See Section 22.11 [Quitting], page 471.

**minibuffer-quit**

The message is ‘`Quit`’. This is a subcategory of `quit`. See Section 22.11 [Quitting], page 471.

**args-out-of-range**

The message is ‘`Args out of range`’. This happens when trying to access an element beyond the range of a sequence, buffer, or other container-like object. See Chapter 6 [Sequences Arrays Vectors], page 102, and see Chapter 33 [Text], page 878.

**arith-error**

The message is ‘`Arithmetic error`’. This occurs when trying to perform integer division by zero. See Section 3.5 [Numeric Conversions], page 43, and see Section 3.6 [Arithmetic Operations], page 45.

**beginning-of-buffer**

The message is ‘`Beginning of buffer`’. See Section 31.2.1 [Character Motion], page 854.

**buffer-read-only**

The message is ‘`Buffer is read-only`’. See Section 28.7 [Read Only Buffers], page 680.

**circular-list**

The message is ‘`List contains a loop`’. This happens when a circular structure is encountered. See Section 2.6 [Circular Objects], page 30.

**cl-assertion-failed**

The message is ‘Assertion failed’. This happens when the `cl-assert` macro fails a test. See Section “Assertions” in *Common Lisp Extensions*.

**coding-system-error**

The message is ‘Invalid coding system’. See Section 34.10.3 [Lisp and Coding Systems], page 979.

**cyclic-function-indirection**

The message is ‘Symbol’s chain of function indirections contains a loop’. See Section 10.1.4 [Function Indirection], page 147.

**cyclic-variable-indirection**

The message is ‘Symbol’s chain of variable indirections contains a loop’. See Section 12.15 [Variable Aliases], page 222.

**dbus-error**

The message is ‘D-Bus error’. See Section “Errors and Events” in *D-Bus integration in Emacs*.

**end-of-buffer**

The message is ‘End of buffer’. See Section 31.2.1 [Character Motion], page 854.

**end-of-file**

The message is ‘End of file during parsing’. Note that this is not a subcategory of `file-error`, because it pertains to the Lisp reader, not to file I/O. See Section 20.3 [Input Functions], page 374.

**file-already-exists**

This is a subcategory of `file-error`. See Section 26.4 [Writing to Files], page 616.

**permission-denied**

This is a subcategory of `file-error`, which occurs when the OS doesn’t allow Emacs to access a file or a directory for some reason.

**file-date-error**

This is a subcategory of `file-error`. It occurs when `copy-file` tries and fails to set the last-modification time of the output file. See Section 26.7 [Changing Files], page 629.

**file-error**

We do not list the error-strings of this error and its subcategories, because the error message is normally constructed from the data items alone when the error condition `file-error` is present. Thus, the error-strings are not very relevant. However, these error symbols do have `error-message` properties, and if no data is provided, the `error-message` property is used. See Chapter 26 [Files], page 608.

**file-missing**

This is a subcategory of `file-error`. It occurs when an operation attempts to act on a file that is missing. See Section 26.7 [Changing Files], page 629.

**compression-error**

This is a subcategory of `file-error`, which results from problems handling a compressed file. See Section 16.1 [How Programs Do Loading], page 298.

**file-locked**

This is a subcategory of `file-error`. See Section 26.5 [File Locks], page 617.

**file-supersession**

This is a subcategory of `file-error`. See Section 28.6 [Modification Time], page 678.

**file-notify-error**

This is a subcategory of `file-error`. It happens, when a file could not be watched for changes. See Section 42.20 [File Notifications], page 1296.

**remote-file-error**

This is a subcategory of `file-error`, which results from problems in accessing a remote file. See Section “Remote Files” in *The GNU Emacs Manual*. Often, this error appears when timers, process filters, process sentinels or special events in general try to access a remote file, and collide with another remote file operation. In general it is a good idea to write a bug report. See Section “Bugs” in *The GNU Emacs Manual*.

**ftp-error**

This is a subcategory of `remote-file-error`, which results from problems in accessing a remote file using ftp. See Section “Remote Files” in *The GNU Emacs Manual*.

**invalid-function**

The message is ‘Invalid function’. See Section 10.1.4 [Function Indirection], page 147.

**invalid-read-syntax**

The message is usually ‘Invalid read syntax’. See Section 2.1 [Printed Representation], page 8. This error can also be raised by commands like `eval-expression` when there’s text following an expression. In that case, the message is ‘Trailing garbage following expression’.

**invalid-regexp**

The message is ‘Invalid regexp’. See Section 35.3 [Regular Expressions], page 995.

**mark-inactive**

The message is ‘The mark is not active now’. See Section 32.7 [The Mark], page 873.

**no-catch** The message is ‘No catch for tag’. See Section 11.7.1 [Catch and Throw], page 177.

**range-error**

The message is `Arithmetic range error`.

**overflow-error**

The message is ‘**Arithmetic overflow error**’. This is a subcategory of **range-error**. This can happen with integers exceeding the **integer-width** limit. See Section 3.1 [Integer Basics], page 38.

**scan-error**

The message is ‘**Scan error**’. This happens when certain syntax-parsing functions find invalid syntax or mismatched parentheses. Conventionally raised with three argument: a human-readable error message, the start of the obstacle that cannot be moved over, and the end of the obstacle. See Section 31.2.6 [List Motion], page 861, and see Section 36.6 [Parsing Expressions], page 1030.

**search-failed**

The message is ‘**Search failed**’. See Chapter 35 [Searching and Matching], page 993.

**setting-constant**

The message is ‘**Attempt to set a constant symbol**’. This happens when attempting to assign values to **nil**, **t**, **most-positive-fixnum**, **most-negative-fixnum**, and keyword symbols. It also happens when attempting to assign values to **enable-multibyte-characters** and some other symbols whose direct assignment is not allowed for some reason. See Section 12.2 [Constant Variables], page 189.

**text-read-only**

The message is ‘**Text is read-only**’. This is a subcategory of **buffer-read-only**. See Section 33.19.4 [Special Properties], page 924.

**undefined-color**

The message is ‘**Undefined color**’. See Section 30.23 [Color Names], page 846.

**user-error**

The message is the empty string. See Section 11.7.3.1 [Signaling Errors], page 180.

**user-search-failed**

This is like ‘**search-failed**’, but doesn’t trigger the debugger, like ‘**user-error**’. See Section 11.7.3.1 [Signaling Errors], page 180, and see Chapter 35 [Searching and Matching], page 993. This is used for searching in Info files, see Section “Search Text” in *Info*.

**void-function**

The message is ‘**Symbol’s function definition is void**’. See Section 13.9 [Function Cells], page 248.

**void-variable**

The message is ‘**Symbol’s value as variable is void**’. See Section 12.7 [Accessing Variables], page 197.

**wrong-number-of-arguments**

The message is ‘**Wrong number of arguments**’. See Section 13.2.3 [Argument List], page 234.

**wrong-type-argument**

The message is ‘Wrong type argument’. See Section 2.7 [Type Predicates], page 30.

**unknown-image-type**

The message is ‘Cannot determine image type’. See Section 41.17 [Images], page 1206.

**inhibited-interaction**

The message is ‘User interaction while inhibited’. This error is signaled when `inhibit-interaction` is non-nil and a user interaction function (like `read-from-minibuffer`) is called.

## Appendix G Standard Keymaps

In this section we list some of the more general keymaps. Many of these exist when Emacs is first started, but some are loaded only when the respective feature is accessed.

There are many other, more specialized, maps than these; in particular those associated with major and minor modes. The minibuffer uses several keymaps (see Section 21.6.3 [Completion Commands], page 400). For more details on keymaps, see Chapter 23 [Keymaps], page 480.

### `2C-mode-map`

A sparse keymap for subcommands of the prefix `C-x 6`.

See Section “Two-Column Editing” in *The GNU Emacs Manual*.

### `abbrev-map`

A sparse keymap for subcommands of the prefix `C-x a`.

See Section “Defining Abbrevs” in *The GNU Emacs Manual*.

### `button-buffer-map`

A sparse keymap useful for buffers containing buffers.

You may want to use this as a parent keymap. See Section 41.20 [Buttons], page 1232.

### `button-map`

A sparse keymap used by buttons.

### `ctl-x-4-map`

A sparse keymap for subcommands of the prefix `C-x 4`.

### `ctl-x-5-map`

A sparse keymap for subcommands of the prefix `C-x 5`.

### `ctl-x-map`

A full keymap for `C-x` commands.

### `ctl-x-r-map`

A sparse keymap for subcommands of the prefix `C-x r`.

See Section “Registers” in *The GNU Emacs Manual*.

### `esc-map`

A full keymap for ESC (or `Meta`) commands.

### `function-key-map`

The parent keymap of all `local-function-key-map` (q.v.) instances.

### `global-map`

The full keymap containing default global key bindings.

Modes should not modify the Global map.

### `goto-map`

A sparse keymap used for the `M-g` prefix key.

### `help-map`

A sparse keymap for the keys following the help character `C-h`.

See Section 25.6 [Help Functions], page 602.

### `Helper-help-map`

A full keymap used by the help utility package.

It has the same keymap in its value cell and in its function cell.

**input-decode-map**

The keymap for translating keypad and function keys.

If there are none, then it contains an empty sparse keymap. See Section 23.15 [Translation Keymaps], page 504.

**key-translation-map**

A keymap for translating keys. This one overrides ordinary key bindings, unlike **local-function-key-map**. See Section 23.15 [Translation Keymaps], page 504.

**kmacro-keymap**

A sparse keymap for keys that follows the **C-x C-k** prefix search.

See Section “Keyboard Macros” in *The GNU Emacs Manual*.

**local-function-key-map**

The keymap for translating key sequences to preferred alternatives.

If there are none, then it contains an empty sparse keymap. See Section 23.15 [Translation Keymaps], page 504.

**menu-bar-file-menu****menu-bar-edit-menu****menu-bar-options-menu****global-buffers-menu-map****menu-bar-tools-menu****menu-bar-help-menu**

These keymaps display the main, top-level menus in the menu bar.

Some of them contain sub-menus. For example, the Edit menu contains **menu-bar-search-menu**, etc. See Section 23.18.5 [Menu Bar], page 516.

**minibuffer-inactive-mode-map**

A full keymap used in the minibuffer when it is not active.

See Section “Editing in the Minibuffer” in *The GNU Emacs Manual*.

**mode-line-coding-system-map****mode-line-input-method-map****mode-line-column-line-number-mode-map**

These keymaps control various areas of the mode line.

See Section 24.4 [Mode Line Format], page 550.

**mode-specific-map**

The keymap for characters following **C-c**. Note, this is in the global map. This map is not actually mode-specific: its name was chosen to be informative in **C-h b** (**display-bindings**), where it describes the main use of the **C-c** prefix key.

**mouse-appearance-menu-map**

A sparse keymap used for the **S-mouse-1** key.

**mule-keymap**

The global keymap used for the **C-x RET** prefix key.

**narrow-map**

A sparse keymap for subcommands of the prefix **C-x n**.

**prog-mode-map**

The keymap used by Prog mode.

See Section 24.2.5 [Basic Major Modes], page 536.

**query-replace-map****multi-query-replace-map**

A sparse keymap used for responses in `query-replace` and related commands; also for `y-or-n-p` and `map-y-or-n-p`. The functions that use this map do not support prefix keys; they look up one event at a time. `multi-query-replace-map` extends `query-replace-map` for multi-buffer replacements. See Section 35.7 [Search and Replace], page 1016.

**search-map**

A sparse keymap that provides global bindings for search-related commands.

**special-mode-map**

The keymap used by Special mode.

See Section 24.2.5 [Basic Major Modes], page 536.

**tab-prefix-map**

The global keymap used for the `C-x t` prefix key for tab-bar related commands.

See Section “Tab Bars” in *The GNU Emacs Manual*.

**tab-bar-map**

The keymap defining the contents of the tab bar.

See Section “Tab Bars” in *The GNU Emacs Manual*.

**tool-bar-map**

The keymap defining the contents of the tool bar.

See Section 23.18.6 [Tool Bar], page 517.

**universal-argument-map**

A sparse keymap used while processing `C-u`.

See Section 22.12 [Prefix Command Arguments], page 473.

**vc-prefix-map**

The global keymap used for the `C-x v` prefix key.

**x-alternatives-map**

A sparse keymap used to map certain keys under graphical frames.

The function `x-setup-function-keys` uses this.

## Appendix H Standard Hooks

The following is a list of some hook variables that let you provide functions to be called from within Emacs on suitable occasions.

Most of these variables have names ending with ‘`-hook`’. They are *normal hooks*, run by means of `run-hooks`. The value of such a hook is a list of functions; the functions are called with no arguments and their values are completely ignored. The recommended way to put a new function on such a hook is to call `add-hook`. See Section 24.1 [Hooks], page 524, for more information about using hooks.

The variables whose names end in ‘`-functions`’ are usually *abnormal hooks* (some old code may also use the deprecated ‘`-hooks`’ suffix). Their values are lists of functions, but these functions are called in a special way: they are either passed arguments, or their return values are used in some way. The variables whose names end in ‘`-function`’ have single functions as their values.

This is not an exhaustive list, it only covers the more general hooks. For example, every major mode defines a hook named ‘`modename-mode-hook`’. The major mode command runs this normal hook with `run-mode-hooks` as the very last thing it does. See Section 24.2.6 [Mode Hooks], page 537. Most minor modes have mode hooks too.

A special feature allows you to specify expressions to evaluate if and when a file is loaded (see Section 16.10 [Hooks for Loading], page 313). That feature is not exactly a hook, but does a similar job.

`activate-mark-hook`

`deactivate-mark-hook`

See Section 32.7 [The Mark], page 873.

`after-change-functions`

`before-change-functions`

`first-change-hook`

See Section 33.34 [Change Hooks], page 961.

`after-change-major-mode-hook`

`change-major-mode-after-body-hook`

See Section 24.2.6 [Mode Hooks], page 537.

`after-init-hook`

`before-init-hook`

`emacs-startup-hook`

`window-setup-hook`

See Section 42.1.2 [Init File], page 1258.

`after-insert-file-functions`

`write-region-annotate-functions`

`write-region-post-annotation-function`

See Section 26.13 [Format Conversion], page 654.

`after-make-frame-functions`

`before-make-frame-hook`

`server-after-make-frame-hook`

See Section 30.1 [Creating Frames], page 786.

**after-save-hook**

**before-save-hook**

**write-contents-functions**

**write-file-functions**

See Section 26.2 [Saving Buffers], page 612.

**after-setting-font-hook**

Hook run after a frame's font changes.

**auto-save-hook**

See Section 27.2 [Auto-Saving], page 664.

**before-hack-local-variables-hook**

**hack-local-variables-hook**

See Section 12.12 [File Local Variables], page 213.

**buffer-access-fontify-functions**

See Section 33.19.7 [Lazy Properties], page 933.

**buffer-list-update-hook**

Hook run when the buffer list changes (see Section 28.8 [Buffer List], page 681).

**buffer-quit-function**

Function to call to quit the current buffer.

**change-major-mode-hook**

See Section 12.11.2 [Creating Buffer-Local], page 208.

**comint-password-function**

This abnormal hook permits a derived mode to supply a password for the underlying command interpreter without prompting the user.

**command-line-functions**

See Section 42.1.4 [Command-Line Arguments], page 1261.

**delayed-warnings-hook**

The command loop runs this soon after **post-command-hook** (q.v.).

**focus-in-hook**

**focus-out-hook**

See Section 30.10 [Input Focus], page 824.

**delete-frame-functions**

**after-delete-frame-functions**

See Section 30.7 [Deleting Frames], page 822.

**delete-terminal-functions**

See Section 30.2 [Multiple Terminals], page 787.

**pop-up-frame-function**

**split-window-preferred-function**

See Section 29.13.4 [Choosing Window Options], page 736.

**echo-area-clear-hook**

See Section 41.4.4 [Echo Area Customization], page 1138.

**find-file-hook**

**find-file-not-found-functions**

See Section 26.1.1 [Visiting Functions], page 608.

**font-lock-extend-after-change-region-function**

See Section 24.6.9.2 [Region to Refontify], page 578.

**font-lock-extend-region-functions**

See Section 24.6.9 [Multiline Font Lock], page 576.

**font-lock-fontify-buffer-function**

**font-lock-fontify-region-function**

**font-lock-mark-block-function**

**font-lock-unfontify-buffer-function**

**font-lock-unfontify-region-function**

See Section 24.6.4 [Other Font Lock Variables], page 571.

**fontification-functions**

See Section 41.12.7 [Automatic Face Assignment], page 1178.

**frame-auto-hide-function**

See Section 29.16 [Quitting Windows], page 749.

**quit-window-hook**

See Section 29.16 [Quitting Windows], page 749.

**kill-buffer-hook**

**kill-buffer-query-functions**

See Section 28.10 [Killing Buffers], page 685.

**kill-emacs-hook**

**kill-emacs-query-functions**

See Section 42.2.1 [Killing Emacs], page 1262.

**menu-bar-update-hook**

See Section 23.18.5 [Menu Bar], page 516.

**minibuffer-setup-hook**

**minibuffer-exit-hook**

See Section 21.15 [Minibuffer Misc], page 421.

**mouse-leave-buffer-hook**

Hook run when the user mouse-clicks in a window.

**mouse-position-function**

See Section 30.16 [Mouse Position], page 835.

**prefix-command-echo-keystrokes-functions**

An abnormal hook run by prefix commands (such as *C-u*) which should return a string describing the current prefix state. For example, *C-u* produces ‘*C-u-*’ and ‘*C-u 1 2 3-*’. Each hook function is called with no arguments and should return a string describing the current prefix state, or *nil* if there’s no prefix state. See Section 22.12 [Prefix Command Arguments], page 473.

**prefix-command-preserve-state-hook**

Hook run when a prefix command needs to preserve the prefix by passing the current prefix command state to the next command. For example, *C-u* needs to pass the state to the next command when the user types *C-u* – or follows *C-u* with a digit.

**pre-redisplay-functions**

Hook run in each window just before redisplaying it. See Section 41.2 [Forcing Redisplay], page 1129.

**post-command-hook****pre-command-hook**

See Section 22.1 [Command Overview], page 423.

**post-gc-hook**

See Section E.3 [Garbage Collection], page 1350.

**post-self-insert-hook**

See Section 24.3.2 [Keymaps and Minor Modes], page 546.

**suspend-hook****suspend-resume-hook****suspend-tty-functions****resume-tty-functions**

See Section 42.2.2 [Suspending Emacs], page 1263.

**syntax-begin-function****syntax-propertize-extend-region-functions****syntax-propertize-function****font-lock-syntactic-face-function**

See Section 24.6.8 [Syntactic Font Lock], page 575. See Section 36.4 [Syntax Properties], page 1029.

**temp-buffer-setup-hook****temp-buffer-show-function****temp-buffer-show-hook**

See Section 41.8 [Temporary Displays], page 1146.

**tty-setup-hook**

See Section 42.1.3 [Terminal-Specific], page 1260.

**window-configuration-change-hook****window-scroll-functions****window-size-change-functions**

See Section 29.28 [Window Hooks], page 779.
